Of course we now know that Parkman had no "inherited affection" and no "affection of the brain." The same superfluous insinuation is shown in Farnham's "The overstrain of his early life was most regrettable in helping to develop some inherited tendency to disorders of the brain and nervous system." There was no more "overstrain of his early life" than thousands of others have endured unharmed. What overstrain there was had no causal relation with his lifelong suffering. He had no "inherited tendency to disorders," and he had no "disorders of the brain and nervous system." Farnham is correct when he writes of Parkman, "He had an 'inborn irritability of constitution,' as he said, which made 'labor a passion and rest intolerable.' His mysterious affection of the brain seems to have consisted in good part of this spurring force." To have hit the truth so patly and to have missed it so completely is strange when every fact of Parkman's life tragedy was glaringly bound up with ocular function.

Miss Parkman in a personal communication to me says she judges that the symptoms that suggested insanity were pressure upon, in or about the head, his "stirred up head" and the rushing activity of the brain. All these are most common symptoms of eyestrain.

Farnham, in another place, says:

His most insidious enemy was brain trouble. His physician in Paris, the most noted specialist of his day, had said that he might go insane and that his cure was extremely doubtful. The wisdom of making known this diagnosis to the patient has been questioned; but it perhaps was the only course, in view of the precautions that had to be an important element of his daily life. In his autobiography he speaks of the medical opinions and his danger in the jocose way frequent with him in mentioning even his worst condition. But the inevitable weighed at times upon his mind. He occasionally expressed wonder at not going insane with so much nervous exhaustion from insomnia, and he asked one or two intimate literary friends to watch for signs of mental disorder in his writings.

Parkman doubtless enjoyed the fun of setting two friends upon such a quixotic hunt! Of a similar chase by expert sportsmen, Parkman himself wrote:

One physician, with grave circumlocution, lest the patient should take fright, informed him that he was the victim of an organic disease of the brain which must needs dispatch him to another world within a twelvemonth; and he stood amazed at the smile of an auditor who neither cared for the announcement nor believed it. Another, an eminent physiologist of Paris, after an acquaintance of three months, one day told him that, from the nature of the disorder, he had at first supposed that it must, in accordance with precedent, be attended with insanity, and had ever since been studying him to discover under what form the supposed aberration declared itself, adding, with a somewhat humorous look, that his researches had not been rewarded with the smallest success.

Mr. Parkman's home physician, Dr. Oliver, writes me that he thinks it was Brown-Sequard who made the statement that there was danger of insanity, and who told Parkman to go home at once, as he would soon be out of his mind. The "danger" was very far from "weighing on Parkman's mind," however puzzled he might be as to the mysterious nature of his malady. Thank heaven the sane mind and heroic character of the man "neither cared for the announcement nor believed it."

Parkman's insomnia.— Farnham has written of the "Oregon Trail" journey:

Suffering as he did from troubles of digestion, he was unable to sleep during the night; when at dawn he dozed off exhausted, his guide had to call him to depart. Thus began the insomnia that wearied him persistently all the rest of his days. From that time onward, during long periods of time, he would get but two or three hours of sleep out of the twenty-four; he often had less than this, or even none, and when four or five hours of unconsciousness came, he enjoyed an unusual blessing. His confidence in nature made him doubtful of physicians and drugs, and gave him most hope in the natural powers of the body. Insomnia so prolonged and persistent was one of the greatest of his physical trials; it indeed seemed that insanity must at last result from this exhausting and irritating form of suffering.

His sister, Miss Eliza S. Parkman, told me in regard to the insomnia that to sleep none at night was uncommon, to sleep about an hour was common and latterly under his physician's advice, and, by the aid of sulphonal, trional or some other hypnotic, to get from four or five hours of sleep was possible. Oculists are now well aware by the reiterated statements of their patients that almost all severe eyestrain produces insomnia. The irritated and surcharged brain, "stirred up" as Parkman described it, during the day cannot be quieted, and the healing power of rest is denied the very organ that brings healing to the rest of the organism.

Parkman's eyes.—Although the method of Zadig is the method of symptomatology and diagnosis, neither the numerous physicians he consulted during his life, nor the patient himself, neither his relatives nor friends, recognized that he had five symptoms which among others are common in eyestrain. These are, in order of their distinctness, redness of and pain in the eyeballs; photophobia, or sensitiveness to light; blepharitis, or inflammation of the edges of the eyelids; inability to use the eyes "at near range," — reading or writing,— and sundry cerebral reflexes, whenever this near use was attempted. The reverse of this order is that of importance, and the fact is suggestive of the dullness of perception and slowness of recognition of the rôle of eyestrain in medicine and in all modern life.

(1) Miss Parkman tells me that her brother did not have what would be called "bloodshot" eyes. In Parkman's nature physical and neural matters never went to the positively fatal ex-

tremes. A wise restraint even in the severest disorders prevented the fatal exaggerations. He stopped in time. But he had red and painful eyes. The pain in the eyes was nearly constant.

(2) *Photophobia.* — In the two pictures of Parkman given in Farnham's biography one will notice that across the coat lapels and shirt front are the lines made by a loop of cord passed about the neck and disappearing beneath the coat. It is striking that few remember his use of these lenses, but this is a common fact, illustrated by many historic cases, notably that of the musician Wagner. Farnham does not speak of the fact that Parkman (as told me by his sister) habitually or often wore eyeglasses after middle life, and he also wore colored glasses when the light was strong. The colored lenses were the old-fashioned "goggles," with wire meshes about the glass. The silk cord was not, of course, used with these. He chose northern rooms for his studies, and when traveling; he disliked reflections of light from other houses, walls, etc., and he chose the shaded portions of the room to sit in, or kept the room itself in a twilight condition of illumination. According to Miss Parkman he was more comfortable in cloudy weather. His eyes, while in Switzerland, gave out entirely in sunny days, and he was especially liable to attacks of cerebral irritation ("stirred up head") during such days. At Blois, France, Miss Parkman remembers that in 1871 he could not walk out in the daytime at all, and driving in the dark was disliked because it strained his eyes and seemed to hurt him to attempt (as he felt impelled to do) to see objects. He therefore was able to be out of doors only in the twilight. Light or multiple lights arouse accommodative effort, and, as we know, Parkman's accommodation was always strained to its utmost. For this reason he never went to the theater, opera, concerts, lectures, etc. His photophobia also doubled his suffering in another way, as it prevented the life out of doors, which he needed so much. He was confined, therefore, to a vicious circle — his sensitiveness to light confined him too much, thus intensifying his ocular and brain irritation, and in its turn making light still more harmful to the eyes. Patients with severe eyestrain showing the reflexes to the head and eyes most commonly complain of this dread of light, and in many cases it is a source of bitter suffering and trouble. Parkman himself thought he could not repeat his "Oregon Trail" experience because the sunlight would have blinded him. Glasses correcting his ametropia would have banished his photophobia instantly. A curious fact in this connection is his use of orange-colored paper for writing upon in the last part of his life. I have known three patients with severe eyestrain who chose such paper, and who believed that its use was almost necessary for their comfort in writing.

(3) *Blepharitis.* — Farnham writes that "his gray, penetrating eyes were, in youth, of good size, but in later years they seemed smaller because of chronic inflammation of the lids." Miss Parkman tells me that she often noticed "scales" on the lid edges and that he had "irritable lids." She also says he habitually used some lotion, probably solutions of boric acid and camphor (now constantly ordered by physicians for such lid affections), usually applied at night. I have learned that he was subject to another result of eyestrain, the lid tumors called "meibomian cysts." Two of these were excised by two of his oculists. Parkman never winced during the operation. Farnham makes an excusable error in supposing the narrowing of the palpebral opening, which he calls smaller eyes, was due to the lid affection. It was, of course, due to the habitual attempt to shut out the painful light by partially closing the lids. In this way the width of the opening of the lids was chronically reduced, and he seemed to have "smaller eyes." All albinos have the same appearance and from the same habit. Although Parkman was not a myope, it may be noted that the word "myopia" is derived from Greek words which mean to close the eyes. The reason that myopes also habitually narrow the lid opening is a different one.

Even in England it is now and at last recognized that blepharitis is usually due to eyestrain, so that whatever palliative measures may be ordered for scaly and ulcerous lid edges, all oculists now tell their patients that the only permanent cure of the condition is properly correcting lenses of the ametropia.

(4) *Inability to use the eyes at near range* is the most glaring symptom of eyestrain. It now seems to us incomprehensible that even in Parkman's early and adult life he, and especially his physicians, should not have recognized that the cause of this anomalous and tragical fact lay in an abnormalism of the optical functions of the eyes. The vast majority of his friends and of all civilized people could work at sewing, reading, writing, and other hand work, and for many hours a day without resultant symptoms and in complete unconsciousness. Parkman shirked study as a boy, as a student and as a young man and each year of added life lessened his accommodative power and narrowed his ocular working ability, until finally this was reduced to a minute or two at a time, and in all to a half hour or so a day.[11] Finally came the "gridiron" period, when he could not even write his name without pain, and he had to renounce all near-range work whatsoever. With the most sympathetic imagination one cannot realize the awfulness of such a fact to a man of Parkman's tastes and will. Ten years of my own life lost in the same way, and from precisely the same causes, help me to understand the workings of the mind of Parkman under this terrible blow of a mysterious fate. If Parkman had lived at the present time he could have found the relief from his disability and suffering in the same way that thousands have done. "The pity of it!"

[11] I have a suspicion that in some cases, especially in such intense natures as that of Parkman, there may be some eyestrain even in dictating with eyes closed. The effort to visualise (and that is the usual mechanics of intellect) the images and sentences might arouse both convergence and accommodation of the eyes, and thus during composition and nonwalking intellectual activity there would not be entire ocular rest.

(To be concluded.)

THREE CASES OF TUMOR OF THE CEREBELLUM.[1]

BY JOHN JENKS THOMAS, A.M., M.D., BOSTON.

It having been my fortune to have the opportunity to observe recently three cases of tumor of the cerebellum, in two of which the diagnosis was confirmed by autopsy, it seemed to me that a report of these cases might not be without interest to this society.

The first case was in an adult. The patient, Lizzie B., aged twenty years, was referred to me by Dr. Edmund W. Clap of Boston, to whom I am indebted for much information about the condition of the eyes, and who has kindly permitted me to report the case. She was first seen by me on April 9, 1900. She was a dressmaker, single, and was born in England. The family history was of no significance, though her father had had an attack of hemiplegia in January of that year. There was a history of her having a fall and hurting the head when a baby, and when very young she had had the measles, but no other injury or illness.

Her present illness began in the preceding October with headache, which was both frontal and occipital. Three weeks before her first visit she had had an attack of vomiting, and also one on that day, and about the same time she noticed a blurring of the vision. The headache is throbbing in character and practically continuous, but perhaps slightly worse in the morning, and it is increased by stooping. The vomiting is not projectile in character. There has been no diplopia, no convulsive movements or twitching of any part of the body, or attacks of unconsciousness. There has been no paresthesia or numbness. Dr. Clap wrote that he saw her first on April 4, five days before her first visit to me, and at that time she had a violent neuro-retinitis in both eyes, with numerous flame-shaped hemorrhages and some exudate. The disk was swollen at least two diopters. On the 7th the swelling of the disk had increased to three diopters, and there was more exudate. The macular region was not much affected, although there was slight edema. Vision O. D. was 20-40, not improved by any glass. Vision O. S. was 20-30 with + 0.75 = 20-20.

On examination the gait is normal except for a slight limp at times, which is due to a blow upon the hip which she received not long ago. There is only slight swaying on standing with the eyes closed. The pupils are normal to light and accommodation. There is no diplopia, and no affection of any of the cranial nerves. The watch is heard at an equal distance, 15 cm., from each ear. There is no paresis of any of the extremities, and no inco-ordination. Sensation to touch, pain, heat and cold is everywhere normal. The reflexes in the arms are equal and normal. The knee jerks are lively and equal. There is a front tap contraction on both sides, but no ankle clonus. There is no tenderness of the head to percussion or pressure. The urine and the heart are normal, and the patient is not anemic.

She had been taking the yellow iodide of mercury in doses of a quarter of a grain three times a day. On April 14 Dr. Clap wrote me that the vision had fallen greatly. Vision O. D. was 6-200, not improved by glass. Vision O. S. was 20-200; with + 1.0 = 20-100. The neuritis then was a marked choked disk, with four to five diopters of swelling in each eye, and a few hemorrhages out in the retina as well as many in the nerve head. There was much exudate extending out from the disk in both eyes. The macular region was edematous in both eyes, which was probably the cause of the low vision. No change was found in her general condition upon examination April 20. She was then put upon the red iodide of mercury, grain 1-16 t. i. d., and the iodide of potassium in increasing doses. In a few days after this she returned to England, and I am indebted to Dr. Mark Farrant, Jr., of Exeter, England, for a report of the further progress of the case, which he kindly sent to me. Writing on July 27, 1900, he states that at first he found nothing more than we had previously found. At first the knee jerks were active and equal, but soon the left one became rather diminished. The vomiting continued. The vomiting varied with the pain in the head, that is, when one was severe the other was. There were no localizing signs at all, and no ataxia. This continued until the middle of May, when there was an almost complete intermission of the symptoms, which lasted until the beginning of July, when they returned. On July 17 ptosis of the left eye and dilatation of the left pupil appeared. About that time the vomiting ceased, but the patient became dull, and finally died in semi-coma on July 20. For the last ten days there was a little fever, reaching 101.6° as the highest on the 17th. The temperature previously had been nearly normal, and a good deal of the time subnormal. The pulse kept about 70 to 80 until just before death, when it was noted as 160.

A post-mortem examination was obtained, and Dr. Farrant found the pia slightly thickened and opaque, especially along the vessels and in the ventricles. There was an excess of cerebrospinal fluid, and the brain was fairly firm, with the convolutions much the usual shape, not flattened. There was a firm tumor, about the size of a large walnut, in the posterior and bi-ventral lobe of the cerebellum on the right side. It shelled out easily. It had not extended to the superior vermiform process, which Dr. Farrant suggests was the reason why we had no ataxic symptoms. The tumor under the microscope showed a large amount of fibrous tissue, with much round cell tissue, presumably, Dr. Farrant says, a fibro-sarcoma.

The second case, Herbert N., a boy five years old, was referred to me by Dr. Durant of Haverhill. The family history was entirely normal. The labor and the development of the child was normal in every respect, except that when one and a half years old and again at two and a half years he had a few slight convulsions, six in all.

[1] Read before the Boston Society of Psychiatry and Neurology, Dec. 18, 1902.

The longest lasted three minutes. They apparently consisted of a slight loss of consciousness only, as the parents noticed no movements of the limbs, and each had been preceded by some indiscretion in diet. Aside from this the child had always been well except for occasional digestive trouble. In November, 1901, he fell and cut the head. He was seen by me first on April 30, 1902. Nine weeks previously, about the last of February, he began to feel poorly and vomited, and there was fever of 103°. He improved for a week and then became worse. At this time there was no fever, but he began to have headache and vomiting. There was some vomiting in the morning, and the child was very constipated. For the three weeks previous to his first visit to me the headache had been better, but for the preceding week he had not been willing to walk, and the parents had noticed some staggering for some three and a half or four weeks. About two and a half weeks before they had noticed that the left eye turned in. No failure of his vision had been noticed. There was certainly no marked mental dullness, and the child noticed everything going on about him as usual. There had been no convulsions, and the hearing was good.

On examination there is considerable unsteadiness in standing and sitting. The pupils are large and react sluggishly to light and accommodation. There is marked optic neuritis in both eyes, with swelling of the disk and tortuous veins. There is a paresis of the left external rectus muscle; no nystagmus, although there is a slight twitching of the eyes at times. There is also a slight but distinct paresis of the muscles of the left side of the face. The watch is heard in each ear at the same distance, 30 cm. Air conduction is better than bone conduction in both ears, and Weber's test is negative. The tongue is protruded straight. The knee jerks are absent, there is no ankle clonus and no front tap contraction. The abdominal and cremasteric reflexes are normal. There is slight inco-ordination and slight tremor of the hands, but this is not marked. There is slight tenderness of the occipital region to light percussion, and the circumference of the head is 55 cm. The pulse is 108.

Operation was declined by the parents. Later the child was seen by Dr. F. H. Williams, who took x-ray pictures of the skull, which he kindly allowed me to see, but these showed nothing definite.

The father reported on June 9 that the child for some time had had no headache, and that the vomiting had lessened, but that he did not seem to see as well, and had lost strength. At this time arrangements were made for an operation.

On June 14 Dr. Lund and I, on seeing the child previous to the operation, learned that twenty-four hours previously he had become markedly dull. On examination the knee jerks were absent, as was also the plantar reflex. The right eye seemed to diverge to the temporal side and the right pupil was widely dilated. The nasolabial fold on the right side was less marked than on the left. The child was in a soporous condition, and could not be roused enough to protrude the tongue or make any voluntary motion. Upon consultation it was decided to operate with the hope of relieving the symptoms of intracranial pressure, leaving until later the decision whether to attempt removal of the growth, or any further procedure.

OPERATION. DR. F. B. LUND.

The patient lay on the right side with the head flexed. A ∩-shaped flap was made with the base at the superior curved line of the occiput on the left, the left limb starting at the posterior border of the mastoid and below the level of its tip, and the right limb extending down the median line of the neck to the same level. The incision was carried down to the bone, and the flap of skin, muscle and periosteum quickly dissected downward with a periosteum elevator. The occipital bone was very thin and bulged downward as if from a high degree of intracranial pressure. The external occipital protuberance could not be felt, in fact, there was rather a depression in its place, and the lines on the occiput and other landmarks on the thin and poorly marked skull were hard to find, apparently on account of the bulging of the skull from internal tension. The flap was carried backward nearly to the foramen magnum, and the hemorrhage was easily controlled by ligature of one or two branches of the occipital artery and veins, and pressure with gauze pledgets in the angle of the flap. A three-quarter inch trephine was applied to the occipital bone between the superior and inferior curved lines, and on removing the button the dura bulged, tense and without pulsation, through the opening. The opening was enlarged to a diameter of a little more than an inch with rongeur forceps, and a semicircular flap of dura was made with the knife and forceps. Edematous cerebellar tissue immediately protruded through the opening with such force that the brain was lacerated against the edge of the dura. A small portion of the tissue was removed for examination, but the condition of the patient precluding any further work, the dural opening was enlarged to the limit of the opening in the skull, and the operation completed by the suture of the periosteo-muscular flap with continuous catgut, and the skin with interrupted silkworm gut sutures. A drain of rubber tissue was left in the lower inner angle of the incision, and an aseptic gauze dressing applied. The patient suffered but little shock from the operative manipulations, which occupied about twenty minutes. Ether was the anesthetic, though owing to the semicomatose condition of the patient only a small amount was required. The pulse at the close was 160 to 180, as before the operation.

The patient did not improve. The coma gradually deepened, and he died at 5 A.M. the next morning, June 15. The examination of the pieces of tissue removed at the operation showed nothing but cerebellar tissue.

At the autopsy the head only was opened. The cerebrum showed nothing abnormal beyond a certain amount of flattening of the convolutions.

The posterior surface of the left lobe of the cerebellum was lacerated.

The vermis of the cerebellum is nearly replaced by a tumor mass which measures about 3 x 2 x 2 cm., and is slightly lobulated on the suface. About the tumor, which is sharply defined, was found a small amount of pus. At the posterior and anterior portions of the tumor, more on the right side, are seen some normal convolutions of the cerebellum. The tumor on section is rather soft, opaque, whitish in color, homogeneous, with here and there softened areas of varying size. The tumor mass has pressed upward and forward into the left cerebellar hemisphere, which shows a marked depression in which the tumor lies; but this hemisphere of the cerebellum appears perfectly normal, except for the marked compression.

Microscopical examination of fresh scrapings of the cut surface of the tumor shows many small mononuclear cells and a few fibrillæ resembling neuroglia cells and fibrillæ. The tumor was hardened in formalin and sections were made of the tumor, of the medulla at the upper border of the pyramidal crossing and of the left cerebellar hemisphere, and stained with hematoxylin and eosin, hematoxylin followed by picric acid and acid fuchsine, Mallory's phosphotungstic acid hematoxylin method for neuroglia fibers, Weigert's myelin sheath stain, Pal's myelin sheath stain followed by picric acid and acid fuchsine, by Marchi's method and by Mallory's connective tissue stain.

The sections of the left lobe of the cerebellum show no changes, except the distortion from the compression.

The sections of the medulla show no changes, except that in the sections stained by Marchi's method there are seen many myelin sheaths which show black drops replacing the sheath or in its periphery, or occasionally a black circle completely replacing the sheath. Fully one-third of all the fibers are affected, and the degeneration is about equal throughout the medulla, no tracts or areas of the medulla appearing more affected than others.

The sections of the tumor show numerous large and small blood vessels, which are without regular arrangement. These are accompanied by a considerable amount of connective tissue, and here and there bands of connective tissue are seen in the tumor substance without any apparent relation to blood vessels, but there is no connective tissue stroma or capsule. The tumor is composed of a closely packed mass of small round or oval cells, with little cellular protoplasm, and oval or round nuclei, which, in general, are distinctly vesicular, though many of them are quite dense and stain deeply and nearly homogeneously. Mitoses, while somewhat rare, are found occasionally. Among the cells are seen a very few neuroglia fibers, and here and there are small areas, with very few nuclei, composed of neuroglia fibers, most of which, however, stain poorly. Larger and smaller necrotic areas are seen often, scattered throughout the tumor.

Anatomical diagnosis.— Glioma of middle lobe of the cerebellum.

The third case is a somewhat uncertain one, though I feel fairly confident that it also is one of tumor of the cerebellum, though the diagnosis was not confirmed by any post-mortem examination.

The patient, Jeanette S., three years and four months of age, was seen by me first on Jan. 26, 1902. The family history was good, except that the mother's grandmother had died of phthisis, and that the same disease had occurred three generations before in the father's family. The child was one of twins, the other child being healthy, as also one younger child. The birth and development had been normal. The only illness had been measles in the summer of 1901. In May of 1901, nine months before, it was noticed that she was inclined to fall, usually backward. No headaches had been noticed. The child complained simply of being tired. She was perfectly bright, and there had been no mental impairment and no convulsions. She had had six attacks of rather severe vomiting. No failure of sight had been noticed.

On examination there is slight staggering and unsteadiness in walking and standing. The circumference of the head is 53.2 cm., and the occiput is rather large. The head is not sensitive to light percussion. The pupils are equal, and react to light and upon accommodating. The external ocular muscles are normal, and there is no nystagmus and no strabismus. There is no paresis of the face or extremities. There is considerable inco-ordination of the movements of both arms and legs. The knee jerks are increased and equal. There is also ankle clonus and Babinski's sign on both sides. The optic nerve appears normal, though it is difficult to obtain a good view of the fundus.

On March 3 the circumference of the head had increased to 54.3 cm., and the patient seemed more unsteady. The optic nerve appeared normal. There was no paralysis anywhere, and the reflexes were the same as at the previous examination. On May 26 there had still been no headache, and the vomiting had been absent for some weeks. The circumference of the head had increased to 55.2 cm., but the inco-ordination in the use of the hands was less, though the child was still very unsteady on standing, but she could stand and with support could even take a few steps. There was no strabismus or nystagmus and no facial paresis and no change in the reflexes. On Aug. 19 the circumference of the head had increased to 56.0 cm., and the parents thought the child had not seemed as well for the week previous, and she had vomited once or twice. The inco-ordination had not diminished, but no new symptoms were present.

Dr. H. K. Faulkner of Keene, N. H., under whose care the child had come, very kindly wrote me in regard to the ending of the case. He stated that the child had remained much the same all summer, though she could not walk, until, on Oct. 14, he was called to see her for what the

parents thought a cold. He found her with edema of the lungs, the pulse 130, temperature 101.5° and respiration 32. There was slight occasional paralysis of the external motor muscles of the eyes, the pupils were dilated, contracting slowly and incompletely to accommodation. The child was unconsicous, and remained in this condition for ten hours before death came. This case for a long time seemed to me to be a doubtful one, and I was inclined to look upon it as one of hydrocephalus; but the sudden termination with symptoms of increased intracranial pressure, and with paralysis of the ocular muscles, make it seem fairly certain that this case should be classed with the two preceding ones as a case of tumor of the cerebellum.

In two of the cases reported the symptoms were very indefinite, and in the first case for a long time it was impossible to say more than that we had to do with an intracranial new growth, as none of the characteristic symptoms of cerebellar tumor were present, unless the ptosis, which appeared three days before death, can be so regarded.

The second case cannot be considered to throw any light upon the chance of success of operation in these cases, as the operation was done *in extremis*, yet it may not be without advantage to note that in this case we had to deal with a glioma of the cerebellum and yet one that was sharply defined and that could have been easily removed by an early operation if it had been in a more accessible part of the cerebellum. It should also be noticed that in this case the diagnosis of location of the tumor upon the left side from the involvement of the cranial nerves upon that side did not lead us astray, as the tumor although in the middle lobe of the cerebellum, had grown almost entirely into the left hemisphere. It is well, however, to note that the conclusions from the involvement of the cranial nerves towards the last, when the patient was in an unconscious condition, would have been misleading, as at that time the right oculomotor nerve was affected, and possibly the right facial, though this was uncertain, as it was impossible to produce any contraction of the facial muscles either voluntary or emotional. In this case it is possible that the injury to the head from a fall which occurred a little over three months before the rather sudden onset of the symptoms may have been an exciting cause of the growth of the tumor, though it seems to me that the interval is rather too great for this to have been the case where we have what was evidently a rapidly growing tumor, judging both from the course of the disease and the histological examination. The entire duration of the disease from the first onset of the symptoms was in this case only about fifteen weeks. In this case we obtained no further light upon the possibility of the diagnosis of the position of intracranial growths from the use of the x-ray, because the pictures were unfortunately taken in such a position as to prevent the comparison of the two sides of the cerebellum.

In two of the cases, the first and the third, we should note the curious intermission in the symptoms, in the first case for a period of about six weeks and in the other for a still longer time, though in this case the most troublesome symptoms, the ataxia and difficulty in walking, did not change materially during the course of the disease.

Another point which should be noted is the condition of the knee jerks in these cases. In the first case the knee jerks were lively and there was a front tap contraction when the case was first seen, and the knee jerks remained the same until far along in the course of the disease, when Dr. Farrant reports that the left one became diminished. The tumor was found in the right side of the cerebellum. In the second case the knee jerks were persistently absent, and the diffuse acute degeneration found in the medulla could hardly account for this condition, as might have been the case if only certain tracts connected with the cerebellum had been found affected. Unfortunately, the autopsy not being a complete one, an examination of the lumbar portion of the cord was impossible. In the third case the knee jerks were increased and there was double ankle clonus and Babinski's sign was present, which I considered to be evidence of pressure upon the motor tracts from increased fluid in the cerebral ventricles. Certainly this case if it were one of cerebellar tumor does not bear out the statement often made that the knee jerks are generally absent in these cases. The diminishing of the knee jerk upon one side only in the first case is, however, suggestive that this disappearance of the knee jerks so often noted in tumor of the cerebellum, as in our second case, is not a mere accident, but the effect of impairment of function of some cerebellar tract affecting this reflex.

TUBERCULOSIS OF THE SPINE. A STATISTICAL STUDY OF THE CASES IN THE ORTHOPEDIC DEPARTMENT OF THE CARNEY HOSPITAL.

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

THE following cases are reported in the hope that the facts as presented, even though incomplete, may be of some value to those interested in this class of disease. The analysis includes all of the cases of tuberculosis of the spine which were treated at the Orthopedic Department of the Carney Hospital in the eight years previous to 1902. The cases in which there could be any question of the diagnosis have been excluded. These represented many cases which in the early years of the clinic, before the spinal diseases were better understood, were considered to be tubercular ostitis, but which later experience showed to be osteo-arthritis, disease of the mesenteric glands, osteo-myelitis, etc.

There are many facts which would be of value in this report but which cannot be included, owing to the imperfect condition of the early records, and because of the impossibility of locating many of the cases in order to obtain a final examination.

In all, 108 cases applied for treatment in the

period mentioned. Of these, 46 failed to carry on the treatment which was prescribed, and were lost sight of. The remaining 62 have been kept under observation and followed the treatment with more or less consistency, and have all recently reported as to their present condition. The interval which has elapsed since the initiation of the treatment averages in these cases 2.1 years, and of this number (62) 36 were males and 26 females.

The ages have been arranged in decades, and as no cases under twelve years of age were treated, there were no representatives of the first period. Twenty-seven cases were from 10 to 19 years of age; 14 cases from 20 to 29; 12 cases from 30 to 39; 4 cases from 40 to 49; 3 cases from 50 to 59; 2 from 60 to 69.

Duration of the disease. — When first seen 18 of the cases had suffered from deformity or other symptoms for a period of one year or less; 16, 1 to 5 years; 11, 6 to 10 years; 6, 11 to 20 years; and 4, above 20 years.

Complications. — In 20 cases there was one or more discharging sinuses at some period of the disease. Of these 20 cases at last report, 8 were improved, the sinus having closed in almost every case; 4 were in poor condition; and 8 were dead.

In 11 cases paraplegia to a varying degree occurred at some period in the disease. At last report the paralysis had disappeared in 7 cases; in 2 this facture was not noted; and 2 were dead.

Results.—At last report 20 were entirely free from symptoms, and the disease was apparently quiescent, with resulting deformity of varying degree. In 18 cases the condition is greatly improved, but in 13 cases there has been no improvement, and the present condition of the patient is poor. Eleven of the cases are dead. Two of these, both of many years' standing, died of intercurrent affections, and of the remaining 9, the cause of death in 4 cases was given as Pott's disease and in 5 as Pott's disease and phthisis. Of the fatal cases, 2 were between 10 and 19 years, 4 between 20 and 29 and 5 between 30 and 39 years of age. The shortest interval from the first symptoms to date of death was less than one year, the longest six years, the average four years. Five were complicated by phthisis, 2 were paraplegic and in 5 there was abscess formation with accompanying discharging sinus.

Conclusions. — The report represents a consideration of all of the cases of Pott's disease which applied to the Orthopedic Department of the Carney Hospital prior to 1902. In all there are 108 cases, of which number 62 reported more or less regularly for treatment. Of this number (62) 41 were under 30 years of age, and in 21 of the cases the disease had existed for from 6 to 20 years before applying for treatment. In 20 cases there was abscess. Of this number 8 died and 4 are at present in poor condition.

In 11 cases there was paraplegia, and of this number 2 died.

Of the 62 cases 11 died, and in nearly all death was due to the extension of the disease locally or to some other part of the body, the average time between the onset of the disease and the time of death being four years.

In considering the report it is to be remembered that the cases here studied are entirely hospital patients, living for the most part necessarily under poor hygienic conditions. A similar number of private cases studied would possibly and probably show more favorable results.

A NOTE ON THE ASSOCIATION OF A RISE IN SYSTOLIC BLOOD PRESSURE WITH THE ONSET OF PERFORATIVE PERITONITIS IN TYPHOID FEVER.

BY JOHN BRADFORD BRIGGS, M.D., BALTIMORE, MD.,

Resident House Officer, the Johns Hopkins Hospital.

During the past two years I have frequently observed a sharp rise in systolic blood pressure, as measured by a modified Riva-Rocci sphygmomanometer, occurring in patients undergoing laparotomy, and produced by mechanical irritation of the peritoneum. Dr. Harvey Cushing suggested that a similar rise in blood pressure might possibly be produced at the onset of intestinal perforation in typhoid fever, by the mechanical and chemical irritation due to the extravasated bowel contents, and might prove of value in the early recognition of typhoid peritonitis. It was soon found, from the observations of Dr. Cook and myself, that patients suffering from acute general or rapidly spreading peritonitis, from whatever origin, uniformly showed, unless in moribund condition, a state of hypertension of the pulse. Similar observations have been made and reported by Dr. G. W. Crile,[1] and the association of high systolic blood pressures with general or rapidly extending peritonitis may be regarded as a constant one. It remained to study the development of the increased pulse tension in these conditions, and with that object in view we have in the past year kept a close watch on the state of the blood pressure in many of the typhoid patients admitted to Dr. Osler's service in the Johns Hopkins Hospital. In two patients, out of a large number followed, abdominal symptoms justifying exploratory laparotomy have arisen, and the relation in each of these of the symptoms to the blood pressure has been of the greatest interest. It is with the idea of stimulating further observations along this line during the approaching "typhoid season" that brief notes of the two cases are here reported.

Case I. The patient was a young white man, admitted about the end of the second week of a typical attack of typhoid fever of considerable severity. His condition was not good, and he soon became delirious. The temperature was high, there was no diarrhea and no intestinal hemorrhage. The abdomen was soft and natural, and remained so during the ten days following admission. During that time from 20 to 200 measurements of systolic blood pressure were made each day, for purposes not connected with the present subject. The pressures ranged from 98 to 115 mm. Hg., with a general downward tendency as the disease progressed, and never rose as high as 120 mm. Hg., except within the hour

[1] Journ. Am. Med. Assoc., May 9, 1903.

following the administration of strychnia hypodermically. At 8 P.M. on the night of Jan. 16, the blood pressure was found to be 106 mm. Hg. At midnight it was 144 mm. Hg. (same observer), the patient's abdominal condition being the same as it was four hours earlier, — absolutely negative with regard to pain, tenderness, rigidity of the muscles or distention. At 4 A.M. the next morning the patient cried out suddenly with severe pain in the abdomen, and was found with knees drawn up, restricted respiratory movements of the abdomen, great tenderness over the right lower rectus muscle and some muscular rigidity at the same point. The signs developed rapidly, and about five hours later laparotomy was done, two perforations being found low down in the ileum. There was rapidly spreading peritonitis with some pus in the pelvis. There had been no sudden drop in the temperature, and the leucocytes had shown no change in frequent counts. The blood pressure remained high, falling slightly in the hours just before operation, but never approaching its pre-perforative level.

CASE II. A young white woman, very well nourished and with slight general arterio-sclerosis, in the fifty-seventh day of a severe attack of typhoid fever. For six weeks the blood pressure had been carefully followed, and had ranged between 104 and 125 mm. Hg., following a rather high level for so severe an attack. Three weeks before the patient had several intestinal hemorrhages. She had passed through one intercurrent relapse, and at the time of the development of grave abdominal symptoms was at the end of the first week of a relapse following two days' apyrexia. Temperatures had been very high, the pulse rapid, and there was slight tympanites; there was low muttering delirium, especially at night, but the patient could be roused to answer questions intelligently. For some days there had been occasional complaint of abdominal pain, never at all extreme, and there had been some tenderness on deep palpation, never well localized. Leucocytes had ranged constantly below 7,000. During the night of the fifty-sixth day there was sudden rapid increase in the abdominal distention. The complaint of pain in the abdomen became more constant and insistent, and the tenderness on palpation increased markedly, while remaining fairly general. The thighs were not flexed, and there was no outcry, and apparently no paroxysmal pain. Abdominal distention progressed, and could not be relieved by turpentine by mouth and locally applied, nor by enemata. The pulse rate was from 150 to 172 per minute, the general condition bad, and evidencing a profound toxemia. Leucocytes rose rapidly to 17,000 at noon of the fifty-seventh day, when in view of the increasing severity of the abdominal signs and symptoms, operation was decided upon. Though the diagnosis was not positively made, it was considered by the surgeon who saw the case "that in the absence of signs of hemorrhage into the bowel, perforation had probably occurred, with extravasation of intestinal contents."

The patient's blood pressure had been carefully recorded. During the relapse it had ranged slightly below 120 mm. Hg., and during the period of abdominal symptoms it followed the same level, rising occasionally as high as 125 mm. Hg. as the result of free stimulation with strychnin and digitalin. In the absence of any fall in blood pressure, it was very improbable that any retained intestinal hemorrhage had caused the abdominal symptoms. The absence of any considerable or abrupt rise in blood pressure, on the other hand, was considered by the writer to be positive evidence that perforation had not occurred, and to justify the expression which I made of that opinion before operation. At 3.20 P.M. the abdomen was opened by an ample incision through the right rectus muscle, under cocaine anesthesia. The intestine was carefully examined, but no perforation could be found, and there was no peritonitis, aside from a light coating of filmy fibrin over the bases of two ulcers low down in the ileum.

The first case was remarkable in that the blood-pressure rise, characteristic of typhoid perforation, occurred so long before the onset of any other suggestive symptoms. At operation the condition of the peritoneum was such as to cause the comment that its inflammation was apparently eight or ten hours old; which would correspond almost exactly with the first observed rise in blood pressure, and not at all with the sudden onset of abdominal pain. I am convinced that perforation in this case had already occurred when the first high blood pressure was noted. It is conceivable that the extravasation at that time was entirely among intestinal coils, and that subjective pain was not felt until the resultant inflammation had extended to the parietal peritoneum. The case suggested to Dr. Cushing the advisability of determining experimentally in animals whether a blood-pressure-raising peritoneal reflex can be elicited which is not associated with sensations of pain.

In the second case the evidence given by the blood pressure was entirely negative. The objection was made during the consideration of the case that the low blood pressure might be due to the profound toxemia; the vasomotor center (and periphery) being perhaps unable to respond typically to peritoneal afferent impulses. That the vasomotor irritability of the patient was not in abeyance was proven by the fact that shortly before operation she reacted to painful stimulation of the skin by characteristic transient elevations in blood pressure, while central stimulation with strychnin also produced a decided and more lasting increase in pulse tension. It seems certain, then:

(1) That patients with general or rapidly spreading peritonitis have constantly, at least in the early period, abnormally high blood pressures.

(2) That in perforative peritonitis a sharp rise in blood pressure *may* precede the onset of other symptoms.

(3) That in doubtful cases, like my second one, where perforative peritonitis is suspected, and the general previous blood-pressure level is known, the course of the blood pressure after the onset of grave symptoms should receive consideration in determining the propriety of operation.

It is to be hoped that the few observations so far recorded will be amplified by other workers in the coming autumn. In general hospitals, at least, it is easily possible to keep run of the blood pressure in all typhoid patients with bi-daily or more frequent determinations with the Riva-Rocci instrument. In this way it will be possible to have valuable data at hand in case of the development of intra-abdominal mischief, when the subsequent more frequent measurements of pulse tension will prove of greater value than if the patient's usual blood-pressure level were unknown. Rapidly rising blood pressures in cases with developing abdominal symptoms will probably prove more significant than any later stationary pressures, at whatever high level. It is the curve of changing direction in a well-plotted blood-pressure chart, rather than the position of that curve with reference to the base line of zero pressure, that should first challenge the attention of the clinician under these conditions.

Medical Progress.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., AND W. D. HALL, M.D., BOSTON.

THE USE OF THE X-RAY IN TRACHOMA.

MAYOU[1] shows that by means of the x-rays we can set up a leucocytosis with minimum destruction to epithelial and other tissues, and by it we can produce inflammation from a very slight leucocytosis to actual gangrene of the part, which, with care and experience, may be under perfect control. As we do not know the organism which causes trachoma, we cannot say whether the irritants which are used in its treatment or the x-rays have any effect on it. But we have in the x-rays a method of producing leucocytosis in any degree of severity, from that following a mild application of perchloride of mercury up to that induced by jequirity, and further, this leucocytosis is much more prolonged than that in any method previously adopted and the destruction is not nearly so great. Although the granules disappear rapidly under the x-rays, operative methods which remove the diseased tissue must be preferred to some extent. The x-rays, however, may be used to complete the work in preference to other irritants now in use. Operations, however, should never follow x-ray treatment until after a considerable lapse of time. The author reported the first case early in 1902. At that time it was the custom to cover the whole face, with the exception of the affected eye, with a metal mask. (Since then he has discarded the mask altogether.) The upper lid is everted and the lower pushed up so as to cover as much of the cornea as possible, although in bad cases of pannus the cornea is exposed. He has never had any trouble with the globe following this treatment, and even in a case of rodent ulcer of the lid, in which the treatment was used for six months, there was only a conjunctivitis noticed, the patient's vision (six-ninths) remaining the same throughout. The patient is placed about nine inches from the anode, with a moderately soft tube and a current of six ampères. Two minutes' exposure from four to six days is given. If much injection, or if the case be acute, four are usually sufficient. After a week's rest, if there has been any reaction, the patient is exposed twice a week until the appearance of a slight photophobia. About this time the granules begin to disappear from the lids. Exposures are then carried on from one to three times a week, until they have disappeared, upon which all treatment must be stopped, as it requires several weeks for the infiltration set up by the x-rays to settle down, and it is difficult to tell whether the disease is eradicated until this injection has disappeared. The final results are very satisfactory, as, instead of the white, puckered conjunctiva there is a supple, non-contracted, non-scarred conjunctiva. Recent pannus then clears up with great rapidity, patients claiming to see more clearly even after the first exposure. Dense corneal opacity, however, requires some time. The granulations sometimes seem to disappear at the first exposure; others do not until after eight or ten. The chronic cases are most suitable for treatment and will stand more frequent exposures. Acute diffuse infiltrations, with lid thickening and photophobia, require much care and longer time. Old cases in which the lid trouble has nearly disappeared, but in which there is dense corneal opacities, will improve under exposure of long intervals after the first mild reaction. There is less deformity resulting, the treatment is practically painless and the pannus clears more thoroughly. It is especially suitable for hospital patients, who cannot attend daily.

Sydney Stephenson and David Walsh[2] refer to the only recorded case thus far of Mayou, and report four cases of their own, in all of which marked improvement was noticed. All were affected with severe trachoma, and corneal involvement in three of the cases. A twelve-inch Cox's coil was used, with the "Record" focus tube of the same maker. At first the apparatus was run with a strong battery and spring break, and afterwards by a Mackenzie-Davidson mercury break, together with current run direct from the main. The focus tube was "hard," with an average existence equal to a seven or eight-inch spark gap on the coil. The anticathode of the focus tube was placed at about eight inches from the eye, and the exposure was from ten to fifteen minutes. They used a mask of lead foil. An average current strength of five ampères and twenty to twenty-five volts was used. They state their results as follows: of the four cases of trachoma treated with the focus tube, the eyes appeared to be cured in two, while such improvement took place in the other cases as to promise equally favorable result with a continuance of the treatment. A slight superficial dermatitis of the lids was noted, and in one case it became a blister. The face was similarly affected once or twice. A moderate dermatitis occurred on the fingers and back of the hand of the nurse who held the lids everted during a four-inch exposure. A shield and mask of lead prevented any further mishaps of this kind. Other cases showed improvement from the first exposure. The immediate effect of the focus tube was to render the granular bodies redder and more prominent, followed by a stage of rapid absorption. Of the five eyes treated in the four patients, two appeared cured at the time of writing, while the others were on the road to cure. On the other hand, the three eyes untreated by the focus tube remain the same as when the patients were first put under this special treatment. During the focus tube exposures, the eyes not exposed have been treated daily with an antiseptic wash. The eversion or otherwise of the lids appears not to make the least difference, which is fortunate, as it is no light task for the operator to keep a child's lid everted for ten minutes at a time.

[1] The Lancet, Feb. 28, 1903.

[2] Med. Press and Circ., Feb. 18, 1903, and the Lancet, Jan. 24, 1903.

The apparent cure of the two eyes resulted from seventeen exposures in one case and from sixteen in another. With regard to the trachoma apparently cured by the high frequency current, the results were obtained after twenty-two applications. A twelve-inch spark coil was run from the main connection with a D'Arsenval high-frequency apparatus. One end of the solenoid was earthed, the other being connected with a vulcanite electrode, with which the closed right lids were gently massaged. A small brush discharge of about half an inch was obtained from the electrode. At times the orbicularis and the corrugator supercilii muscles were thrown into action. This is probably the first application of high frequency current to the eye. Treatment by the focus tube and by the high frequency current is painless, and it is common for the children to fall asleep. The rapidity of recovery is an important factor, and almost if not quite absolute safety may be claimed for both forms of treatment if applied with skilled hands. The application of the focus tube to the eye by an unskilled or careless person may, however, play havoc. In addition to surface burns, the eyelashes become thinner in some of the eyes treated by focus tubes. In one case, after ten exposures with everted lids, a small infiltration resembling an ordinary phlyctenular appeared in the lower quadrant of the corena, followed in the course of a week by several similar deposits, both of which developed into small ulcers.

PARAFFIN AFTER ENUCLEATION.

Dr. G. H. Suker[3] of Chicago employs paraffin injected into the scleral cup as a substitute for the Mules operation, or into the capsule cavity instead of the Frost-Lang method, or instead of the glass or gold ball method of Fox, and finally to take the place of such absorbable material, as agar, sponge, etc., as used by Claiborne and others. He considers the final result as far better, insomuch as there is practically no contraction due to cicatrical formation, resulting from absorption of the media employed. It may be mentioned, however, that there is a very slight absorption and contraction due to the vaseline, necessarily used with the paraffin, to obtain the required melting point and consistency. As a result of this, the paraffin may be said to become encysted and partially fenestrated. The paraffin can be injected immediately into the capsule cavity, after the hemorrhage has been stopped, or at some subsequent time. If at the time of the operation, pack the cavity with gauze and suture the wound, leaving a small opening at one end, through which the gauze may be withdrawn and the paraffin injected. By this means you can control the hemorrhage, a matter of great importance, and also better suture the cavity when packed. Careful coaptation is necessary in order to avoid oozing of the paraffin, as considerable force must be used at the time of injection in order to fill out the cavities. The reaction with edema and infiltration of the orbital and adjacent tissue will be considerable, but not more than is noticed in other methods of implantation. He prefers to inject the paraffin about a week after the primary operation, during which time the cavities are to remain packed with gauze, which can be removed through a small opening, and thereby will be obtained a firmer union of the edges of the wound and time for the edema infiltration to subside; besides, all hemorrhage will be absent. He thinks the greatest field for usefulness will be in the restoration of the sunken socket after a remote enucleation, the method of which is as follows: "After thoroughly cocainizing the socket and using freely adrenalin (1–1000), with a pair of tissue forceps, pick up the apex of the socket-pit; then with a narrow scalpel you enter the subconjunctival space at the apex to the extent of 3 mm.; then make an elliptical cut at about the point of entrance," thereby obtaining a pocket in both cul-de-sacs, with but a single opening. The higher you cut into the cul-de-sac, the more prominent will be the stump after the injection. After checking the trivial hemorrhage, inject about a drachm of paraffin, properly prepared, or enough to give the desired fullness, but do not overdistend the cavity, on account of the great pain, sloughing and probable ultimate expulsion of the paraffin. It is well to put a suture in place, in order to be able to close the opening immediately after the injection, as it will be difficult to do so afterward. The reaction is quite severe, but may be controlled by a cold pack. The artificial shell may be inserted within a week or ten days. Although the opening may not close readily, even though sutured, granulation will usually accomplish this. The paraffin used for this purpose is chemically pure, white and mixed with pure vaseline, in the proportion of 3-5 of the latter and 2-5 of the former, which mixture melts at 102° F., and does not solidify too rapidly. If the syringe is of proper construction so as to retain the heat for a length of time, and the tip is not of too fine a caliber, there will be no trouble about the injection. One advantage in using paraffin in this class of cases is that should one injection prove inefficient a second or third may be undertaken at a subsequent time. That excessive heat does not liquefy the paraffin when injected into the socket is shown by the fact that it has been used among men employed about furnaces. Neither do high fevers cause liquefying, because the vaseline being practically absorbed, the melting point is materially raised. Pure paraffin has a higher melting point than any patient may have under ordinary circumstances. The melting point may be regulated by the amount of vaseline added.

[3] Annals of Ophthalmology, January, 1903.

EMBOLISM AND THROMBOSIS OF THE CENTRAL VESSELS OF THE RETINA.

Panas,[4] reviewing this condition, states that, although sudden loss of vision, the characteristic

[4] Archiv. d'Ophtal, .October, 1902.

appearance of the arteries and dimunition in caliber of the veins, the cherry spot at the fovea and cloudiness of the surrounding retina, absence of signs of stasis and want of prominence of the papilla, suggest complete obstruction of the central artery by an embolus, still hemorrhage into the vaginal sheath and certain forms of acute retrobulbar neuritis may produce similar changes. After the lapse of a few months it becomes impossible to differentiate between an embolus and a thrombus by the microscope, insomuch as the majority of patients so affected are of advanced age or affected with some condition in which arterio-sclerotic changes, due to syphilis, alcoholism, diabetes,etc., are well marked. He has found that changes noticed in thrombosis are much more common than those caused by embolism, and in this opinion he claims to have been supported by an increasing number of authorities. Haab may be especially mentioned as supporting this opinon. Michel has demonstrated a number of cases of thrombosis of the retinal veins, and it has been noticed that out of fifteen such cases ten developed glaucoma within a few months after the onset of the blindness, tending to prove that the process in the veins was not primary but consecutive to disturbances arising from senile changes. Ischreyt reports complete obliteration of the nasal branch of the vein by a thrombus with foci of obliterating endarteritis in the eye removed for glaucoma. The diagnosis of venus thrombus depends upon the retention of some visual power, the alternating distention and contraction of the veins, the absence of the venous pulse, small caliber of the arteries and retinal hemorrhages near the disc. He considers the prognosis to be less serious than in cases of embolism. Little can be done in the treatment of this condition, but mydriatics should be avoided. Alcohol should not be used, but iodide of potassium in small doses may be prescribed.

THE PROGNOSIS IN VISUAL DISTURBANCE OF ELECTRIC ORIGIN.

Terrien[5] has collected forty-five cases of ocular disturbances resulting from exposure to intense light produced by short circuits. In only one case did the current pass through the body of the patient. He notices three classes of symptoms — inflammatory, functional and nervous. In the first are noted transitory redness and swelling of the skin and burns accompanied by conjunctival injection without great chemosis or edema, and followed frequently by mucopurulent secretion. He has noticed neither corneal involvement nor changes in the lens, but hyperemia of the iris and a neuroretinitis were frequently present. Of the functional disturbances, a dazzling, which came on almost immediately, its severity being directly dependent upon the intensity of the light and the individual susceptibility, was noted. Vision when affected usually improved in a few hours. There might be erythropsia. The diminution in vision was usually accompanied by contraction of the field. Seven per cent of the cases seemed to have sustained considerable and permanent impairment of vision. In 14% the visual loss was not so great. Asthenopic symptoms were frequent, and continued for some time. Hemeralopia was quite common, as was also photophobia. Of the nervous disturbances, the photophobia bore a direct relation to the degree of severity of the lesion. Cephalagia was quite constant early, while ocular and periorbital pain, often severe, came on at variable periods. Later, however, these pains were not continuous, were usually worse at night and might be entirely absent in mild cases. Tenderness of the globe and along the course of the supraorbital nerves occurred in severe cases. Blepharospasm was almost always present. The pupil, generally quite small immediately after the accident, recovered its normal size in a few days, although in severe cases mydriasis was sometimes present. Although the diagnosis is rarely a matter of doubt, where simulation is suspected an examination of the fundus and a diminution in the visual field will aid in determining the real condition. It is sometimes very difficult to say that it is not a case of traumatic hysteria. In making a prognosis, the duration of the symptoms is more important than the question of the degree of initial severity. Mydriasis, contracted fields, severe neuralgia and pain on pressure, tardy improvement of the vision are suggestive of a serious condition. As regards the treatment, the wearing of colored glasses interferes with return to work, and should therefore be ordered. For the ocular pains, cold compresses and cocaine may be tried; and for the neuralgia, one of the bromides, quinine and antipyrin. For the functional disturbances nux vomica, nitrate of amyl, lactate of zinc and electricity may be tried. Almost any procedure will, however, unfortunately be unsatisfactory.

(To be continued.)

Reports of Societies.

AMERICAN THERAPEUTIC SOCIETY.[1]

Report of Meetings Held at Washington, D. C., May 11, 12 and 13, 1903.

Dr. Thomas E. Satterthwaite (New York) in the Chair.

The address of welcome was delivered by Dr. Robert Reyburn (Washington), Dr. R. W. Wilcox (New York), responding for the visiting members.

Presidential address by Dr. Satterthwaite:

RECENT ADVANCES IN MEDICAL THERAPEUTICS.

The greatest achievement of recent years has been the suppression of yellow fever in Havana by our Government Commission, consisting of Drs. Reed, Carroll, Lazear and Agramonte, appointed in 1901. They soon proved that the ste-

[1] Prepared exclusively for this Journal.

gomyia fasciata is the immediate host of the germ, and after eight months' work of extermination, yellow fever disappeared entirely from Havana, and, to the writer's knowledge, there has not been a case there since. Several diseases have recently become of interest to Americans on account of immigration from our new possessions. In the treatment of cholera, which is epidemic in the Philippines, Freer and Marshall obtained good results from benzoyl-acetyl-peroxide as an intestinal antiseptic. The guaiacol carbonate and calomel treatment has also been used, and appears to have reduced the mortality one-half. After reviewing the etiology of the plague and the history of the recent epidemic in San Francisco, Dr. Satterthwaite refers to treatment by the Yersin-Roux serum and Haffkine's prophylactic; the former gave satisfaction, but the latter appeared to be of doubtful value. Unless our colleges rise to the emergency, the government will be compelled to found schools of tropical medicine. The recent discovery of uncinariosis in our Southern States shows what an intelligent study of these affections will accomplish. After referring to the terrible mortality from tuberculosis, Dr. Satterthwaite discusses the advantages and cost of sanitorium treatment. Statistics prove its superiority for suitable cases. The expense at Bedford, N. Y., was found to be only 76.8 cents per day for each patient. Dr. MacDonald has treated patients in tent hospitals at even less expense. The method deserves further trial. A campaign of education is needed to teach the laity how to avoid consumption, and how to avoid giving it to others. Statistics show that we are already reducing the mortality. The mortality from typhoid also has been reduced from 20 to 10%. Abt, of Chicago, claims a mortality of only 5% in 40 cases in children, using benzoyl-acetyl-peroxide. Hirshfeld uses hot baths, and claims a reduction in mortality of over one-half. The mortality from diphtheria has fallen 50% since the introduction of the antitoxin treatment. In considering dosage, Dr. Satterthwaite states that in one case the administration of 92,000 units was followed by recovery. In the treatment of cardiac affections the tendency is to use indirect rather than direct methods; hydrotherapy, exercise, diet, tonics and purgatives are assuming deserved prominence, while the nitrites are substituted as far as possible for digitalis and similar drugs. Many surgeons now admit that simple acute appendicitis is best treated by internal medication, the chronic and relapsing forms calling for surgical intervention. The paper concludes with a plea for a central supervision of the materia medica supply. Pharmacists are not sufficiently controlled by the sanitary authorities. If we are losing faith in the efficacy of drugs, it is largely because of the wide difference in the drugs of commerce as regards purity and strength. Methods have been devised for determining the precise medicinal value of drugs, and all medicinal substances, before being put up for sale, should be subjected to these tests.

SYMPOSIUM: THE TEACHING OF THERAPEUTICS.

DR. REYNOLD W. WILCOX of New York, in introducing the subject, said that there is much room for improvement in medical school teaching. If post-graduate instruction is elementary at times, it is because of the necessities of those who demand it. When the undergraduate shall be brought to his doctorate as well equipped for treating as he is now for recognizing disease, the work of the post-graduate school will be post-graduate in deed as well as in name. He suggested the following topics for discussion as indicating causes of failure in the past: (1) A practical acquaintance with remedial measures and remedies, and methods of preparing the latter. (2) A knowledge of their action acquired by experimentation and demonstration under the teacher's eye. (3) Their application to diseased conditions, under proper supervision. (4) The rational and logical prescription of remedies and physical agencies.

ON THE TEACHING OF PHARMACOLOGY AND THERAPEUTICS IN OUR MEDICAL SCHOOLS.

DR. JOHN J. ABEL (Baltimore). The great value of laboratory experimentation is evidenced by the brilliant discoveries of the past, the promising investigations of the present and the ever-increasing importance of laboratory methods in diagnosis. A knowledge of experimental details teaches conservatism; it makes the student hesitate to accept a current hypothesis as a general law of nature; it tends to arouse an appetite for the fundamental in medicine; it stimulates to inquiry and to a logical analysis of phenomena. At Johns Hopkins, the course in Pharmacology is preceded by a study of the intoxications. Accompanying this is a chemical course dealing with the isolation of alkaloids, tests for poisons, blood, etc., There are also numerous recitations and conferences, but little didactic instruction. Pharmacology is taught by experiments and demonstrations, the object being to illustrate the effects of the more important drugs. Such a course is valuable even if the student can perform only six or seven experiments himself. The teacher, while not necessarily an active practitioner, should be familiar with clinical work. Therapeutics, however, is best taught by the various clinicians. A course in Practical Therapeutics is desirable. Detailed instruction in Materia Medica is unnecessary. A brief course in Pharmacy is desirable, but not indispensable.

DR. OLIVER T. OSBORNE (New Haven), in discussion, described the method used at the Yale Medical School. After a brief course in Pharmacy, the students take up Materia Medica in their second year; it is made as practical as possible. Experimental Pharmacology follows, and then, in the junior year, the students take up Pharmacology. The drugs are studied in groups, according to their therapeutic uses. The teacher should be familiar with clinical work. As a rule the men write better prescriptions early in their

course than they do later, because later they come in contact with those who use the old system, which introduces an element of confusion. They memorize an average dose for each remedy rather than the range of dosage. Therapeutics is introduced in the latter part of the junior year; it is taught by lectures, recitations and clinics. In the last, case-history cards are carefully filled out by the students; they serve to aid the memory, and when completed furnish a complete history of each case, with the object of treatment and result plainly stated.

Dr. Torald Sollman (Cleveland): The objects of medical school instruction are best gained by lectures, recitations and practical work. The lectures should not be too full, or the student will depend upon them to the exclusion of outside reading. Lectures, however, are indispensable; the personal influence of the teacher is of great value. The recitations teach men to think. In teaching Pharmacology, laboratory instruction is desirable, but not absolutely indispensable. Generally speaking, it is not advisable for a professor to be also engaged in practice. He agreed with previous speakers as to the best methods of furnishing clinical instruction. Only the essential portions of Materia Medica should receive attention. As a rule, the less Pharmacy taught, the better. The metric system is the system of the future.

FROM PHARMACOLOGICAL SCIENCE TO THERAPEUTIC ART.

Dr. Eli H. Long (Buffalo). Medical school instruction in the first two years is better than in the last two, because the earlier work is more definite in character, more teachers are engaged in it and the student does more for himself; third and fourth year classes are taught together, which minimizes individual instruction and leads to a faulty adaptation of the needs of each class. Pathology and diagnosis are emphasized at the expense of treatment. In the earlier years the student acquires a groundwork of facts; in the final years he should be taught to use them — to associate facts, to recognize principles and to form conclusions. Mind training rather than fact getting should be the main object. In his opinon these objects are best gained by informal conferences between teacher and class. Clinical instruction must also be provided, and the courses in Pathology and Practice should be correlated to that in Therapeutics. The student must be guarded against the prevalent scepticism as to the efficacy of drugs, and the tendency to use commercial preparations. Two features should be given especial prominence: the clinical sessions and an endeavor to train the students to use their own efforts in all that pertains to treatment.

DISCUSSION.

Dr. Howard Vanrensselaer (Albany) described the method used in the Albany Medical College. The first two years are largely didactic; the third is didactic and laboratory; and in the fourth the lectures are eliminated as far as possible. Clinical instruction is given to classes of about eight men each. The physiological effects of drugs are illustrated by actual administration. The case-history card requires too much time, and does not teach the student to think for himself.

WHAT OUGHT WE TO EXPECT FROM CARDIAC DRUGS IN HEART DISEASE?

Dr. Oliver T. Osborne (New Haven). Important causes of early cardiac disease are the "strenuous life" and abuse of alcohol and tobacco. Acute weakness calls for cardiac stimulants — alcohol, ammonia, etc.; chronic weakness calls for cardiac tonics — digitalis and drugs of its class. Digitalis is the queen of heart tonics. After reviewing indications and contraindications for the use of digitalis, Dr. Osborne statet that strophanthus is the best substitute, and it is even preferable in some conditions. Sparteine is not a substitute. Fresh fluid extract of cactus regulates and quiets the heart. It is useful as an adjuvant to digitalis, and is preferred in cardiac debility of convalescence, in old age when digitalis is contraindicated and in functional diseases. Convallaria and adonidin proved unsatisfactory in his hands. Barium chloride is a powerful heart stimulant. Suprarenal extract is a vasomotor and cardiac stimulant only when absorbed from the nose or mouth. Notwithstanding its value we are inclined to give too much strychnia. It should be reserved for emergency. Caffeine is a useful substitute for alcohol in prolonged fevers; it is also an adjuvant and temporary substitute for digitalis. The beneficial effects of alcohol are due to reflex stimulation; it is not a stimulant after absorption; if too much is absorbed it acts as a depressant. Hence it is the poorest stimulant we can use to combat continuous heart failure.

DISCUSSION.

Dr. Eli H. Long (Buffalo). The first effect of digitalis, the direct effect upon the heart, is the most desirable; the slowing comes later, and may or may not be desirable. He liked the terms "kinetic" and "potential" as applied to heart stimulants — digitalis and caffeine are kinetic stimulants; strychnia, which acts by irritation of tissue, is a potential stimulant. Dr. Robert Reyburn (Washington) advocated smaller doses of digitalis, strychnia and alcohol. Strychnia is given for almost everything. He had seen a case in which it caused cerebral hemorrhage by raising arterial pressure. It is often well to combine digitalis and aconite. Dr. T. E. Satterthwaite (New York) ascribed the increasing frequency of diseases of the heart and arteries largely to syphilis, gout, the "strenuous life," abuse of alcohol, tobacco, coal-tar products, etc. The nitrites are often preferable to digitalis. In determining treatment it is necessary to distinguish between functional and organic cardiac affections, and also between cardiac stimulants and tonics. Serious mistakes have resulted from a failure to observe the first precaution. In functional derangements digitalis often does

harm, but the antispasmodics do good. A slow or a fast pulse in heart affections has little significance. In his experience suprarenal extract has acted well as a heart tonic when given by mouth. He usually prohibits tea, coffee and tobacco. Coffee is a poison to about one-third. DR. ARTHUR T. HALL (Washington) commended caffeine as a valuable heart tonic. DR. OSBORNE, in closing, spoke of the connection between the declining function of the thyroid gland, which begins at about the forty-fifth year, and arterio-sclerosis. Thyroid extract, in small doses, tends to minimize the changes resulting from atrophy of the gland.

WHO MAY BE BENEFITED BY ALTITUDE TREATMENT?

DR. J. N. HALL (Denver). Unfortunately, many patients are sent to higher altitudes who cannot possibly be benefited thereby, either through faulty diagnosis or lack of judgment on the part of the physician. If patients with pulmonary tuberculosis are sent away *early*, a recovery may be expected in 90% of cases; after considerable dullness and even excavation has occurred at one apex there is a fighting chance of arrest and a good chance of delayed progress; but involvement of both lungs, unless purely catarrhal, generally precludes hope of complete arrest. Those who are predisposed to tuberculosis may well consider removal to a high, dry region. Other conditions which are benefited are glandular tuberculosis, asthma, chronic bronchitis, malaria and some forms of anemia and hay fever. In the presence of a complication of organic heart disease, one should respect the predominant condition. Little difference is observed if compensation is good; but if it is on the point of failing, it is risky to send the patient to any great elevation.

THE RATIONALE OF THE CURE OF MORBID GROWTHS BY PHOTOTHERAPY AND X-RAYS.

DR. ROBERT REYBURN (Washington), After reviewing our knowledge of the x-rays and Finsen light, Dr. Reyburn expresses the opinion that they destroy the tumors in lupus and epithelioma by an escharotic effect. Continuous application, in addition, forms a zone of lymph around the morbid cells, which protects the body from further invasion. They are superior to other causties because they do not cause such a wasteful destruction of tissue. The opinion is growing that only superficial growths are amenable to their powers.

DISCUSSION.

DR. W. J. MORTON (New York) said that Finsen light had served its purpose and had retired to the background. Superficial growths, like squamous epithelioma, can be cured by phototherapy in 100% of cases; deeper growths are also benefited, but not to the same extent. He had cured twelve cases of early primary cancer of the breast by phototherapy. He did not think that the action is like that of caustics; also, the protection is more through leucocytosis than the formation of a "protective wall." The treatment should be tried before resorting to the knife.

DR J. H. METZEROTT (Washington) commended Dr. Morton's remarks. There is still, however, a field for Finsen light, for example, in lupus. He related instances of successful treatment by phototherapy. He had cured some cases of deeper malignant growths. He believed that the x-rays will have a brilliant future.

THE THERAPEUTICS OF POTASSIUM COPAIVATE.

DR. LOUIS KOLIPINSKI (Washington). Potassium copaivate is the potassium salt of copaivic acid, and is made by the action of potassium hydroxide upon copaiba. It is a clear, reddish-brown fluid, gelatinous at 50° F., oily at 65° and liquid at 70–80°; taste, peppery; odor, like copaiba; dose, 50 to 150 gr. daily, best in capsules. The untoward effects are like those of copaiba, but are much less marked. It is useful in chronic eczema, acne vulgaris and rosacea, etc. Applied to ulcerating cancerous surfaces it removes fetor, arrests purulent discharge and prevents hemorrhage. Two or three drops to the ounce makes an agreeable detergent spray for nose and throat. Internally, its uses resemble those of copaiba. He had used it to advantage in non-obstructive anuria, acute and chronic cystitis and cholelithiasis. Its main use is in acute gonorrhea; if given early, it will in some cases produce a cure in a few days; it lessens the liability to complications, and is superior to copaiba.

CAFFEINE IN THE TREATMENT OF ALCOHOLIC TOXEMIA.

DR. ARTHUR J. HALL (Washington). Caffeine is directly antagonistic to alcohol in effect, and is almost a specific in alcoholic toxemia. After contrasting the action of the two drugs, Dr. Hall states that when given in 1 or 2 gr. doses every two or three hours it will usually within twenty-four to forty-eight hours effectually quench the appetite for liquor so that the *habitué* will voluntarily give up its use. He cites four cases in illustration, and advocates its use in all forms of alcoholic toxemia.

DRUG STANDARDIZATION IS ABSOLUTELY NECESSARY TO ACCURACY IN DRUG THERAPEUTICS.

DR. F. E. STEWART (East Orange, N. J.). Dr. Stewart emphasizes the importance of the subject, and states that the profession is largely responsible for the present deplorable lack of uniformity of drugs in quality and strength. Physicians and pharmacists should co-operate to secure remedial legislation. What is needed is a *profession of pharmaceutical experts* who shall ensure a standard materia medica supply. It must be created by legislation limiting the manufacture and sale of medicinal products to pharmacists, forcing them to carry on their vocation on a professional plane, and protecting them from unfair competition by obliging manufacturers to publish the true composition of their medicinal products and to tell the truth about them in their advertisements.

CONTROL OF THE PURITY AND STANDARD QUALITY OF DRUGS.

Dr. H. W. Wiley (Chief Bureau Chemistry, United States Department Agriculture Washington). After emphasizing the importance of drug control Dr. Wiley told of the investigation now being pursued by the Department of Agriculture. The object is to ascertain by analyzing thousands of samples purchased in the open market, the extent to which adulteration and fraud are carried in the drug trade, and then by bringing the facts before Congress to secure legislation which will protect pharmacists and the public against fraud, and guarantee to the physician drugs pure and of standard quality. This method was used successfully in securing the Pure Food Law, which went into effect July 1.

Dr. Satterthwaite spoke of the importance of the subject. He was glad that the work had been taken up by the government, and hoped that it would be carried to a successful termination. Publicity as to the quality and composition of medicinal products is the great thing necessary. He commended the investigation under the direction of Dr. Wiley.

SYMPOSIUM: RECENT ADVANCES IN SPECIAL THERAPEUTICS. SURGERY.

Dr. Carl Beck (New York). Schnitzler's statement that leucocytosis is present in cases of purulent appendicitis has been corroborated by many observers. Kyroscopy gives valuable information in the diagnosis and prognosis of renal affections calling for nephrectomy. X-rays have simplified the diagnosis of many disorders. Phototherapy has given good results in the treatment of external malignant growths. Senn also reports curative effects in two cases of Hodgkins' disease. The treatment will not, however, replace surgery; it should be reserved for inoperable cases. Edebohl's statement that stripping the kidney capsule will cure some renal disorders requires further confirmation. Kehr's work in the surgery of the biliary passages marks a new epoch. Czerny shows that renal tuberculosis is generally unilateral. Kronlein concluded from 264 cases of gastric carcinoma that unoperated patients will live one year; gastro-enterostomy prolongs life three and a half months; extirpation of the growth also adds fourteen months more.

LARYNGOLOGY.

Dr. Charles H. Knight (New York). Paraffin prosthesis for nasal deformities has become an established method. The paraffin is best introduced in a semi-solid state. It ultimately becomes organized, and ceases to be a foreign body. Some untoward effects have been noted. Some even claim for it curative effects in atrophic rhinitis. Suppurative affections of the accessory sinuses are receiving more attention, particularly the sphenoidal sinus. Grunwald claims that intranasal atrophy is due to suppurative disease of the sinuses; Minder claims the reverse. Conservative treatment, free drainage and irrigation give good results in most cases. The value of the new silver preparations is still *sub judice*.

ROENTGEN RAYS IN SKIN DISEASES.

Dr. E. B. Bronson (New York). Dr. Bronson discusses the nature of the rays, and contrasts the beneficial effects with those resulting from reckless usage. The agency requires careful management, and is potent for good or evil according to how it is used. The principal factors in the production of reactions are, the susceptibility of the individual, the condition of the tube, the distance from the focus and the duration of exposure. After considering each of these in detail, he states that the effect of successive irradiations is in a sense cumulative; if the first is sufficient to produce a therapeutic effect, additional irradiations may produce a burn. Hence some begin with a weak dose and increase; others, however, like Schaltz, begin with the maximum, having first tested the susceptibility of the patient. The method, viewed as a therapeutic measure, is still in the experimental stage.

GYNECOLOGY.

Dr. H. J. Garrigues (New York). Subcutaneous injections of gelatin to control hemorrhage are falling into disuse; suprarenal extract is preferable. Wernitz combats sepsis with rectal enemata of normal salt solution, continued an hour each time until temperature falls and diuresis is established. Two new mercury antiseptics have been introduced, the citrate and sulphate; they are bland, and equal the bichloride in antiseptic power. The Alexander operation for correction of retroflexion is gaining ground. Kreutzmann rejects ventro-fixation and ventro-suspension; in several instances it has necessitated subsequent Cæsarean section. He recommends low vaginal fixation, or shortening of the round ligaments. Garrigues does not favor the former. Oldebrecht has adopted Menge's method of treating chronic endometritis, the application of a fifty per cent formalin solution for one or two minutes, repeated in a week if necessary. The tendency to use the vaginal route in every possible case is abating. Downes of Philadelphia has perfected Skene's method of extirpating cancer of the uterus with electro-cautery clamps.

MATERIA MEDICA.

Dr. A. A. Stevens (Philadelphia). Protective vaccination with sterile cultures of typhoid bacillus has been used with some success in the British Army. Statistics do not credit antistreptococcus serum with any decided reduction of mortality. Leyden reports fourteen cases of scarlet fever treated with serum from convalescents with favorable results. After discussing lumbar puncture and phototherapy, Dr. Stevens refers to the use of benzoyl-acetyl-peroxide in typhoid fever; it has been recommended by several writers, but it seems doubtful whether any intestinal antiseptic has power to stay the course of the disease.

Adrenalin chloride has gained a reputation as a vaso-constrictor. Untoward effects have been noted in animals; among them, glycosuria and degeneration of the islands of Langerhans of the pancreas, after intraperitoneal injection of a 1 to 1,000 solution in dogs. This suggests that diabetes may be due to disease of the suprarenals. Kelynack demonstrates that alcohol predisposes an individual to tuberculosis. Gelatin maintains its value as a hemostatic. Methylene blue, while not as potent an antimalarial as quinine, deserves trial when quinine cannot be given. Thiosinamin is recommended for softening keloid growths, cicatricial tissue, etc.

OPHTHALMOLOGY AND OTOLOGY.

DR. J. E. WEEKS (New York). Acoin has been recommended in 1 to 3% solution as a local anesthetic for the eye; Randolph claims that it does not affect pupil, accommodation or intraocular tension. It is inferior to cocaine, but is useful in some conditions. Ethylmorphine hydrochlorate in 5% solution produces anesthesia which may last 36 hours; it is useful in inflammatory diseases of the eye. Benzoylmorphine hydrochlorate, an anesthetic and mydriatic, is recommended in 1% solution as an adjuvant to cocaine, atropine, etc. Holocain, in 1% solution, is antiseptic and anesthetic, and is more energetic than cocaine. Haab of Zurich uses small iodoform rolls or plates in the anterior chamber in beginning panophthalmitis, post-operative infection, etc. The drug is gradually absorbed. In twenty-three cases he obtained good results in ten, fairly good in five and failure in eight. Injections of bichloride of mercury deep into the orbital tissues for cellulitis have given good results. Loss of sight from diphtheria is now entirely avoidable; before the introduction of antitoxin it occurred in 95% of cases.

ORTHOPEDIC SURGERY.

DR. H. L. TAYLOR (New York). The writer commends Dr. Lorenz' work, and states that within the age limit the bloodless method is the method of choice. The present tendency is toward radical interference by simple methods. Forcible correction of the kyphotic spine has largely been abandoned, corrective postures without anesthesia taking its place. Early incision for joint disease in children has been abandoned, and excision of the knee absolutely rejected except to save life. X-rays have proved an invaluable aid to diagnosis. The brilliant work of Goldthwait upon joint affections of adult cripples deserves especial mention. It has been demonstrated that Paget's disease of the bones is a fairly common cause of pain and disability in adult life. Locke of Boston reports twenty-one cases; only eleven had previously been reported in this country. Transference of function by tendon grafting has proved disappointing. Function transference through nerve suture is in its infancy and of uncertain value.

GENITO-URINARY DISEASES.

DR. JAMES PEDERSEN (New York). Advances have been made in the surgery of the kidneys, ureters and prostate, in the medical aspects of gonorrhea, asepsis of the genito-urinary tract and in the determination of the functional integrity of the kidneys. Young shows that calculi can be removed from the ureters and strictures divided in the intrapelvic portion extraperitoneally, by an iliac incision beginning above Poupart's ligament and running upward and outward one inch anterior to the anterior-superior spine; on stripping up the peritoneum, the ureter is usually found adherent to it. Castration, vasectomy, and ligation of the vas have been discarded. After describing the latest methods of performing prostatectomy, Dr. Pedersen mentions a unique operation performed by a French surgeon, "prostatomonose," or isolation of the gland. The prostate is reached by a prerectal incision and freed from surrounding tissues; this is supposed to cause atrophy. The paper concludes with a reference to newer remedies and the method of determining the functional activity of the kidneys by the freezing point of the blood.

OBSTETRICS.

DR. CHARLES M. GREEN (Boston). The paper first deals with the treatment of puerperal infection; interest in antistreptococcic serum has waned, but hope is not yet dead. The intravenous injection of formalin has proved a failure. Prophylaxis is, after all, the best therapeusis. After discussing this subject, the writer advocates the scopolamine-morphine method of producing narcosis in labor in suitable cases. Von Steinbuchel concluded that this is an ideal method. Dr. Green relates nineteen cases, sixteen primiparæ and three multiparæ, in which he used the remedy with marked success. Scopolamine hydrobromate and morphine nitrate were so combined that a dose of ten minims contained $\frac{1}{100}$ gr. of the former and $\frac{1}{4}$ gr. of the latter. The beneficial effects were very marked. The treatment is of especial value in primiparæ of nervous and hyperesthetic organism. The remedy should be given hypodermically as soon as nervous symptoms appear. In heroic doses it is also a potent remedy for controlling the convulsions and nervous manifestations of eclampsia. The paper concludes with a report of three cases in which it gave perfect satisfaction.

PEDIATRICS.

DR. N. P. BARNES (Washington). Dr. Barnes commends dessicated thyroid in mammary inactivity, and reports four cases in which it acted beneficially. Neisser reports eight cases in which nursing children failed to contract diphtheria from diphtheritic mothers; possibly the milk acts as an antitoxin to the child. After discussing infant feeding the writer quotes the conclusions of the United States Bureau of Animal Industry as to the infectious quality of milk from tuberculous cows. Convulsions of childhood are always, according to his experience, associated with intestinal indigestion. They demand immediate relief. Reports differ as to the value of anti-scarlet-fever serum. Aronson's appears to have given the best results. It has been shown that measles

and pertussis are amenable to serum obtained from convalescents; Silvester reports good results in seven cases of whooping cough. Eberson claims that potassium guaiacol sulphonate has a specific effect in pneumonia, causing crisis in twenty-four to seventy hours. Lumbar puncture has become a valuable diagnostic and therapeutic measure in certain cases.

The following officers were elected for the ensuing year:

President, Dr. H. H. Barker, Washington; First Vice-President, Dr. J. N. Hall, Denver; Second Vice-President, Dr. Oliver T. Osborne, New Haven; Third Vice-President, Dr. Carl Beck, New York; Secretary, Dr. N. P. Barnes, Washington; Recorder, Dr. W. M. Sprigg, Washington; Treasurer, Dr. J. S. McLain, Washington.

Recent Literature.

Tuberculosis. By Norman Bridge, A.M., M.D. Philadelphia, New York and London: W. B. Saunders & Co. 1903.

Under the above comprehensive and terse title the author has written a small and compact volume meant for the use of the profession at large, although the chapters are practically didactic lectures intended for students.

The first few chapters are devoted to the discussion of the etiology and pathology of the disease, and, while containing nothing especially new, present the subject in a condensed form suitable for the general reader. In the chapter upon methods of examination, the author evidently believes that in percussion the fingers are the best instruments, although other devices may be of use at times. He has little regard for so-called "auscultatory percussion." He believes that the monaural wood stethoscope is the best one for faithfulness of transmission and accuracy of tone, and yet feels that it is one not so easily or correctly used by the majority of medical men as the double stethoscope originally devised by Camman, or some modification of the instrument.

The author rightly shows skepticism as to the confessed ability of many to discover the existence of cavities in the lung, believing that misstatements are often made upon this point.

He believes in the diagnostic value of tuberculin, and shares the common belief that no possible harm can come from such use of the substance. Later he discusses the therapeutic use of tuberculin, and somewhat at length quotes the experience of others upon whose judgment we have learned to rely, notably Trudeau, in support of the theory that the substance produces an apparent immunity in a small percentage of cases, and yet he would seem to be uncertain in his conclusions as far as permanent benefit to the patient is concerned.

The author's somewhat extreme views upon the great value of absolute rest for a diseased lung and his well-known attitude upon the subject naturally bring much criticism from those who believe that he goes too far in claiming that every diseased lung should be kept quiet and that the more common practice of moderate expansion of the lungs in incipient cases should be avoided. The writer of this review, while believing that judgment must be used in every case, differs in opinion almost entirely from what he considers the author's unwarranted claims. Naturally Dr. Bridge's belief leads him to support the theory of the Murphy treatment, which immobilizes the lung by injections of nitrogen into the pleural cavity, a method which the writer believes will fall into disuse, as have many other highly-vaunted methods of cure in the past.

The chapters upon the climatic and sanatorium treatment are all characterized by good sense and judgment, based, evidently, upon the author's well-known, long practical experience in the treatment of the disease in widely different sections of the country,— Chicago and Los Angeles and their vicinity. One could wish, however, in his discussion of sanatorium treatment, that he had emphasized the vital importance of keeping all such institutions absolutely to the purpose for which they were intended and of not attempting to make them hotels and sanatoria at the same time, a method which can only prove disastrous to the cause of the sanatorium treatment of tuberculosis, which has justly received such marked attention in recent years.

The book is embellished with several excellent illustrations, is of clear plain type and is worthy of a permanent place in every medical library.

A Manual of Refraction and Motility. For Students and Practitioners of Medicine. By William Norwood Suter, M.D., Assistant Surgeon to the Episcopal Eye, Ear, and Throat Hospital, Washington, D. C. 12mo. 382 pp., with 101 engravings and 4 colored plates. Philadelphia and New York: Lea Brothers & Co.

It has been the endeavor of the author to place in the hands of the advanced student and practitioner a manual on refraction and motility of the eye which shall contain the essentials of the more elaborate treatises without at the same time being too elementary in character. In this respect certainly Dr. Suter has succeeded very well, as the volume is of a convenient size and contains only about three hundred and eighty pages of text, which is divided into the following four parts: The theory of refraction and incidentally the optical principles upon which rest the various examination methods; the normal eye; errors of refraction; disorders of motility. Only such formulæ have been included as seem necessary for a proper comprehension of the theory of refraction, but still if the reader is not inclined to follow carefully the various demonstrations the rest of the book may be as intelligently read by simply attending to conclusions. The presswork is of excellent quality, and the illustrations are many and apt.

THE BOSTON

Medical and Surgical Journal

THURSDAY, SEPTEMBER 24, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE OPENING OF THE SCHOOLS.

IT is the laudable custom of our contemporaries, the *British Medical Journal* and the *London Lancet*, to devote practically an entire issue in the fall to the general question of medical education. This year the numbers of these two journals for Sept. 5 are given up to what the *British Medical Journal* calls an educational number and what the *Lancet* calls a students' number.

The *British Medical Journal* discusses at the outset the advantages and disadvantages of the profession of medicine. It can hardly be said that this contribution savors of originality, but nevertheless it contains many facts which the young man about entering upon his professional work will do well to ponder. The profession is discussed from the physical, financial, intellectual, ethical and social standpoints, with the general conclusion that it "affords a fairly certain means of livelihood with unrivaled opportunities for that development of the faculties which, as Goethe said, is a duty of the highest importance for every man; moreover, it opens a field for the exercise of his faculties in which he will have the sense of doing good with more certain purpose than in any other." This incentive should certainly prove sufficient to lead many a wavering youth into the ranks of medicine. The "portals" and "prospects" of the profession are likewise discussed in a separate article, and herein are noted many facts concerning choice of a medical school, cost of a medical education, waiting time, with its dangers, all of which again are to be commended to the young student. The medical curriculum also demands attention, and the remainder of the number is taken up with details which concern British medicine more particularly than medicine at large.

The *Lancet* does a similar service for prospective students. The leading article is entitled "An Address to Students," in which again advice of the most fatherly sort is given to the young matriculant. Surely the youth of Great Britain should appreciate the solicitude which these leading medical periodicals devote to their future. This number of the *Lancet* contains in addition a vast amount of information concerning universities in the United Kingdom, and we can easily see that this information may be of the greatest advantage to postgraduate as well as undergraduate students in determining their selection of hospitals and schools for later study.

Conditions of medical instruction in this country are such that at present there is no demand for such an exhaustive yearly consideration of various schools and their particular claims to recognition. The time is, however, no doubt coming when just such a statement of facts connected with medical education will be of the greatest possible advantage to intending students. As our medical schools attain to a higher degree of uniformity of requirement, and our state registration laws become more complex, it will be altogether desirable that students and physicians alike should be kept informed of the details which are sure to develop. When such a time comes, we may well take as a model these remarkable yearly issues of the *Lancet* and the *British Medical Journal*.

THE CONSUMPTION OF HORSE MEAT AS FOOD.

THE high price of meat as compared with other articles of food, the frequency of different diseases among animals whose meat and milk are used as food, raises the question whether the meat of some other animal may not be employed advantageously for food purposes.

When we consider the fact that hogs, and especially those which are kept in the neighborhood of large cities, are fed upon the most putrid of all substances, city offal, it is not a matter of surprise that the pork of such animals should often cause serious illness. Nor is it to be wondered at that the meat and especially the milk of cows is not regarded as a perfectly wholesome food, when such animals are often fed upon exhausted and fermented food, such as distilling refuse, brewer's grains, gluten meals, cotton seed meal and ensilage, in some of which the most nutritious

portions have been extracted and in others fermentation has taken place, the object being to increase the flow of milk, but not to improve its quality, or that of the animal.

In times of emergency, conditions of siege in war and of great scarcity of meat, the meat of the horse has been introduced and used without injury to health. Many horses are killed on account of some accident when in perfect health, or on account of lameness, which may not affect their general health. The possible use of diseased horses could easily be prevented by a system of inspection such as is employed for other slaughtered animals at the abbatoir. The food of the horse is much cleaner than that of most animals used as food, consisting as it does chiefly of hay and grain, and the horse is scarcely ever attacked with tuberculosis.

In a recent Italian health report,[1] the author, Dr. Frassi, presents some interesting facts relating to the consumption of horse meat in the city of Parma, as well as in the country of Italy at large. He does not agree with the common opinion that the sale of horse meat injures the sale of other meat on account of its lower price, but believes that the food supply of the working classes has improved in proportion to the introduction of horse meat as an article of food. The number of horses slaughtered varies much at different seasons, the greatest number being killed in November and December, the difference being accounted for by the higher cost of feeding in winter and the decrease in the demand for horses.

There were fifteen shops in Parma in 1901 where horse meat was sold, most of which were open only from October to April, only one or two remaining open later in the season. In this category nearly one-half of the animals included were asses and one-tenth mules. The customers are mostly of the working classes. About 20% of the meat is used in hotels, and some goes to restaurants. A considerable quantity is employed in making sausages. The author considers the use of this meat as a matter of decided hygienic importance, in consequence of the almost absolute immunity of the horse to one of the most common of all diseases to which other food animals are subject, — tuberculosis.

OPPOSITION TO MANILA BOARD OF HEALTH.

The Board of Health usually experiences little opposition in carrying out measures among the poorer class of Filipinos and Chinese in Manila, but the Spanish element and more wealthy Filipinos have bitterly opposed the Board of Health, particularly with respect to sanitary improvements relating to the disposal of excreta and the installation of waterclosets in lieu of the filthy sinks and vaults which were the rule under Spanish administration. The latter class is largely the landlords in Manila, who resent any effort to make them spend money in improving the sanitary condition of houses for which they exact a relatively enormous rent. As a result of their neglect to obey sanitary regulations, a number of prominent Filipinos and Spaniards have lately been sent before the courts and fined. One wealthy banker who had been fined ten dollars appealed his case to a higher court, where the decision of the lower court was not only confirmed, but the sentence increased to one hundred dollars fine, with thirty days in jail in addition; but sentence was suspended for fifteen days on condition that the banker place his premises in good sanitary condition. As this case had been largely regarded as a test case, a reversal of the verdict of the lower court would have seriously impaired the efficiency of the Board of Health. As it is, the opposition has been effectually disposed of, and the eagerness manifested on all sides to comply with any sanitary requirements imposed by the Board of Health is somewhat amusing. A strong point of the American government is its absolutely unbiased and incorruptible judiciary, which is not understood by the wealthy native element, accustomed in the old Spanish days to buy any kind of "justice" it was willing to pay for. The American judges have uniformly supported the sanitary authorities in carrying on their work, and have thus rendered it possible to obtain good results in Manila and the larger cities. The native judges in the smaller towns take an entirely opposite stand and render the enforcement of sanitary regulations practically impossible where such cases are brought before them for decision. It is most fortunate that the right of trial by jury cannot yet be demanded in the islands, as under such conditions it would be practically impossible to convict a Filipino on any charge preferred by a white man, and laws governing sanitary matters would be a dead letter all over the Philippines, as they now are in the provinces and country districts. Manila is the Paris of the Philippines, however, and with it in good sanitary condition there is an ever-present object lesson which cannot fail to ultimately impress

[1] Dr. Frassi: Atti del Ufficio d'igiene della Città di Parma, 1902.

itself upon the other people of the islands and tend to raise their sanitary standards.

MORTALITY STATISTICS.

A PAMPHLET has recently appeared from the United States Census Office on the question of the "Relation of Physicians to Mortality Statistics," being the international classification of causes of death adopted by the United States Census Office and approved by the American Public Health Association. This circular is published for the benefit of physicians who are obliged to make out death certificates in compliance with registration laws.

As stated in the introduction, it is clear that statistics, to be comparable, must be uniform and also accurate. A proper classification demands that the cause of death be accurately stated, and, inasmuch as the chief value of these statistics is in the distribution of death by causes, it is clear that physicians must supply the necessary information with certainty and after a more or less definite plan. An error into which physicians fall is to define the cause of death by some indefinite term which frequently is a cloak for their ignorance of the exact cause. This naturally is in a measure excusable, but it is none the less desirable that a general and comprehensive plan be in use so far as possible to avoid the uncertainties which are sure to arise.

The circular before us is designed to furnish just this information. It will be sent to every physician in the country, and it is suggested that they will manifest their appreciation by conforming as far as possible to the suggestions made. The classification offered is essentially a selection and arrangement of titles merely, under which deaths variously reported must be compiled. The classification itself is arranged with such explanations that it is easy of understanding, and should prove of the greatest use in stimulating accuracy in this matter in which physicians are notoriously lax. Inasmuch as the pamphlet is to be generally distributed throughout the profession, it is not necessary that we should call attention to details of its arrangement beyond saying that for purposes other than death certifications it should prove valuable reading.

MEDICAL NOTES.

APPOINTMENTS TO HENRY PHIPPS INSTITUTE FOR STUDY OF TUBERCULOSIS. — The following additions to the staff of the Henry Phipps Institute have been made: Dr. M. P. Ravenel has been appointed Assistant Medical Director and Chief of the Laboratory; Dr. E. A. Shumway has been appointed Ophthalmologist; and Dr. J. F. Wallis has been appointed Dermatologist.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Sept. 23, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 30, scarlatina 9, typhoid fever 41, measles 15, smallpox 0.

A CENTENARIAN. — Mrs. Ruth Curtis has recently died in Kennebunkport, Me., at the reputed age of one hundred and four years. She had spent her entire life in Kennebunkport, and presumably at the time of her death was the oldest person in Maine.

BEQUESTS TO HOSPITALS. — By the will of the late Francis J. Lawrence of Waltham the Waltham Hospital receives $5,000, the Leland Home for Aged Women $1,000, the Massachusetts General Hospital $1,000 and what remains, after various other bequests are made, goes to the Waltham Hospital.

AN ITEM IN THE LONG ISLAND HOSPITAL INVESTIGATION. — It is reported in the daily press that the bill for stenography presented to the city in the recent investigation of the Long Island Almshouse and Hospital amounts to nearly $8,000. In view of the result of the investigation, this will be regarded in the popular mind as a wholly useless expenditure of city money.

WALTHAM, MASS., TRAINING SCHOOL FOR NURSES. — With the graduation of the present class at the training school of the Waltham Hospital, certain changes will be made in the course. Up to this time two classes have been graduated annually, spring and fall. Hereafter but one class will be graduated, in the spring. A four years' course will be substituted for the former course of three years and six months, but a certain reduction in the age of those entering the school will be made to meet this extra requirement. This training school, although connected with a relatively small hospital, has established for itself a most enviable reputation for thoroughness and efficiency.

NEW YORK.

DEATH FROM ETHER. — A death under ether is reported to have occurred at the New York Eye and Ear Infirmary on Sept. 14. The patient

was a girl thirteen years of age, and the fatal accident occurred in the middle of a trephining operation for the relief of mastoiditis.

Bequests to Hospitals. — By the will of Dr. Joseph Schnetter, formerly of New York, who died recently in Germany, $50,000 is left in trust to be invested in State or United States Government bonds, the interest of which is to be paid regularly to a certain legatee. On the death of this individual $35,000 of the amount is left to the German Hospital and Dispensary, New York, and the remaining $15,000 to the Mount Sinai Hospital, New York; the money in each instance to be used to endow free beds for women. The residue of the estate, which is said to amount in all to about $140,000, is left to the widow, with the request that at her death she bequeath it to the German Hospital.

Straus Milk Depots. — The various Straus depots for the dispensing of pasteurized and sterilized milk were recently closed for the season. During the summer 1,593,726 bottles of milk and milk foods were dispensed, besides 600,000 glasses of milk in the public parks. This has no doubt been an important factor among the various agencies which have contributed to the reduction of mortality among infants and young children, which in the summer of 1892, the year before the charity was inaugurated, reached the rate of 136.1. In 1893 the rate was 117.9, and since then, with the exception of the year 1895, when there was a retrogression of about 4%, it has steadily declined, until during the summer of 1903 the rate was only 63.6. The past summer has, of course, been an unusually cool one, but this was the case last year also, when the rate was 71.1.

Dr. Thomas Addis Emmet, Author. — In recognition of the centenary of the death of Robert Emmet, which occurred Sept. 20, 1803, the Putnams have just published an elaborate work on "Ireland under English Rule," from the pen of Dr. Thomas Addis Emmet, the distinguished gynecologist, who is a grandnephew of the Irish patriot.

A Venerable Life Insurance Policy. — On Sept. 13, 1803, Charles Henry Booth of Engelwood, N. J., who enjoys the distinction, so far as can be ascertained, of being the oldest person in the world holding a life insurance policy, celebrated his one-hundredth birthday. In 1843 he insured in the Mutual Life Company, then in the first week of its existence, and the policy has been kept up ever since. In honor of the event the company has had prepared for Mr. Booth a testimonial handsomely engrossed on parchment, and inscribed "The Oldest American Company to Its Oldest Policyholder."

Notes from the Philippines.

X-Ray and Finsen Light. — An x-ray machine and a Finsen-ray apparatus have been received by the Board of Health, and will be installed at the San Lazaro Hospital, where they will be given a thorough test on the more than two hundred lepers now isolated there, with respect to the cure of this disease through their agency.

Cholera. — The report of the Board of Health for the month of May, just issued, shows a mortality for the month at the rate of 30.02 per annum. This was a considerable increase over the rate for April, 22.12, but was much less than that for May, 1902, which was 65.81. The increase for the present month was due almost wholly to a sudden rise of cholera cases, there being 230 during the month, of which number 92.17% ultimately died. This rise was not unanticipated, as the general history of cholera in the tropics shows a sharp increase coincident with the beginning of the rains, when infectious material, rendered temporarily harmless through local conditions, is washed into the water-courses and perhaps widely spread through a source of water supply. The May outbreak occurred under such conditions. It was noteworthy that the greater part of those who contracted cholera were boatmen, laundresses, fishermen and others whose occupations brought them into close contact with the Pasig River and certain esteros. Most of the cases occurred in districts along the water front, and of these cases a large part occurred on boats moored in certain backwater reaches. Careful examination of the waters of the Pasig River and the larger esteros was therefore made, and the presence of cholera germs in large numbers determined, particularly in the slack water anchorages, where the greatest number of cases had occurred on boats. This latter fact was attributed to the throwing overboard of the discharges from cholera cases, and in some instances the disposal of the dead in this way. The water so contaminated was backed by the rising tide into the esteros, and the infection was thus conveyed to other quarters of the city. It was quite impossible to entirely prevent the boat population from using the river

water for domestic purposes. In some instances attributed by the natives to the use of infected foods purchased in the Tondo market, investigation usually determined the fact that such food had subsequently been washed in river water and had probably become infected after purchase. The Board of Health met the situation by increased vigilance in respect to sanitary inspections, more stringent oversight of the markets and by the issue of 35,000 circulars giving a few simple rules for the prevention of cholera, one of these circulars being posted in every house and on every water craft in the city. There was an immediate decrease in the number of cases of cholera, and by the end of the first week in June the outbreak was entirely under control and the cases few and scattering. During the outbreak of the month more than twice as many males as females died of cholera, and of the 194 deaths reported as occurring during the month but twelve occurred in children under the age of fifteen years.

DECREASE IN PLAGUE. — During a recent month there were 27 cases of plague as compared with 52 the previous month. This decrease was apparently in direct response to the special efforts made for its control, including the destruction of plague houses, rat-catching and, of most importance, the general inoculation of the Chinese population, inaugurated during the month. A total of 10,051 rats were destroyed by rat-catchers, and of those examined none were found to be affected with plague. It cannot be fairly expected, however, that the proportion of plague in captured rats will be the same as for the general rat population, as the diseased rats soon die and their physical condition is such that they are not liable to be tempted to destruction by baited traps or poison.

Miscellany.

LECTURES ON TUBERCULOSIS.

THE Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis has arranged for the coming fall and winter a series of lectures by well-known physicians on the various phases of tuberculosis. Some of these lectures will be more or less popular in character, and all will be free to the public. The auditorium of the Witherspoon Hall, at Juniper and Walnut streets, Philadelphia, has been selected for the purpose, having a seating capacity of nearly twelve hundred people.

The first of these lectures will be given by Dr. E. L. Trudeau of Saranac Lake, N. Y., during the last week in October, his subject being, "The History of the Development of the Tuberculosis Work at Saranac Lake."

The following gentlemen have been invited to give the subsequent lectures: Dr. Pannwitz of Germany, in November; Dr. William Osler of Baltimore, in December; Dr. Calmette, Director of the Pasteur Institute at Lille, France, in January; Dr. Herman M. Briggs of New York, in February; and Dr. Maragliano, of Italy, in March. All of them have accepted with the exception of Dr. Calmette, who will come if it is possible for him to leave his work in connection with his institute and the International Congress on Tuberculosis, to be held in Paris in 1904. Subjects and exact dates will be announced as soon as possible.

The director and members of the staff of the Henry Phipps Institute extend a most cordial invitation to the profession in general to attend these lectures. It is greatly desired that this inaugural series of lectures given by these gentlemen will prove a success and be largely attended.

VIVISECTION IN ENGLAND.[1]

UNDER the provisions of an Act of 1876 (39 and 40 Victoria, 77) licenses are granted for the performance of experiments on living animals. A report for the year 1902 presents a summary of the names of all persons who held licenses or special certificates under this Act, together with a statement of the registered places at which the licenses were valid, and of the persons who applied for licenses and granted certificates. It also states the total number of experiments performed in 1902, classified according to their nature.

The total number of persons licensed was 319, of whom 112 performed no experiments.

The tabular statements show: (1) That licenses and certificates have been granted and allowed only upon the recommendation of persons of high scientific standing.

(2) That the licensees are persons who, by their training and education, are fitted to undertake experimental work and to profit by it.

(3) That all experimental work has been conducted in suitable places.

Another table shows the number and nature of the experiments performed by each licensee, specifying whether these experiments were done under the license alone or under a special certificate. In another table the experiments performed without anesthetics are separated from those in which anesthetics were used.

The total number of experiments reported under the Act was 14,906, or 3,261 more than those which were reported in 1901. The number involving serious operations were 2,130 the larger part of which were unattended with pain

[1] Return showing the number of experiments performed on living animals during the year 1902, under licenses granted, distinguishing painless from painful experiments. Ordered by the House of Commons to be printed, June 8, 1903, London.

because they were performed with anesthetics, the animal experimented upon being kept under their influence during the whole experiment. In these cases, if the pain is likely to continue after the effect of the anesthetic has ceased, or if serious injury has been inflicted on the animal, it must be killed before it recovers from the effect of the anesthetic.

The experiments without anesthetics were 12,776, mostly inoculations, with a few feeding experiments and others involving the abstraction of minute quantities of blood for examination. Among this number there were 3,857 inoculation experiments for the testing of antitoxins and 3,997 others performed by official bodies, including the Local Government Board, the House of Commons Ventilation Committee, the Loyal Commission on Tuberculosis, the Board of Agriculture and several minor local authorities. A large number of experiments were performed for the purpose of testing milk for tuberculosis, others for ascertaining whether hair is infected with anthrax and for the examination of sewage. Numerous inoculations were made for the diagnosis of disease in animals, and many were performed in the course of cancer investigations.

The number of injections made during the year for the diagnosis of rabies in dogs was 153.

Correspondence.

LUSCHKA'S TONSIL—THE SITE OF INFECTION IN ARTICULAR RHEUMATISM.

Boston, Sept. 18, 1903.

Mr. Editor: My acceptance of the doctrine of infection as a cause of rheumatism has enabled me to discover, clinically, the usual channel by which the micro-organisms or their toxins enter the economy to produce this disease. An undoubted connection between attacks of rheumatic arthritis and sore-throat (tonsilitis), together with many published observations regarding the microbic origin of rheumatism (v. *Edin. Med. Journal*, August, 1902), gives the necessary suggestion of this true source of infection. Because of long experience with diphtheritic and other similar infections of the faucial tonsils, which promptly ceased after direct sterilization of the post-nasal tonsil *through the nose*, I was made cognizant of this important fact. After selecting severe cases of acute articular rheumatism I treated thoroughly this (Luschka's) tonsil with local applications of hydrogen peroxide and astringents, and obtained immediate results in entire relief of the constitutional and local symptoms, with rapid convalescence in a few days.

It is unusual for either physician or patient to trace any connection between early local symtomatic manifestations and other apparently more important ones in distant parts of the body, because of the accompanying pain (in the joints), and for which ordinary remedies for rheumatism (alkalis and salicylates) are prescribed.

Rheumatic throats have been recognized for years, but the original and probably the only site of infection, namely, Luschka's tonsil, has not been pointed out (unless Woakes of London did this incidentally in his admirable description of the process of "catching cold"). The cause was undiscovered, the remedy was wanting.

The duty of bacteriologists is to decide upon the character and life history of these "cocci" and "toxins" of rheumatism, while it is the privilege and duty of the physician to record the location of the original site of entrance of this disease as well as to distinguish between cause and effect in the measures adopted in treatment of it.

One would imagine that the mere suggestion of a local cause for a systemic affection so serious, with its possible cardiac complications, as acute rheumatism would suffice to arouse every physician to investigate the matter. One might then weigh his knowledge against the empiricism of ages, which has piled up an array of drugs greater in the aggregate than the impedimenta of a Roman army! Their daily use likewise provides similar impediments to progress.

Truly yours,

Edmund D. Spear, M.D.

AN INCORRECT ANNOUNCEMENT.

Pathological Laboratory,
McGill University, Montreal, Sept. 18, 1903.

Mr. Editor: Upon my return from abroad a few days ago, I learned for the first time that I had been announced as one of the honorary presidents of the American Congress of Tuberculosis. This announcement had been made without my knowledge and had been communicated to the public press before ever I had been approached in the matter. After that communication (June 11) I find that I was addressed upon the subject (June 12). The notice which I have before me is in the form of a copygraph letter upon the flimsiest of yellow paper, dirty and badly folded, and is not to the effect that I had been appointed honorary president, but merely a curt reference to an enclosed list of officers elected at a recent session, ending with the expression of the hope that I would accept. The enclosure consists of two columns cut out of the New York *Daily Tribune*, which, it is true, contains my name (misspelled) on the list of honorary presidents. I am not in the least surprised that my first assistant when opening my correspondence in my absence mistook the communication for a second-class advertisement, or something of the kind, and never realized that this was matter which should be forwarded to me.

Under no circumstances would I have consented to allow my name to be connected with the organization in question. The employment of that name as that of an honorary president is, and has been, wholly unauthorized, and I have written asking that it be withdrawn.

Yours faithfully,

J. George Adami, M.D.

Obituary.

NORTON FOLSOM, M.D.

Norton Folsom, M.D., was born in Boston, April 15, 1842, and died in Cambridge, Sept. 12, 1903. He was educated in the Cambridge schools, to which city his parents removed soon after his birth. In 1859 he entered the Harvard Medical School. He was appointed medical cadet in the United States Army Sept. 24, 1861, and served until Sept. 25, 1862. He returned to the medical school, and took his degree in 1864. April 10, 1864, he was appointed surgeon of the Forty-fifth Regiment of colored troops. He was soon appointed on the staff of General Weitzel, where he served as acting medical inspector and director. April 10, 1865, he was made Brevet Lieutenant-Colonel of United States Volunteers. He was mustered out of service Nov. 4, 1865. He was soon after appointed assistant physician to the state hospital for the insane at Taunton, where he remained for several years. He then began practice in New York City, but soon accepted the appointment of resident physician at the Massachusetts General Hospital. He held this position from 1872 to 1877, leaving it on account of failing health. He resumed practice in Boston and Cambridge, paying special attention to mental diseases. He never regained his health, and for several years has been unable to practice his profession. He discharged the duties of all the positions he held with distinguished ability.

Deaths reported, 2,964; under five years of age, 1,097; principal infectious diseases (smallpox, measles, scarlet fever, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 888, acute lung diseases 224, consumption 317, scarlet fever 16, whooping cough 21, cerebrospinal meningitis 7, smallpox 5, erysipelas 2, measles 7, typhoid fever 73, diarrheal diseases 386, diphtheria and croup 50.

From whooping cough, New York 12, Philadelphia 4, Baltimore 2, and Boston, Springfield and Beverly 1 each. From erysipelas, New York 1, Chicago 1. From smallpox, Philadelphia 5. From scarlet fever, New York 6, Chicago 2, Philadelphia 4, Baltimore 1, Fall River 1, Cambridge 1, North Adams 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Aug. 29 the death-rate was 16.0. Deaths reported, 4,616; acute diseases of the respiratory organs (London) 114, whooping cough 61, diphtheria 62, measles 60, smallpox 2, scarlet fever 32.

The death-rate ranged from 3.5 in Devonport to 26.3 in Sheffield; London 14.3, West Ham 18.3, Brighton 20.8, Portsmouth 17.1, Southampton 11.4, Plymouth 18.6, Bristol 9.8, Birmingham 18.7, Leicester 15.9, Nottingham 21.0, Bolton 16.5, Manchester 19.3, Salford 20.5, Bradford 14.5, Leeds 18.2, Hull 21.9, Newcastle-on-Tyne 20.4, Cardiff 11.5, Rhondda 15.3, Liverpool 20.8, Hornsey 10.0, Bootle 18.0.

METEOROLOGICAL RECORD.

For the week ending Sept. 12, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

URETHRAL TUBERCULOSIS, WITH REPORT OF A CASE.*

BY ARTHUR L. CHUTE, M.D., BOSTON.

RELATIVELY few cases of urethral tuberculosis are reported; of the reported cases nearly all show extensive lesions of other portions of the genito-urinary tract, so that this lesion appears more as an incident in a urogenital tuberculosis than as a distinct disease. There are, however, instances in which the urethral lesion is the prominent one, though the disease is rarely, if ever, strictly confined to this organ. Urethral tuberculosis assumes the character of a distinct disease in proportion to the extent of involvement of the anterior urethra. When the posterior urethra only is involved, it is hardly to be distinguished from tuberculous cystitis or prostatitis.

The case which I have to report shows some particularly interesting features, in that the disease, while not confined to the urethra, was most marked in the anterior portion. The acute stage of the disease ran a favorable course without any treatment; healing of the urethral process was accompanied by calcification of the submucous lesions. Of this last condition I have been unable to find a similar instance.

P. C., a married laborer, thirty-five years old, was first seen in March, 1902. He had always been well with the exception of his present trouble. His family history was good. He never had any venereal trouble. Two years before he began to pass urine frequently, both night and day; urination was painful. At the same time the glands in his left groin enlarged very rapidly and were painful for some two or three months. He had several attacks of hematuria, the source of which seemed from the history to be the posterior urethra. Now and then he noticed a little discharge from his urethra, but this was neither constant nor profuse. He had discomfort referred to his perineum and rectum, particularly when he sat down. For a time he had painful erections, and coitus was impossible. During the following two years his stream gradually became smaller and his urinations more frequent; they remained painful. For some minutes after micturition urine would exude from his meatus a drop at a time.

Two weeks before he was seen, he felt a sudden pain during coitus; this was referred to the general region of the peno-scrotal angle; following this he had the feeling as of "something moving" at that point. There was increased difficulty in passing urine, and he felt that the obstruction was at the peno-scrotal angle. When seen he was having to urinate four times or more at night and very often during the day.

The man's general condition seemed good. There was no urethral discharge. He was able with difficulty to pass a few ounces of urine; the stream was very small. Following urination there was for some minutes a dripping of urine, a drop at a time. The urine was very pale, acid, specific gravity 1009; it showed a very slight trace of albumin. The urine contained a few shreds, which when stained showed pus and urethral cells, a few cocci and bacilli, but no gonococci. No renal elements were found in the sediment.

On palpating his urethra it had the feeling of a stiff tube of about the size of a 24 F. sound. At a point one and a half inches from the meatus there was a bulbous enlargement which was very hard; there was a similar enlargement near the peno-scrotal angle, at the point where he felt the sensation as of "something moving." By moving the urethra laterally at this point a perfectly distinct crepitus was gotten.

An attempt was made to explore his urethra with various sized instruments; finally a small silver probe was passed to the bulb; with this in place it was impossible to get crepitus. The probe gave a grating sensation when it passed the two bulbous enlargements.

His left groin contained a mass of glands three or four inches long and about an inch wide; they were very hard and felt as though they were calcified. These glands were not tender. The skin over them was thin but neither red nor attached. He said these glands had been painless and had not changed for more than a year. In his right groin the glands were only slightly enlarged.

His prostate was enlarged, particularly on the right, where there was a small, very hard mass, which felt like a calcified area. There was no tenderness in the renal regions. The kidneys were not palpable. There was no suprapubic tenderness. The testes, epididymes and vesicles showed no signs of disease.

Although at this time the etiology of the trouble was not at all clear, the indications for treatment seemed evident.

Gradual dilatation gave immediate relief to his frequency and difficulty in micturition. At first there was moderate bleeding; this gradually grew less. When dilatation had progressed somewhat, a third area of calcification could be felt in his deep urethra. After a few dilatations, I was able to remove with alligator forceps several irregular bits of calcified material; some from the point near the peno-scrotal angle and some from the point one and a half inches behind the meatus.

Since that time he has rarely had to urinate during the night. His diurnal frequency has been within the limits of normal. Urination has been painless and he has had less dribbling. A search for tubercle bacilli was made in this little material which could be gotten from the urethra, also in the urine; the results were negative, as was an inoculation test made in September, 1902. A second inoculation, made in January, 1903, was also negative.

In July, 1902, the glands in his left groin were removed. This was done largely in the hope that their examination might clear up the diagnosis. Dr. George B. Magrath of the Pathological Department of the Harvard Medical School reported that these glands showed amyloid infil-

*Read before the American Urological Association, in New Orleans, May 8, 1903.

tration, a condition which apart from general amyloid disease is very rare, and usually means tuberculosis somewhere in the territory of the lymphatics involved.

Dr. William B. Hills of the Chemical Department of the Harvard Medical School found the concretions were made up for the most part of carbonate and phosphate of lime, with traces of the corresponding magnesium compounds, also a minute trace of triple phosphate.

The patient is still under observation. At the present time (April, 1903), his urethra allows the passage of a 25 F. sound. Slight grating can be felt at a point one and a half inches from the meatus, at the peno-scrotal angle and at a point in the membranous urethra. On several occasions small pieces of calcified material have been removed, and frequently after instrumentation he has passed fragments of the same. He has at present no subjective symptoms other than an occasional feeling of discomfort in the rectum. Endoscopic examination shows an abnormally pale, fibrous-looking canal, for the most part smooth, but with an occasional small eroded spot, also with little fibrous tabs which project into the lumen. The canal is very stiff, and instead of rolling in about the end of the endoscope stands rigidly open, as though distended with air. At one or two places little whitish points are seen, which are apparently little bits of calcified material projecting through the mucous membrane.

His prostate remains about as at first, larger on the right with the same apparently calcified nodule. The left lobe is smaller but more sensitive. After very gentle massage the urine contains bloody shreds, showing that the prostatic process is not entirely quiescent. The rectal discomfort which he occasionally feels he refers to the left.

In spite of not finding tubercle bacilli, the non-venereal origin, the symptoms, the course of the disease and the outcome warrant the conclusion that this patient had an urethral tuberculosis. The condition of the inguinal gland adds confirmatory evidence.

In this instance the tuberculosis involved particularly the glandular elements of the canal. During the healing process there was a deposition of lime salts in the diseased glands, similar to that seen from time to time in other tuberculous glands. These masses gradually ulcerated through the mucous membrane into the urethra. The mass at the peno-scrotal angle was apparently more or less cylindrical, and after fracture, the two sections not being in perfect alignment, the difficulties of urination were increased. The feeling of "something moving" was produced by the ends rubbing together.

The condition found in this patient bears no resemblance to the many reported cases of urethral calculi. I have been unable to find any reported case in which a similar deposition of lime salts has taken place. Case I of Berard and Trillat is the nearest approach. This refers to a child with urethral tuberculosis, in whose urethra they felt what seemed to be points of calcification. The child was under observation only a very short time. The description of the case is very meager.

A brief review of tuberculous urethritis is of interest in connection with this case. What follows applied more particularly to tuberculosis of the anterior urethra. Tuberculosis of the posterior urethra is so intimately connected with tuberculosis of the bladder and prostate that it does not present a distinctive picture.

All writers agree that it is a rare disease. Few textbooks give it more than casual mention. The lesions of the anterior urethra are much rarer than those of the posterior urethra.

Ahrens [1] gives the findings of several observers as to the frequency of urethral tuberculosis; all of these are based on autopsies. Steinthal is quoted as having found 6 instances of urethral involvement in 24 cases of urogenital tuberculosis; Krzywicki, 5 instances in 29 cases; Pavel in 1,455 autopsies on tuberculous subjects found urogenital tuberculosis 380 times, but urethral lesions in only 7 of these cases.

Halle and Motz [2] state that for the past twelve years there have been at the Hospital Necker from 12 to 15 deaths a year from genito-urinary tuberculosis; that during this time they have found but 12 cases of urethral tuberculosis.

The disease occurs in early childhood and in old age, but is, like all forms of urogenital tuberculosis, much more common during the years of sexual activity. In the reported cases men have been affected much more often than women. This greater frequency in men can be attributed to several very evident reasons: the greater length of the male urethra; the fact that it is more often the seat of post-gonorrheal lesions; the ease with which the urethra can be infected in tuberculosis of the genital organs proper.

It is probable that a previous gonorrhea has some influence on the occurrence of urethral tuberculosis, especially when it is followed by chronic urethral lesions. A previous gonorrhea has been noted in a large number of reported cases, and it seems reasonable to suppose that a diseased urethra is a more favorable soil for tuberculosis than a healthy one.

Keyes [3] and Alexander [4] both believe that pus infections of the urethra predispose to tuberculosis.

While a previously infected urethra is probably a more favorable soil, many cases are reported in which there seems to be no question of a previous gonorrhea, as cases by Berard,[5] Stone,[6] Halle and Motz [2] and other writers.

The source of the infection in urethral tuberculosis has excited a good deal of interest and some controversy.

Baumgarten is cited by Ahrens as having produced a classical urethral tuberculosis by injecting tubercle bacilli into the urethra of a buck rabbit. The conclusion which he drew from this was *not* that infection was usually from without, but that the urethra had no peculiar immunity to the tubercle bacillus. He felt that the opportunity for infection from without was usually lacking, because, according to his statement,

patients with genito-urinary tuberculosis ordinarily have little sexual desire.

Paladino Blandini [7] found that it was possible for tubercle bacilli, when introduced into the urethra of animals, to traverse the canal and set up a tuberculous epididymitis. He found the bacilli could be diffused through the whole genito-urinary tract in a relatively short time. He reported no instances in which he noticed urethral tuberculosis following the introduction of tubercle bacilli into the canal.

Several cases of tuberculosis of the glans penis are reported in which the process extended to the urethra either by perforation, (Poncet,[8] Kraske,[9] Hartmann [10]) or by extension through the meatus (Erhmann [11]). In these instances the infection was by continuity.

These facts point to the possibility of infection through coitus, but I have been unable to find a single reported instance in which it seemed probable. Hogge [12] goes so far as to say that there is not on record a single case of primary tuberculosis of the anterior urethra.

Kraske [9] thought that in his case of tuberculosis of the glans, which extended to the urethra, the infection was probably through the blood stream, as no tuberculous lesions of the genital or urinary apparatus could be discovered. The case did not come to autopsy.

Alexander [4] has suggested the possibility of a well kidney excreting tubercle bacilli, and that these bacilli might, in an urethra previously damaged by pus infection, set up a tuberculosis. Halle and Motz [2] speak of the difficulty in any given instance of ruling out the possibility of a small area of renal tuberculosis.

While it is impossible to say that the urethral infection may not in rare instances be primary, either from without or by the blood stream, the weight of clinical evidence shows that it is in almost all instances secondary to other tuberculous lesions of the genito-urinary tract.

In the cases which have come to autopsy there have been present, almost without exception, other lesions of the genital or urinary tract. Usually some of these other lesions have had the appearance of antedating the urethral trouble. In almost every instance there has been disease of the deep urethra. In some instances the disease in the anterior urethra has been less marked, as it approached the meatus in Kidd's [13] case. In young children the process is necessarily secondary, except for the possibility of hematogenous infection.

Urethral tuberculosis may be secondary to a purely genital tuberculosis or to a tuberculosis of the urinary tract. The first is illustrated by the case I have reported, the second by Michaut's [14] case. Usually there is disease of both the urinary and genital tracts.

Lesions of the prostate, epididymes and vesicles are nearly always associated with urethral tuberculosis, and the extension to the urethra seems commonly to be by way of these organs.

It seems rather improbable that the mere passage of urine can often infect a healthy urethra, even when that urine contains tubercle bacilli in considerable numbers. When there are old lesions of the canal, either infiltrations, which interfere with the action of the accelerator urinæ, or obstruction to the passage of urine, the probability of this manner of infection is increased. I have found but one instnce in which an autopsy has shown a urethral tuberculosis as secondary to a purely urinary lesion. This is the case reported by Michaut.[14] In this patient there were no lesions of the genital organs or of the prostatic urethra, and the infection must have been by way of the urine. The patient gave the history of two attacks of gonorrhea, the last three years previous to the time of observation. As the urethral discharge had persisted since the second attack, it is reasonable to suppose that there were chronic lesions of the urethra which made it particularly susceptible. The patient had renal tuberculosis. In both genital and urinary infections the process seems usually to get a foothold in the prostatic urethra and then gradually to extend to the anterior part of the canal.

The lesions in urethral tuberculosis can be conveniently grouped under three headings: those of the mucous membrane; those of the corpus spongiosum; and those of the periurethral tissues.

Two sorts of lesions of the mucous membrane are commonly seen — the granulation and the ulcer. To these lesions Ahrens [1] and Halle and Motz [2] add the diffuse caseous infiltration.

The granulations or tubercles vary considerably in color and size. They may be either gray or yellow; they may be the size of a pin-point, as in Halle and Motz'[2] Case III, or the size of a pea, as in Michaut's case. Sometimes few are present, at other times the urethra is studded with them.

The ulcers also differ within wide limits. They may be small and superficial, as when the covering layer of a granulation has been destroyed, or the mucous membrane of nearly the whole urethra may be destroyed to its full depth.

Diffuse caseous infiltration is the name applied when a considerable area of the membrane has undergone the pre-ulcerative tuberculous infiltration.

Of the mucous lesions, the ulcer is the most common. The granulations and diffuse infiltrations are less often seen, presumably because they give place to ulcerations within a relatively short time. In the case reported by Michaut,[14] he had the opportunity of watching the evolution from granulation to ulcer.

Lesions of the corpus spongiosum are for the most part direct extensions of lesions of the mucous membrane; they may be infiltrations, ulcerations extending into the substance, or cavities filled with pus and granulations. Occasionally the process is for the most part confined to the urethral glands, with relatively little disease of the spongiosum, as illustrated by my case. Instances have been noted where the spongiosum was infiltrated without any neighboring lesion of the mucous membrane and separated from it by an area of non-tuberculous tissue (Halle and Motz [2]). The process in the spongiosum is, how-

ever, usually a direct extension of the disease from the mucous membrane.

The name "periurethral" has been given to all processes extending outside the fibrous sheath of the corpus spongiosum. They may be little abscesses which resemble the suppurative folliculitis seen in pus infections; when they open externally they usually leave persistent fistulæ. In the other extreme the whole perineum may be infiltrated, or converted into one or several cavities filled with pus and granulations. These pus collections may open spontaneously, but more often they are incised to relieve symptoms. They are usually followed by fistulæ with pouting granulations.

Quite a distinct type of periurethral tuberculosis is that affecting the glands of Cowper. Englisch [15] was one of the first to call attention to the nature of this lesion. In typical cases there is a slowly-growing, more or less circumscribed tumor in the perineum, which usually goes on to suppuration, and either opens spontaneously or is incised, leaving a urinary fistula. Where the process bursts through the capsule of the gland, the perineum may present a general boggy, infiltrated condition. Instances have been reported in which this process in a Cowper's gland has become cystic.

While the periurethral lesions usually extend from the under surface of the urethra, some extend from the roof and appear in the septum between the corpora cavernosa, or invade the corpora themselves. This extension is supposed to take place commonly through the urethral glands.

Symptoms. — Since in urethral tuberculosis there is almost always a certain amount of involvement of the posterior urethra, frequency and tenesmus are early symptoms. For the same reason hematuria is often seen. This hematuria, however, is not necessarily from the prostatic urethra. Michaut's [14] case, in which there were no lesions of the deep urethra, presented it. In that instance it was presumably of renal origin. So, too, the frequency and tenesmus may be due to associated renal or bladder disease. Incontinence has not been a very unusual symptom; Senn [16] and Malécot [17] report cases, as do others. It is presumably due to involvement of the posterior urethra.

The symptoms which are due solely to involvement of the anterior urethra are: discharge, pain on urination, nodular enlargements of the urethra, signs of obstruction to urination.

The discharge in urethral tuberculosis is commonly scanty and whitish rather than purulent. It has the appearance of the so-called "gleety discharge." It not infrequently follows without appreciable interval the discharge of a gonorrheal urethritis. Senn [16] reports a case in which there was a profuse purulent discharge and the meatus had the puffy appearance seen in gonorrheal urethritis.

Pain on urination is a pretty constant symptom. Its location and extent depend on the situation and amount of the urethral disease. It is usually a moderate sensation of burning. It has been likened in some patients to the ardor of acute gonorrhea. It differs from this in that it usually persists for a much longer time.

A nodular condition of the urethra is less common than the discharge or pain. It is probably never seen while the disease is strictly confined to the mucous membrane. The nodes are more numerous than those seen in the glandular involvement of gonorrheal urethritis. They are usually along the floor of the canal.

In certain of the reported cases obstruction to urination has been a prominent symptom. In some instances it is undoubtedly due in part to a previous pus infection. In others it is purely the result of the tuberculous process, as in Case I, Berard and Trillat,[5] Stone's [6] case, Malécot's [17] case, Halle and Motz' [2] eleven-year-old child, my patient and others.

In the instances where the obstruction is purely the result of the tuberculous disease, it may be of two sorts — that due to stricture and that due to infiltration. Because of the deep ulceration of the urethra true stricture may come on relatively early. These strictures are not infrequently multiple (Berard,[5] Stone,[6] Halle and Motz [2]). The other type of obstruction may arise even earlier, and is caused by a submucous infiltration which encroaches on the lumen of the canal (Halle and Motz, Case II; my patient).

The painful erections from which my patient suffered for a time seems to be an unusual symptom. Judging from his description, they were not of the acuteness of gonorrheal chordee.

Diagnosis. — The finding of tubercle bacilli in the urethral discharge is undisputable proof. Granulations or multiple ulcers of the urethra are almost pathognomonic. A urethral discharge with no history of exposure to venereal infection is very suggestive, especially so if no gonococci can be found. This last condition when combined with tuberculous lesions of the urinary, or particularly of the sexual organs, makes the diagnosis fairly certain. Stricture or the symptoms of urinary obstruction, coming on relatively soon after the onset of a urethritis, should raise the question of a tuberculous origin, as should the presence of any considerable number of indurated points in the corpus spongiosum. If there are enlarged inguinal glands, their examination may throw light on the nature of the condition.

Prognosis. — As this disease is so essentially a secondary one, the prognosis depends very largely on the extent and importance of the primary focus. If we base the prognosis on the reported cases it is very bad indeed; the great majority have terminated fatally. The disease has as yet received so little attention from clinicians that I doubt if the reported cases give an accurate idea of it. There can be no doubt that the prognosis is grave, and that the cases that recover will run a long and tedious course. It is to be expected too that in a large proportion of the recovered patients the urethra will show marked secondary changes.

Englisch [15] reports a case that recovered; the patient was under treatment for a number of

years. Poncet [8] has reported recoveries, as have Kraske,[9] Halle and Motz [2] and others.

Treatment. — Treatment must depend in the first instance on the extent of the primary tuberculous disease. In a considerable number of cases it will have to be purely palliative, it being manifestly improper to subject a patient with a hopelessly advanced pulmonary or renal tuberculosis to any considerable procedure for his urethral trouble.

In all patients with urethral tuberculosis the hygienic treatment should hold the most important place. In connection with this, forced feeding, arsenic, guaiacol, creosote, together with the aids to appetite and digestion, are of service.

I wish to call particular attention to the advantages of seashore camping for patients with the various forms of genito-urinary tuberculosis. It is of great advantage in the case of poor patients, as the expense can be made very slight. In this climate the tent life can be carried out for at least four months of the year and sometimes for longer. The work of camp life, fishing and the like, keeps the patient occupied and out-of-doors. He is of little danger to others as a source of infection. If he is troubled with frequency of urination, he is where he can relieve himself at almost any moment, without embarrassment. A patient with a marked tuberculosis of the bladder improved greatly under such conditions during last summer, and the expense, which was to him all important, was very small.

As regards the local treatment by applications to the urethra, I feel there is a great question as to its utility or desirability. Any instrumentation is usually very painful in urethral tuberculosis, and the possibilities and dangers of a mixed infection must be borne in mind. Hogge,[12] however, recommends the use of injections or irrigations. Solutions of nitrate of silver, so commonly used in chronic urethral troubles, seem to be particularly badly borne by these patients. Very weak corrosive solutions, or iodoform suspended or in emulsion, seem more desirable.

When the lesion is of the mucous membrane, or consists of a moderate involvement of the corpus spongiosum, I feel that one should depend on general hygienic treatment during the acute stage. I would make the only exception to this, those instances where a stricture or infiltration offers obstruction to urination; here internal urethrotomy should be done. In the instances where the disease in the spongiosum goes on to the formation of tuberculous cavities, these should be laid open and either curetted or cauterized. This applies to all sorts of periurethral disease with pus cavities. When the urethra is greatly ulcerated, perineal urethrostomy, as carried out by Poncet [8] and in Berard and Trillat's [5] second and third cases, will give great relief and may bring about recovery.

In some instances of very advanced disease, amputation is the best procedure, as in Kraske's [9] and Hartmann's [10] cases. When the disease is marked, but almost wholly confined to the anterior part of the canal, a temporary perineal fistula would probably be of help. I know of no instance where this has been purposely carried out. In Englisch's [15] Case I, a fistula resulted from opening a perineal abscess; this fistula persisted for some years, the urethral disease recovering during that time. Whatever operative procedure may be indicated, the importance of keeping up hygienic treatment must not be overlooked. The patients who recover will probably all require more or less treatment for the secondary lesions of the urethra: dilatation or urethrotomy for strictures or narrowed places; plastics for the closure of persistent fistulæ. When the strictures are multiple and intractable, or when there are fistulæ with so much loss of substance that they cannot be closed, Poncet's operation of perineal urethrostomy may be advisable.

A NOTE ON THE TRANSMISSION OF WHOOPING-COUGH BY INDIRECT CONTAGION.

BY JOHN LOVETT MORSE, A.M., M.D., BOSTON.

Instructor in Pediatrics, Harvard Medical School; Assistant Physician at the Children's Hospital and at the Infants' Hospital, Boston.

DURING the epidemic of whooping-cough in Boston last winter I was repeatedly asked whether or not whooping-cough could be carried by third persons or by clothing, and whether the disease could be contracted by going into a house in which there was whooping-cough, providing there was no contact with the patient. On the answers to these questions depended, of course, the management of the isolation. When I attempted to answer these questions I at once found that, although I had pretty definite opinions on these points, they were not based on any reliable data. I then attempted to get some more accurate information from the various textbooks, but found in them nothing but the most general statements, which showed very plainly that their authors were in much the same predicament as myself.

I then wrote a circular letter to the members of the American Pediatric Society, thinking that they, if any, would be able to furnish answers to these questions. The letter was as follows:

I am anxious to get some data as to whether whooping-cough may be transmitted by clothing or third persons. I am also anxious to get some data as to whether it may be

contracted by going into a room or house in which there has been a patient with whooping-cough, there being no direct exposure to the patient.

Some textbooks say that whooping-cough may be transmitted through third persons; others that it may be, but probably rarely is; others refrain from making any statement.

You will oblige me greatly by giving me your personal opinion on these points, and also any data which you may have which prove that whooping-cough may be transmitted through clothing, third persons or houses.

Replies were received from forty men. Thirty-seven gave no data; three reported five cases, one of which seemed to me rather doubtful. These cases were briefly as follows:

Dr. C. W. Townsend, Boston: A baby of eighteen months had never been in a railway car or in any house or carriage but its own. A friend came directly from a whooping-cough house, wearing the same clothes and muff that she had worn there. She allowed the baby to play with the muff which she had held in her hand when she was visiting and talking with the children with whooping-cough. No other exposure was known.

Dr. C. G. Jennings, Detroit: The eight-months-old child of a physician was very carefully watched and guarded. The children of its wet nurse lived about a mile away, and were taken sick with whooping-cough unbeknown to the doctor. Their mother visited them two or three times during the first two weeks of their cough. Within ten days of her last visit the physician's infant came down with whooping-cough. There was no other exposure.

Dr. C. G. Jennings, Detroit: An infant who was very carefully guarded from exposure was taken sick with whooping-cough, the source of which could not be made out. Repeated inquiry drew out the fact that about a week before the child began to cough the mother had unpacked a trunk containing a number of articles of child's clothing, among them a quilted hood that several months before had been worn by an infant through the greater part of an attack of whooping-cough. This hood was worn by the infant in question throughout one day.

Dr. D. J. M. Miller, Philadelphia: A family of adults loaned one of two copies of a book to the children of some friends who had whooping-cough. After four weeks the book was returned and placed upon the shelf alongside of its fellow. The son, twenty-four years old, who had never had whooping-cough, desiring to ascertain which of the copies had been used by the children with whooping-cough, and, knowing that a cresolene lamp had been used in the treatment, picked up one of the volumes which happened to be the one loaned to the children and smelt of it, passing the leaves to and fro before his nose as one does in looking rapidly through a book. In twelve days he developed whooping-cough. Other exposure, although unknown, cannot be positively excluded in this case.

Seven gave no opinions on the questions asked, probably because, as two of them said, opinions are of no value. Five thought that third persons may carry the contagion; six that they may, but rarely do; two that they probably may carry it; seven that they possibly may carry it; three that they may possibly carry it if they are coughed or vomited on and the exposure occurs very quickly. One thought that the contagion is not likely to be carried by third persons; one that it practically is not carried; four that it is very doubtful if it can be carried.

Two thought that clothing may carry the contagion; four that it may, but rarely does; two that it probably may carry it; and three that it possibly may carry it. One thought that it is not likely to be carried in the clothes; one that it is practically not carried; and four that it is very doubtful if it can be carried.

One thought he had seen whooping-cough develop after entering a room in which a whooping-cough patient had been. Six thought that whooping-cough may be contracted from rooms which have been occupied by patients with whooping-cough, but that it rarely is so contracted. Two thought it may possibly be contracted in this way. One suspected that it may be contracted in this way, while four were very doubtful if it can be.

Three men gave hospital experience going to show that contagion is not carried by third persons; and another, hospital experience going to show that it is not carried in clothing.

Two stated that they took slight precautions against carrying contagion when seeing cases of whooping-cough. Three stated that they took none. I regret that one of my questions was not what precautions were taken against contagion when seeing cases of whooping-cough. It seems to me that the answers to this question would have shown more truly how the men really felt as to the chances of carrying contagion themselves or in their clothing than do those to the others.

It seems hardly possible to draw any very positive conclusion from these replies, except that very little is known as to the indirect contagiousness of whooping-cough. The cases reported, although very few, seem to justify the presumption that whooping-cough may be carried by third persons or by clothing and other articles. The fact that forty men of such wide experience have seen such a small number of cases in which they could satisfactorily to themselves exclude direct contagion shows, however, that it must be very seldom that whooping-cough is carried in this way.

THE ILL HEALTH OF FRANCIS PARKMAN.

BY GEORGE M. GOULD, M.D., PHILADELPHIA, PA.

(Concluded from No. 13, p. 338.)

(5) *Cerebral reflexes.*—In his boyhood Parkman had headaches, and was spoken of as "a headachy child;" but in his adult life, according to his sister, he did not have what was ordinarily called headache, although Farnham speaks of "pains in the head" as continually sapping his force. The most revelatory statement I have been able to get from Miss Parkman is that the expression he used most was that his head was "stirred up," and that this was used by him when he could not work or listen to reading any longer. Miss Parkman understands by this expression what physicians call subjective vertigo and an indescribable confusion. Objects did not whirl or seem unstable, but the patient himself. There was also a rush of vague and uncontrollable sensations. Sometimes these were roused by talking or noises, so that silence was necessary even at meals in order not to bring on irritation. From a study of the few hints I can gather I feel that the morbid reflexes from the eyes kept his brain in a chronic state of hyperesthesia, the centers so surcharged

that he was in a constant state of great tension, and a slight excess of irritation at any time was more than could be correlated or drained off physiologically. It was his splendid will and by infinite precautions that he could prevent harmful results.[12]

From this cause also what is commonly called irritability or temper was never shown. His sister remembers no cross, unkind or petulant expression to have escaped him, however great the provocation. His beautiful mind seemed guarded against such outbreaks by a subtle feeling that it was his own nervous mechanism that was at fault. He never mistook the "wild whirl" in his head as caused by any whirl of the outside world. When it was impossible for him to listen longer to reading, or to conversation, or to apply himself mentally to any work, he seemed to find relief in inventing a string of nonsensical or ridiculous stories *à propos de rien*. Introspective he was not, and as to neurasthenia, hysteria or melancholy, the words are not to be thought of. Finally it must not be forgotten that the vagueness of the cerebral symptoms is no proof of their unreality or lack of intensity, as shown by the fact that he was supposed to be on the verge of insanity, and that first and last he consulted many physicians about his condition of mind and nerves. There was nothing vague, however, about his terrible and lifelong insomnia, which was certainly a consequence of his eyestrain.

The reactions or responses of each organism under the morbid stimulus or "insult" of eyestrain differ from those in any other case. That every case of disease is individual, impossible to bring into any narrow or exact classification is of course a truism in medicine. The typical case exists only in the textbook. But holding the essential fact in view one easily recognizes a common law that runs through and harmonizes all individual variations and renders clear the unity in all exceptions. All this is illustrated and verified by Parkman's case. In a general way the symptoms in severe cases of eyestrain roughly divide patients into three classes: (1) Those in whom the reflexes are to the eyes themselves, resulting in inflammations, disordered function and local diseases of many varieties. (2) Those to the brain, followed by a large variety of kinds of headache, psychic and nervous abnormalism, insomnia, etc. (3) Those to the digestive and nutritional systems, with "biliousness," anorexia, dyspepsia and any of the diseases of denutrition. It goes without saying that these types may be mixed in infinite degrees of complexity and intensity, but as a rule a certain case belongs in one of these three classes.

When the reflex is exclusively to the organs of nutrition, as in Carlyle's case, the mental concomitant is likely to be hypochondriasis, irascibility, etc. In Parkman's case the morbid reflexes expended themselves upon the eyes and the cerebral centers. Cheerfulness and a noble high-heartedness are noteworthy characteristics of the man, although none ever had better reason for despair and complaint. That neither black bile nor yellow bile tinged Parkman's brain is shown by the following sentence written of himself:

> His dislike of everything morbid — melancholy, misanthropy, depression — amounted to abhorrence, and if he could not be cheerful he went away if he was able; and if not, he held his tongue or turned to merry thoughts.

In many cases of reflex ocular neuroses we can find crises of the resultant symptoms occurring at certain life periods. In Parkman's case these crises are not evident. But one exists with any clearness, that of presbyopia. The others are at best masked. But one can see why they are masked. As in everything else this man was exceptional, logical to the limit. Every day and year was critical. He was of the heroic type, and not measurable by our little rules of thumb, applicable to the weaker and commoner man. Evidently his eye defect was of an exceptional kind, such as a low degree of unsymmetric astigmatism and anisometropia would produce. I say a low degree, because Parkman had sharp distant vision, showing that he could neutralize the abnormalism for distant vision. Most surely he could only do so for a minute or so at a time for near vision. A man of his iron will and exactness would also never give up the attempt to do so as long as it was humanly possible. I have known hardly any patient so incapable of reading and writing as he, or with a photophobia so intense. His astigmatism was of a kind that his ciliary muscle or his accommodative power could in adult life bear the strain of the attempt to neutralize it at near range for but a minute or two at a time. Even as a boy it produced headaches and truancy, and the crisis of adolescence is represented by the breaking off the college course by the trips to Europe. Using up each minute every infinitesimal gathering of accommodative power, both ocular and cerebral, by his studies and by the intensity of his nature, crises could not be as marked and differentiated as in less stalwart men and less resistant cases. Hence the steady decrease of reading and writing power went on exactly *pari passu* with the yearly lessening of the power of the ciliary muscle to overcome the lenticular inelasticity. The eyeglasses prescribed or that he picked up could only further mask the critical periods that would normally have appeared in early manhood and at the usual presbyopic time of life.

Even with the life of terrible suffering he had lived, and with the resultant injuries to the ocular and cerebral centers, the completion of presbyopia at about sixty brought him, as it does all others, a comparative ease and happiness and power of using the eyes during the last ten years of life. "During the last few years of his life," says Farnham, "his eyes allowed him to write quite freely for very short periods of time. Thus he was able to write out by himself with pencil on orange-colored paper the greater part of his

[12] Influences tending to depress the mind had at all times proved far less injurious than those tending to excite, or even pleasurably exhilarate, and a lively conversation has often been a cause of serious mischief. A cautious vigilance has been necessary from the first, and this cerebral devil has perhaps had his uses as a teacher of philosophy. (Autobiography.)

'Half Century,' and 'Montcalm and Wolfe.'" "He was better and a happier man after sixty," said his sister to me. "From the earliest of his married life," adds Farnham, "onward till near the close, the condition of his brain seemed to make it necessary for him to be silent and alone most of the time. But, as years rolled on, the improvement in his health, the easier progress of his labor and the development of his sympathy enabled him at last to meet life with happier moods and habits."

There can be no doubt in the mind of the modern ophthalmologist as to the cause of Parkman's eyestrain and hence of all its results. Every symptom enumerated can be entirely and only accounted for on the supposition that he had hyperopic astigmatism, probably unsymmetrical, and with anisometropia. There is every reason for the conviction that he had no organic disease of the eyes. He saw as well at night as other people, and so had not any form of retinitis. He recognized things and people so accurately in the daytime that one may be sure there was no considerable amblyopia or other limitation, or organically-caused defect of vision. No operation except upon the lids was ever performed upon his eyes.

I had written thus far from all the data that I could gain by reading and correspondence. It now occurred to me that a personal search might win the confirmation of my view which, not needed by oculists to bring conviction as to the true nature of Parkman's disease, would serve to prove the necessary inferences I had drawn, and would also make the fact plainer to general physicians and laymen. I therefore made a journey to Parkman's home, and after an active hunt of the records of oculists, physicians and of opticians I secured precisely the scientific confirmation of my theory desired. I found that Parkman from the first had not failed, at least partially, to recognize — how could he fail to do so? — the importance of his ocular condition. In 1849 he had gone to New York, and for a long time placed himself under the care of an oculist. No good, of course, came of it, and as this specialist is now dead we could not learn much of value from any case records that might still exist. The ophthalmoscope had not yet been invented, and as for astigmatism none had thought of it as having a pathogenic significance.

By the courtesy of an optical firm I found the following filed prescriptions:

(1) One from an excellent oculist dated April 12, 1881, ordering:

For the right eye + Sph. 2 + Cyl. 0.50 ax. 108°.
For the left eye + Sph. 2.75.

(2) From another equally competent specialist in 1883:

R. + Sph. 2.75 D.
L. + Sph. 2.75 D.

(3) From the same oculist, in 1885:

R. + Sph. 3.00 D.
L. + Sph. 3.00 D.

(4) In December, 1890, another equally trustworthy oculist ordered:

R. + Sph. 3.25 D.
L. + Sph. 3.25 D.

In addition he was wearing prior to 1881 from a famous European oculist:

R. + Sph. 2.25 D.
L. + Sph. 2.60 D.

I was greatly aided in my search by the courtesy of several oculists, who kindly placed their case records at my disposal.

I may at this point settle the question as to any abnormal or inflammatory disease of the retina. One oculist had kept no case records of Mr. Parkman's case. A second had made no entry as to any retinal condition, and being a capable ophthalmoscopist he would have noted the fact had the funduses of the eyes not been normal. The third positively placed in his notes "Fundus normal." Had this testimony not been found, the ignorant-wise might have said that Parkman must have had some retinal disease that caused the inability to read and the photophobia.

The notebook of one oculist says that the patient had recently consulted a most famous nerve specialist whom he had journeyed to see on account of "pressure and confusion in the head," which symptoms came on with literary overwork or excitement. This man had ordered some bicarbonate of soda and wet packs. Many years before Parkman had tried hydropathy and he would no more of it.

We see, therefore, that one European oculist found some difference in refraction in the two eyes but no astigmatism. An American oculist found a similar difference in the hyperopia of the two eyes, and he alone of all found astigmatism "against the rule." Three other prescriptions by two different oculists were for nonastigmatic lenses, alike in both eyes. A revelatory and explanatory fact was found in the case records of one of the latter oculists. This was that the astigmatic lines of the test card running at about axis 120° (judging from the penciled diagram drawn in the notebook) were chosen by the patient as being the plainest at fifteen feet distance, as seen by the right eye, and those running about 155° or 160° were seen more clearly with the left eye. Why glasses correcting this astigmatism were not ordered I do not know. Why the astigmatic correction ordered for the right eye by the other oculist was put at 180°, and why no correction of astigmatism was ordered for the left eye is also not clear.

I may parenthetically state that one oculist found the acuteness of vision in the right eye with — Cyl. 0.5 D. ax. 90° a little less than normal, and with + Sph. 0.25 that of the left eye was about the same. The oculist who noted that the patient chose the asymmetric astigmatic lines found the "media good," and that without any correcting lenses the visual acuteness was with the right eye 12/20, and with the left less, that is, a little more than one-half that of normal eyes.[13] If any deduction is justified by this it is only that there was a decided lessening of the 20/20? visual acuteness from 1881 to 1889, when it was men-

[13] He also notes — what was to be expected — that there was no hyperphoria and, as measured by vertical prism diplopia, no considerable exophoria or esophoria.

tioned as only 12/20 or less. As the "media were good" at the latter date no cataract was present. Retinal sensibility was doubtless dulled by the life of abnormal function. Confirmatory of this is the fact that Parkman used a crossed cylinder hand lens during the last years of his life, besides his spectacles, to magnify the size of printed letters.

Incidentally we may understand how it was that Parkman did not get all the relief from completed presbyopia that others do. It was because, with his intense will and powerful innervation, presbyopia was probably never quite complete, and some ability to overcome his hyperopia and astigmatism would remain farther into old age than with others. The same fact also suggests that his astigmatism and hyperopia were always masked, and consequently underestimated without mydriasis, by the patient's exceptional ability to conceal it by his accommodation. Hence, in part, at least, the differences among oculists in estimating the ametropia and in discovering the very existence of astigmatism. It should also be noted that with an organization both mental and neurologic, dominated as it were by a passion for exactness, the comparatively low astigmatism and anisometropia that could be neutralized for only a minute or two at a time would be exceptionally tormenting, its conquering never renounced, nor never for more than an instant overcome.

From comparison of all the data the demonstration is therefore perfect that:

(1) Parkman had unsymmetric astigmatism.

(2) There was a certain difference in the hyperopia (that is, anisometropia) of the two eyes.

(3) There was a probable difference in the amount of astigmatism of the two eyes. Most important is the fact that it was unsymmetric.

(4) This unsymmetric astigmatism and anisometropia was not corrected by any of the glasses that were ordered for him.[14]

(5) These ametropic defects were of such a low degree that prior to completed presbyopia they did not prevent fairly accurate distant visual acuteness, the power of accommodation being sufficiently great to neutralize them for this purpose.

(6) But they were so high that even with Parkman's marvelous vigor of will and innervation they could not be overcome for but a minute or two, or at best five, at near range (that is, in reading and writing), and during many years, not even for a minute.

(7) The effort of overcoming the unsymmetric astigmatism and anisometropia was so great and so expensive of nerve force that it resulted in the ocular and cerebral symptoms enumerated.[15] The almost unexampled severity of these symptoms was exceptional, because of the heroic resolution of the man and his indomitable perseverance in his chosen work.

[14] Two of the sets of lenses I have before me as I write, and the fact is proved true by "neutralization."

[15] People who cannot hold their arm horizontal for five minutes think it is exaggeration when a worse muscular and nerve strain cannot be endured by steady innervation of the ciliary muscle for ten or fifteen hours a day!

The professional lesson. — Parkman had the best professional advice that the medical science of his time could offer. He consulted the best physicians of Europe and of America, but all, in fact, in vain. During the last fifteen years of his life, after Dr. S. Weir Mitchell and other Philadelphia physicians, about 1875, had demonstrated the relief of reflex ocular diseases by means of the correction of astigmatism, Parkman might have and should have found at least some relief, and at least might have learned the solution of the terrible mystery of his life which had made tragedy of its every day. Prior to 1868 he had written as follows of his experiences with our profession:

> Meanwhile the faculty of medicine were not idle, displaying that exuberance of resource for which that remarkable profession is justly famed. The wisest indeed did nothing, commending his patient to time and faith; but the activity of his brethren made full amends for this masterly inaction. One was for tonics, another for a diet of milk; one counseled galvanism, another hydropathy; one scarred him behind the neck with nitric acid, another drew red-hot irons along his spine with a view of enlivening that organ. Opinion was as divergent as practice. One assured him of recovery in six years; another thought that he would never recover. Another with grave circumlocution, lest the patient should take fright, informed him that he was the victim of an organic disease of the brain which must needs dispatch him to another world within a twelvemonth; and he stood amazed at the smile of an auditor who neither cared for the announcement nor believed it. Another, an eminent physiologist of Paris, after an acquaintance of three months, one day told him that, from the nature of the disorder, he had at first supposed that it must, in accordance with precedent, be attended with insanity, and had ever since been studying him to discover under what form the supposed aberration declared itself, adding with a somewhat humorous look that his researches had not been rewarded with the smallest success.

Farnham also says:

> His general troubles were believed by the doctors to "come from an abnormal state or partial paralysis of certain arteries of the brain."

The last statement, while we smile, may afford a little instruction, because it is so characteristic of some puzzled practitioners when in the presence of a baffling mystery to fly to a word or term, or a far more mystifying explanation, and call that diagnosis.

The query remains as to Parkman's quizzical but no less terrible arraignment of us. There can be no more loyal member of the medical profession than I, none who believes more thoroughly that it is motived upon an earnestness and unselfishness of purpose unequalled in any so large body of men, none who is more deeply convinced that the brethren of his guild are doing more for civilization and the world's regeneration than any other; and yet, in the face of the long delay before the pathologic significance of ametropia was discovered, before the still more criminal silence and neglect and even opposition to that truth by so many physicians since the discovery was made, — the philosophic observer gets a decided shock. This is all the more startling when we learn that many of the leaders of the profession were consulted by Parkman and since 1875,

with no word of the explanation they should have known and of the cure they might have given. Many of them did not even keep any records or notes of the symptoms, diagnosis and treatment in his case. And yet more close comes the lesson when it is observed that despite the existence of hundreds of oculists at present capable of diagnosing and curing such diseases there are to-day in America at least a million such sufferers unrelieved, and in Europe many millions. In the presence of those who sneer at "exaggeration" and who kill by silence, before such wilful, not to say selfish ignoring, knowing the tons of "headache powders" sold by quack drug stores and even prescribed by medical men, viewing the vogue of the permitted and even encouraged "eyes-examined-free" criminal optician,—pondering upon the dignity of the "leading practitioner" and the "ophthalmic surgeon," who cannot bring himself to become "a spectacle peddler,"— one is constrained to echo Parkman's splendid indignation as to the pompous historical writer who is more concerned about himself and his profession than about prosaic truth. Once when upbraided for some accurate but "undignified" truth he broke out with, "Damn the dignity of history! Straws are often the best materials." The same splendid spirit should motive us. Let us cure our patients!

The following is the second autobiographic letter, now preserved by the Massachusetts Historical Society, and copied by the kindness of Miss Parkman. As it has never been printed I reproduce it herewith, because it presents his own view somewhat differently from the first letter, and as seen from a later time in life.

My dear Brimmer, — I once told you that I should give you some account of the circumstances under which my books were written. Here it is, with some preliminary pages to explain the rest. I am sorry there is so much of it:

Causes antedating my birth gave me constitutional liabilities to which I largely ascribe the mischief that ensued. As a child I was sensitive and restless, rarely ill, but never robust. At eight years I was sent to a farm belonging to my maternal grandfather on the outskirts of the extensive tract of wild and rough woodland now called Middlesex Fells. I walked twice a day to a school of high but undeserved reputation about a mile distant, in the town of Medford. Here I learned very little and spent the intervals of schooling more profitably in collecting eggs, insects and reptiles, trapping squirrels and woodchucks, and making persistent though rarely fortunate attempts to kill birds with arrows. After four years of this rustication I was brought back to Boston, when I was unhappily seized with a mania for experiments in chemistry involving a lonely, confined, unwholesome sort of life, baneful to body and mind. This lasted till the critical age of fifteen, when a complete change came over me — I renounced crucibles and retorts and took to books; read poetry and fancied for a while that I could write it; conceived literary ambitions, and, at the same time, began to despise a literary life and to become enamored of the backwoods. This new passion — which proved permanent — was no doubt traceable in part to fond recollections of the Middlesex Fells, as well as to one or two journeys which I was permitted to make into some of the wilder parts of New England. It soon got full possession of me, and mixed itself with all my literary aspirations. In this state of mind I went to college, where I divided my time about equally between books and active exercises, of which last I grew inordinately fond, and in which I was ambitious beyond measure to excel.

My favorite backwoods were always in my thoughts. At first I tried to persuade myself that I could woo this new mistress in verse; then I came down to fiction, and at last reached the sage though not flattering conclusion that if I wanted to build in her honor any monument that would stand, I must found on solid fact. Before the end of the sophomore year my various schemes had crystallized into a plan of writing the story of what was thus known as the "Old French War;" that is, the war that ended in the conquest of Canada; for here, as it seemed to me, the forest drama was more stirring and the forest stage more thronged with appropriate actors than in any other passage of our history. It was not till some years later that I enlarged the plan to include the whole course of the American conflict between France and England; or, in other words, the history of the American forest; for this was the light in which I regarded it. My theme fascinated me and I was haunted with wilderness images day and night.

From this time forward, two ideas possessed me. One was to paint the forest and its tenants in true and vivid colors; the other was to realize a certain ideal of manhood, a little medieval, but nevertheless good. Feeling that I fell far short of it, I proceeded in extreme dissatisfaction to apply heroic remedies. I held the creed that the more hard knocks a man gets, whether in mind or body, the better for him, provided always that he takes them without flinching; and as the means of forcing myself up to the required standard, I put my faith in persistent violence which I thought energy. I held that the true aim of life was not happiness but achievement; had profound respect for physical strength and hardihood when joined with corresponding qualities of character; took pleasure in any moderate hardship, scorned invalidism of all kinds, and was full of the notion, common enough with boys of a certain sort, that the body will always harden and toughen with exercise and exposure. I remember to have had a special aversion for the Rev. Dr. Channing, not for his heresies, but for his meager proportions, sedentary habits, environment of close air and female parishoners, and his preachments of the superiority of mind over matter; for, while I had no disposition to gainsay his proposition in the abstract, it was a cardinal point with me that while the mind remains a habitant of earth, it cannot dispense with a sound material basis, and that to neglect and decry the corporal part in the imagined interest of the spiritual is proof of a nature either emasculate or fanatical. For my own part, instead of neglecting, I fell to lashing and spurring it into vigor and prosperity.

Meanwhile I diligently pursued my literary scheme. While not exaggerating the importance of my subject, I felt that it had a peculiar life of its own of which I caught tantalizing glimpses, to me irresistibly attractive. I felt far from sure that I was equal to the task of rekindling it, calling out of the dust the soul and body of it and making it a breathing reality. I was like some smitten youth plagued with harrowing doubts as to whether he can win the mistress of his fancy. I tried to gauge my own faculties and was displeased with the result. Nevertheless I resolved that if my steed was not a thoroughbred I would at least get his best paces out of him, and I set myself to a strenuous course of training for the end in view. A prime condition of success was an unwearied delving into dusty books and papers, a kind of work which I detested; and I came to the agreeable yet correct conclusion that the time for this drudgery was not come; that my present business was, so to speak, to impregnate myself with my theme, fill my mind with impressions from real life, range the woods, mix with Indians and frontiersmen, visit the scenes of the events I meant to describe, and so bring myself as near as might be to the times with which I was to deal. Accordingly I spent all my summer vacations in the woods or in Canada, at the same time reading such books as I thought suited, in a general way, to help me towards my object. I pursued these lucubrations with a pernicious intensity, keeping my plans and purposes to myself, while passing among my companions as an outspoken fellow.

The danger into which I was drifting rose from the excessive stimulus applied to nerves which had too much stimulus of their own. I was not, however, at all nervous in the sense in which that term is commonly understood,

and I regarded nervous people with more piety than esteem. The mischief was working underground. If it had come to the surface the effects would probably have been less injurious. I flattered myself I was living wisely because I avoided the more usual excesses, but I fell into others quite as baneful, riding my hobbies with unintermitting vehemence and carrying bodily exercise to a point where it fatigues instead of strengthening. In short, I burned the candle at both ends.

The first hint that my method of life was not to prove a success occurred in my junior year, in the shape of a serious disturbance in the action of the heart, of which the immediate cause was too violent exercise in the gymnasium. I was thereupon ordered to Europe, where I spent the greater part of a year, never losing sight of my plans and learning much that helped to forward them. Returning in time to graduate with my class, I was confronted with the inevitable question, What next? The strong wish of my father that I should adopt one of the so-called regular professions, determined me to enter the Harvard Law School.

Here, while following the prescribed courses at a quiet pace, I entered in earnest on two other courses, one of general history, the other of Indian history and ethnology, and at the same time studied diligently the models of English style; which various pursuits were far from excluding the pleasures of society. In the way of preparation and preliminary to my principal undertaking, I now resolved to write the history of the Indian War under Pontiac, as offering peculiar opportunities for exhibiting forest life and Indian character; and to this end I began to collect materials by travel and correspondence. The labor was not slight, for the documents were widely scattered on both sides of the Atlantic; but at the beginning of 1846 the collection was nearly complete.

I had been conscious for some time of an overstimulated condition of the brain. While constantly reminding myself that the task before me was a long one, that haste was folly and that the slow way was the surer and better one, I felt myself spurred forward irresistibly. It was like a rider whose horse has got the bit between his teeth, and who, while seeing his danger, cannot stop. As the mischief gave no outward sign, nobody was aware of it but myself. At last, however, a weakness of the eyes, which was one of its symptoms, increased so fast that I was forced to work with the eyes of others. I now resolved to execute a scheme which I had long meditated. This was to visit the wild tribes of the far West, and live among them for a time, as a necessary part of training for my work. I hoped by exchanging books and documents for horse and rifle to gain three objects at once — health, use of sight and personal knowledge of savage life. The attempt did not prosper. I was attacked on the plains by a wasting and dangerous disorder,which had not ceased when I returned to the frontier five months later. In the interval I was for some weeks encamped with a roving band of Sioux at the Rocky Mountains, with one rough though not unfaithful attendant. It would have been suicidal to accept the part of an invalid, and I was sometimes all day in the saddle, when in civilized life complete rest would have been thought indispensable. I lived like my red companions, and sometimes joined them in their hunting, with the fatiguing necessity of being always armed and on the watch. To one often giddy with the exhaustion of disease, the strain on the system was great. After going back to civilization the malady gradually subsided after setting in action a train of other disorders which continued its work. In a year or more I was brought to a state of nervous prostration that debarred all mental effort, and was attended with a weakness of sight that for a time threatened blindness. Before reaching this pass I wrote the "Oregon Trail" by dictation. Complete repose, to me the most detestable of prescriptions, was enjoined upon me, and from intense activity I found myself doomed to helpless inaction. Such chance of success as was left lay in time, patience and a studied tranquility of spirit; and I felt, with extreme disgust, that there was nothing for it but to renounce past maxims and habits and embrace others precisely the opposite. An impulse seized me to return to the Rocky Mountains, try a hair of the dog that bit me, and settle squarely the question to be or not to be. It was the time of the Mexican War, and I well remember with what envious bitterness I looked at a colored print in a shop window, representing officers and men carrying a field battery into action at the battle of Buena Vista. I believe that I would willingly have borne any amount of bodily pain, provided only I could have bought with it the power of action.

After a while — as anything was better than idleness — I resolved on cautiously attempting to make use of the documents already collected for the "Conspiracy of Pontiac." They were read to me by friends and relatives at times when the brain was least rebellious, and I wrote without use of sight by means of a sort of literary gridiron, or frame of parallel wires, laid on the page to guide the hand. For some months the average rate of progress did not exceed three or four lines a day, and the chapters thus composed were afterwards rewritten. If, as I was told, brain work was poison, the dose was homeopathic and the effect was good, for within a year I could generally work, with the eyes of others, two hours or more a day, and in about three years the book was finished.

I then began to gather materials for the earlier volumes of the series of France and England in North America though, as I was prevented from traveling by an extreme sensitiveness of the retina which made sunlight insupportable, the task of collection seemed hopeless. I began, however, an extensive correspondence, and was flattering myself that I might succeed at last when I was attacked with an effusion of water on the knee which subsided in two or three months, then returned, kept me a prisoner for two years, and deprived me of necessary exercise for several years more. The consequence was that the devil which had been partially exorcised returned triumphant. The evil now centered in the head, producing cerebral symptoms of such a nature that, in 1853, the physician who attended me at the time, after cautious circumlocution, said in a low and solemn voice that his duty required him to warn me that death would probably follow within six months, and stood amazed at the smile of incredulity with which the announcement was received. I had known my enemy longer than he, and learned that its mission was not death but only torment. Five years later another physician — an eminent physiologist of Paris, where I then was — tried during the whole winter to discover the particular manifestations of the insanity which he was convinced must needs attend the symptoms he had observed, and told me at last what he had been about. "What conclusion have you reached?" I asked. "That I never knew a saner man in my life." "But," said I, "what is the chance that this brain of mine will ever get into working order again?" He shook his head and replied, "It is not impossible" — with which I was forced to content myself.

Between 1852 and 1860 this cerebral rebellion passed through great and seemingly capricious fluctuations. It had its ebbs and floods. Slight and sometimes imperceptible causes would produce an access which sometimes lasted with little respite for months. When it was in its milder moods I used the opportunity to collect material and prepare ground for future work, should work ever become practicable. When it was at its worst the condition was not enviable. I could neither listen to reading nor engage in conversation, even of the lightest. Sleep was difficult and was often banished entirely for one or two nights, during which the brain was apt to be in a state of abnormal activity, which had to be repressed at any cost, since thought produced the intensest torture. The effort required to keep the irritated organ quiet was so fatiguing that I occasionally rose and spent hours in the open air, where I found distraction and relief in watching the policemen and the tramps on the malls of Boston Common, at the risk of passing for a tramp myself. Towards the end of the night this cerebral excitation would seem to tire itself out, and gave place to a condition of weight and oppression much easier to bear.

Having been inclined to look with slight esteem on invalidism, the plight in which I found myself was mortifying; but I may fairly say that I never called on others to bear the burden of it, and always kept up a show of equanimity and good humor. The worst strain on these was when the Civil War broke out and I was doomed to sit an idle looker on.

After it became clear that literary work must be indef-

initely suspended, I found a substitute in horticulture; and am confident that I owe it in good measure to the kindly influence of that gracious pursuit that the demon in the brain was gradually soothed into comparative quiet. In 1861 I was able, with frequent interruptions, to take up my work again. At the same time there was such amendment as regards sight that I could bear the sunlight without blinking and read for several minutes at once without stopping to rest the eyes, though my chief dependence was still in those of others. In 1865 "The Pioneers" was finished, and the capacity of work both of brain and eye had much increased. "The Jesuits" was finished in 1867; "The Discovery of the Great West," in 1869; "The Old Régime," in 1874; and "Frontenac," in 1877. "Montcalm and Wolfe," which involved more labor, was not ready till 1884.

While engaged on these books I made many journeys in the United States and Canada in search of material, and went four times to Europe with a similar object. The task of exploring archives and collecting documents, to me repulsive at the best, was, under the circumstances, difficult, and would have been impossible but for the aid of competent assistants working under my direction.

Taking the last forty years as a whole, the capacity of literary work which during that time has fallen to my share has, I am confident, been considerably less than a fourth part of what it would have been under normal conditions. Whether the historical series in hand will ever be finished I do not know, but shall finish it if I can.

Yours faithfully,

F. PARKMAN.

JAMAICA PLAIN, 28 Oct., 1886.

Clinical Department.

REPORT OF CASES FROM THE SURGICAL SERVICE OF THE CHILDREN'S HOSPITAL.

BY DRS. H. L. BURRELL, H. W. CUSHING AND J. S. STONE.

Reported by Dr. W. C. Howe.

1. *Simple papilloma of abdominal wall;* 2, *scalp wound: concussion;* 3, *branchial cyst;* 4, *bullet wound of left chest;* 5, *abscess of abdominal parietes;* 6, *congenital deformity of hands and feet.*

SIMPLE PAPILLOMA OF ABDOMINAL WALL.

O. M., a boy of eleven years, admitted Feb. 5, 1903. Family history negative; previous history negative. At birth showed a minute verrucous growth on abdominal wall, which gradually grew to size of a pea. Four weeks ago it was irritated by the child's finger-nails, some bleeding occurred and it has since then increased in size (Fig. 1). Physical examination: Well developed and nourished. Marked glandular enlargement in neck, glands size of beans. No glands in axillæ; few in groin. Heart sounds regular, normal, no murmurs. Lungs show numerous wheezy râles, scattered throughout front and back; percussion normal. Abdomen negative. Upper and lower extremities normal. On abdominal wall, 2 inches below lower end of sternum, is a reddened area 1¾ inches long, 1½ inches wide. In the center of this area is a verrucous growth ¾ inch long, ½ inch wide, elevated ¼ inch. This growth is very vascular and bleeds easily; not painful. Operation; Dr. Cushing: The papilloma, with the surrounding skin at its base, was removed. The growth evidently did not extend below the skin. Slight bleeding. Wound closed with a subcutaneous catgut suture. Crêpe lisse dressing. Bandage. Sixth day: The wound was dressed and found closed by first intention. Linear cicatrix firmly healed. No bulging on cough. Tenth day discharged well. Pathological report from Dr. H. A. Christian stated that the growth was a simple papilloma with lymphoid and plasma cell infiltration. We are also indebted to Dr. Christian for the photomicrographs which follow (Fig. 2 and Fig. 3). This case is of interest in that it had the gross appearance of an epithelial carcinoma. It was a simple papilloma which had increased in size as the result of irritation.

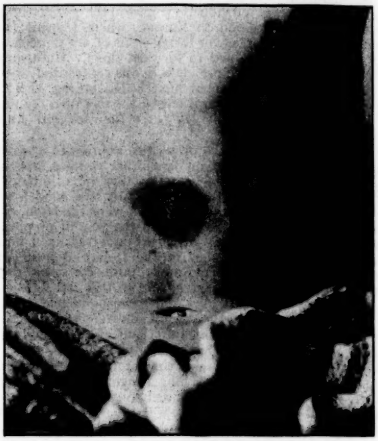

FIG. 1.—Simple papilloma of abdominal wall.

SCALP WOUND: CONCUSSION.

F. K., a boy of ten years, admitted March 30, 1903. Family history negative. Previous history: Diphtheria six years ago; following this there has been internal strabismus of right eye. There has also been paralysis of right arm since birth. Present illness: At 5.30 P.M. to-day, boy was struck on head with stone about size of a fist. At 6 P.M. was seen by a doctor, who cleaned up the wound, put in one suture and dusted wound with iodoform. While being dressed, the boy became drowsy and could be aroused only with difficulty. He was brought to the hospital at 9 P.M. Physical examination: Well developed and nourished. Pupils semi-dilated, left slightly larger than right, both react to light. Internal strabismus of right eye. Pulse regular, 76, good volume and tension, alike in the two wrists. Temperature 98.8°. On posterior aspect of head, at base of left parietal bone, is a contused wound 1 inch long. No depression or fracture can be made out. Boy not drowsy; is clear mentally. Heart, lungs and abdomen negative. Knee jerks normal. Right arm 21 inches, left arm 23 inches in length.

No muscular atrophy. The wound was cleaned with corrosive solution: corrosive dressing. On third day the wound was dressed; it was found to be clean. No symptoms. On sixth day the boy was up and about the ward. He showed no symptoms. On tenth day the patient was seen by Dr. W. N. Bullard, who made diagnosis of obstetrical paralysis, right arm. The patient was discharged well.

Injuries of this description in children are not uncommon, and unless one has seen the clinical picture of concussion, with pupils semi-dilated, one slightly larger than the other, internal strabismus of one eye, one might be led to localize a cerebral injury and operate. This patient, immediately following the injury, was mentally clear; but while the wound was being dressed stupor, a serious symptom, appeared. We have seen instances in which convulsions occurred which were so alarming as to cause the attending surgeon to operate.

BRANCHIAL CYST.

T. S., a girl of seven years admitted April 6, 1903. Family history and previous history negative. Present illness: When two years of age, the mother noticed a small lump, size of a pea, on left side of neck. This lump ruptured spontaneously and discharged. The patient was operated four years ago at another hospital by an incision and curetting. Two weeks ago the tumor reappeared and began to discharge a thin, purulent fluid. Physical examination: Situated on anterior aspect of neck, at the level of the thyroid cartilage and at the apex of the left submaxillary triangle, is a raised reddened area about the size of a pea, covered with a slight crust in the center. It is superficial and freely movable and not tender. It has a deep attachment running in toward the median line (Fig. 4).

April 13, operation, Dr. Burrell. An elliptical incision was made circumscribing this raised, reddened area and a dense, tubular sinus found which extended downward to the wing of the left thyroid cartilage. The sac was dissected free from the cartilage. In removing the tubular sac, the dissection opened the crico-thyroid membrane, which was sutured with fine silk. The dissection was difficult, and to remove the whole of the branchial cyst it was necessary to recognize clearly the difference between the cyst wall and the adjacent tissues. The separated muscular tissue and fascia were sutured with catgut and the skin was closed with silkworm-gut sutures. In a week's time the wound was united and the patient was discharged well. In removing a branchial cyst it is necessary to dissect out the continuity of the sac. Otherwise there will be a relapse from the secreting membrane that is left from the incomplete removal.

FIG. 4. — Branchial cyst, showing opening of sinus just to left of median line.

BULLET WOUND OF LEFT CHEST.

C. G., a boy ten years of age, admitted March 23, 1903. Family history and previous history negative. On March 20, 1903, the patient was one of a band of "white settlers" who were defending a town on Cape Cod from the attack of "Indians;" the Indians ranged in age from eight to twelve years; both the white and red men were armed for the most part with bows and arrows, but the Indians were fortunate in the possession of one 22 cal. revolver. The attacking party was rapidly being repulsed, until their solitary firearm, which throughout the conflict had been discharged over the heads of the whites, was turned against the patient, at a distance of about six feet. The bullet entered his left chest. The wound was dressed with gauze and corrosive sublimate; and was not probed by the attending physician. In the afternoon he had considerable pain in the left chest. No evidence of hemorrhage. Temperature 99.5. Pain on respiration. Morning of 21st, temperature normal, respiration 30, pulse 110; evening of 21st, temperature 100, pulse 120, respiration 32; 22d, temperature 101, pulse 120, respiration 35, wound looked well; evening of 22d, restless, temperature 102, pulse 124, respiration 40; 23d, temperature 101, pulse 124, respiration 36. Physical examination: Well developed and nourished. Expression anxious; tongue slightly coated; pupils equal and react. Slight glandular enlargement in left axilla and groin. Heart rapid, regular, no murmur. No friction rub. Heart's dulness extends to right, ¼ inch beyond the right border of sternum. Right

lung normal. Left lung shows good resonance in front, becoming dull in posterior axillary line, dulness over lower third of back. Just inside nipple on the left is a slight discoloration in fourth interspace; 1 inch inside and ½ inch below nipple is a circular wound in the skin, with surrounding yellowish discoloration (Fig. 5.). Wound ¼ inch

FIG. 5.

in diameter. Swelling and tenderness over pectoral muscle. No râles in lung. Slight discoloration in back over lower end of scapula. March 24, some pain in left chest. Physical signs in left lung have increased and lower third of back is flat, with bronchial breathing and increased voice sounds. March 25, seen by Dr. T. M. Rotch, who made diagnosis of pericarditis with effusion. Cardiac dulness now extends to line midway between right nipple and sternum. Slight friction rub over third space on left. Lung on left is now flat for lower two-thirds of back. March 27, respirations have dropped to 30. No râles in lung. Physical signs in heart and lungs the same. Small amount of bloody sputum to-day. March 28, heart's dulness ½ inch to right of strenum. Lung is not so flat. No râles. March 29, just below angle of left scapula, slough seen in back. Bullet not felt. April 1, pericardium evidently not so markedly stretched to right as before. April 5, temperature 99.5, respiration 30, child comfortable. Dulness in lower left back, several moist râles. Condition satisfactory. April 10, steady improvement since last note. April 13, child is improving in general condition and temperature is falling. Dulness in left back persists. April 17, this morning child developed swelling in region of right parotid. Some tenderness to touch and pain on opening mouth. Isolated on suspicion of epidemic parotitis. Dr. Rotch confirms diagnosis. April 22, temperature down. Throat not sore. Isolation stopped. April 27, last night temperature was up. No cause found. Up on go-cart in sun parlor. May 2 boy has been up and dressed about the ward. May 6, x-ray shows bullet about in middle of lung. May 7, physical examination: Heart sounds regular, not rapid, no murmurs. Relative dulness from anterior axillary line, third rib down to seventh rib. Area of dulness below and to right of angle of left scapula. Breathing somewhat diminished in left back in region of scapular angle. In left axilla, from fourth to seventh rib, extending to post-axillary line, is a region where breathing is almost entirely absent. Boy discharged relieved.

It is a fair presumption, from the situation of the wound externally, the situation of the bullet in the lung and the existence of pericarditis, that the apex of the heart muscle was perforated. A few years ago such injuries were assumed to be fatal, but to-day we know that punctured wounds of the heart may recover under suitable treatment. The immediate dangers are profuse, overwhelming hemorrhage, or a hemorrhage which trickles into the pericardial sac and thus gradually compresses the heart and stops its action. Life has been saved by operating and removing the clots which interfered with the action of the heart and suturing the heart muscle.[1]

ABSCESS OF ABDOMINAL PARIETES.

A. A., age six years, was admitted March 2, 1903. Family history and previous history negative. Present illness: Three weeks ago was struck with a club on right side of abdomen. Has not been in bed; has walked, but with considerable pain, leaning to one side. Bowels have moved with aid of castor oil. Sleep is prevented by pain; appetite very poor. Physical examination: Fairly developed and nourished. Looks sick. Lies by preference with thighs flexed. Pupils equal and react. No efflorescence. Throat normal. Linear scars behind each ear and on left side, in posterior triangle. Heart and lungs normal. Glands in each groin. Hyperextension of right hip limited. Limbs otherwise normal. Spine held somewhat stiff, especially to hyperextension. Child cannot be made to stoop or bend over while sitting. Walks rather guardedly, but not with the characteristic gait of Pott's disease. In right side of abdomen, just above McBurney's point, is a visible and somewhat indefinitely palpable tumor about two inches in diameter. No redness, increased surface temperature or fluctuation. Tumor moves with respiratory movement of abdominal wall and appears confined to abdominal parietes. Extremely sensitive. No general abdominal tenderness or distention. No evidence

FIG. 3. — Photomicrograph of section of papilloma, showing that the growth is superficial, and does not involve the deeper layers.

FIG. 7. — Radiograph of hands.

Radiographs by Percy E. Brown, M.D.

FIG. 9.

of ascites. Right rectus more tense than left. Whole abdomen, except upon pressure over tender area, is flaccid. Operation, Dr. Cushing: Ether. Incision one inch long over abscess and small amount of pus evacuated. Abscess evidently between external and internal oblique. Irrigated with peroxide. Iodoform wick. Dressing. Good recovery from ether. One week later the wound was nearly healed, the granulations were healthy, slight discharge. Motions of hip apparently normal. Flexibility of lumbar spine normal. Lumbar spine slightly flattened. Discharged relieved. Blood examination, March 3: 21,400 leucocytes. Bacteriological record: Streptococcus pyogenes aureus. Apparently this was a hematoma, following the injury, which later suppurated. The case was sent to the hospital with the diagnosis of appendicitis with abscess.

CONGENITAL DEFORMITY OF HANDS AND FEET.

P. F., a boy of eleven years, admitted Dec. 5, 1902. Family history negative. Only child. Previous history: Normal labor, full term, measles. Present illness: Right hand operated on at another hospital when one year old. No other treatment. Since that time, so far as known, the child has had no trouble of any sort except the deformity. Physical examination: Peculiarly developed, strong, well nourished, good color. Tongue large, flat and fissured. Intelligence good. Ears outstanding. Forehead low and slightly retreating. Head, normal shape, rather small. Chest flattened at the sides. Costal cartilages prominent. Heart and lungs normal. Abdomen soft and full; normal. Penis small. Testicles in scrotum. Thighs large. Spine normal. Right arm normal. Right thumb, terminal phalanx, turned out at angle of 30°. Right little finger abnormally wide at base, as though there were an extra metacarpal. At base, scar of old operation for supernumerary finger. Left arm normal. Left thumb similar to right. On left hand the supernumerary finger beyond little finger, which seems to consist entirely of an extra metacarpal; between it and main body of hand is a web ½ inch wide, which runs up on outer side of little finger (Figs. 6 and 7). Movements of fingers not interfered with. Each foot presents six webbed, rudimentary toes, with imperfectly formed nails. Right foot apparently has five distinct metatarsals with corresponding phalanges and on inner side of these, an imperfectly formed metatarsal, with which articulate distally and internally irregular phalanges, three or four in number, forming a broad, flattened great toe. The left foot is similar in conformation. (Figs. 8 and 9). The great toe of

Fig. 6.

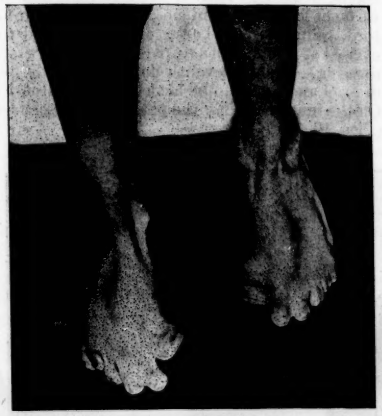

Fig. 8.

Fig. 10.

each foot is turned in at an angle of 30° with the axis of the foot. Operation, Dr. Burrell: Ether. *Left hand:* Incision starting at end of ulna and coming up around extra finger, forming an oval. The dissection was carried down to the joint of supernumerary finger and the finger was removed. Skin sutured with interrupted catgut sutures. Sterile dressing. *Feet:* Great toes removed. Incision at joint of toe and metatarsal up and around toe. Skin dissected back. Muscles cut and toes excised at joint. Skin sutured with catgut. Sterile dressing. On the seventh day the wounds were dressed and found to be healed by first intention. On the fourteenth day the patient was discharged (Figs. 10 and 11).

FIG. 11.

Medical Progress.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., AND W. D. HALL, M D., BOSTON.

(Concluded from No. 13, page 347.)

FUNCTIONAL OR HYSTERICAL AMBLYOPIA.

GUNN [6] divides this class of patients into idiopathic, usually occurring in women, sometimes in children, and traumatic, occurring probably to an equal degree in both sexes, but always in adults, according to his experience. He thinks that we do not understand the nature of the affections of the nervous system resulting in hysterical manifestations, although many forms admittedly have an element of simulation. In many cases a single central lesion will not account for all the symptoms. When such lesions actually exist it is not a pure functional disorder, but an obscure early manifestation of real organic disease. Many hysterical persons subsequently become affected with an ailment such as insular sclerosis, consequently these symptoms should be considered carefully. It may be assumed that in most of these cases there is a temporary, partial or complete loss of the power of conduction between the lower or middle visual centers and the highest conscious centers. Gunn has noticed in cases of supposed blindness in very young children that the child pays no special attention to moving objects, although ophthalmoscopically nothing appears to be wrong. He thinks the prognosis to be favorable in such cases, and considers it an instance of delayed visual consciousness, in which there may be retarded development of higher association fibers. He thinks that there may be some similarity between this class of cases and those which later in life are called "hysterical amblyopia," insomuch as in both the retinæ are perfect, the optic nerve seems to be perfectly able to transmit impressions, the tracts seem normal, the sight centers presumably are fit for work and actually are receiving impressions, and yet there is no consciousness of these impressions, or a consciousness lessened to the degree occasioning no response. In hysteria the association fibers have been normally developed and efficient, but from some unknown cause their functions seem to have been suspended. This loss of conducting power may be re-established by shock, suggestion, surprise or even a voluntary exertion, on the part of the patient, of his own will power. In hysteria a peculiarly suceptible nervous organization is to be considered. As regards the treatment, change of scene if it can be arranged; but if not, friends must be careful to avoid drawing attention to, or showing regard for, the symptoms. Nourishing diet, assafetida and faradism may be of value.

THIOSINAMINE.

Dr. George F. Suker [7] has carried on a series of experiments to determine the efficacy of this remedy as an absorbent of corneal opacities, cicatricial contraction of the lids, exudative chorioiditis, symblepharon, capsular opacities and cicatricial ectropion. It is an active alterative belonging to the same group as iodide of potash and mercury, and has been favorably mentioned as a resolvent of cicatricial tissue in other locations. Experiments made to determine whether it would prevent the maturing of cataracts were without results. The best mode of administration is in 3-gr. capsules once or twice a day, and after it has been used for five or six weeks, it is well to intermit for a week or ten days. It occasionally produces vertigo when first taken, which is an indication for diminishing the dose. Therapeutically it is a marked tonic, favors the absorption of exudates, transudates

[6] Ophthal. Rev., October, 1902.

[7] Journ. Amer. Med. Assoc. Aug. 9, 1902.

and clears corneal nebulæ, produces local reactions without general disturbances, reduces glandular enlargements, causes cicatricial tissue to become pliable. The writer has used it in 6 cases of exudative chorioiditis, with improvement in 4; in 10 cases of dense corneal opacities, with improvement in 6; in 8 cases of opacities less dense, with marked improvement in 4, moderate in 2; in 6 cases of plastic iritis, with benefit in 3; in 3 cases of capsular cataract, with not the slightest improvement. The author recommends it only as one of many drugs which have been used for similar purposes with possibility of improvement, but it should not be given in cases where there are cicatrices resulting from operation, when the scars are expected to act as supports.

OPHTHALMOL LINDEMANN.

Dr. Donath[8] believes this to be the best remedy for trachoma and other diseases of the eye. It is a carefully sterilized, oily product, showing the presence of iodide and traces of arachin acid. In the healthy eye it causes slight burning and redness of the conjunctiva, slight blepharospasm and photophobia, all of which disappear in a few minutes. In acute inflammatory conditions, after its use relief from the unpleasant symptoms is noticed. In those diseases characterized by secretion, these latter at first increase after its use and then rapidly diminish, and at the same time the swelling of the lids and chemosis of the bulb greatly subsides. Corneal ulcers are favorably affected through the formation of new blood vessels and reaction of corneal tissue. The opacities become certainly more transparent. In chronic inflammatory conditions, as, for instance, old trachoma with diffuse infiltration and hypertrophy, this drug at first causes an increase in the symptoms, but after the reaction the swelling subsides. Pannus is favorably affected by it, the ulcerative form especially, which at first shows an increase in circulation and new blood vessel formation, followed by resorption and clearing. The author prefers this drug to the nitrate of silver and sulphate of copper, as there is neither pain nor danger in its use. It may be said to favor resorption, increase the vitality of the tissues, act as an antiseptic by the lacrimation it produces and as a protective through its oily consistency.

SUBCONJUNCTIVAL INJECTIONS OF HETOL.

Dr. Lezenius[9] uses either a 1 or a 5% solution of hetol in water or salt solution. The solution must be clear, neutral or slightly alkaline; never acid. After two or three days the irritative symptoms of herpes cornea disappear. It relieves pain in a marked degree. The ulcers rapidly clear, and a cure takes place in ten days or even less. No constitutional treatment was used. In ulcers of the cornea, especially when sluggish in nature, this method of treatment is valuable, in that it starts up an acute process, which precedes healing. The duration of treatment of interstitial keratitis is very much shortened by the injection method. Of course atropine and internal medication should not be omitted. The injections do not seem to have much affect upon pannus. Iritis and choroiditis of the non-purulent variety, although not especially benefited, were not affected unfavorably, and possibly the duration was somewhat shortened. The same was noticed in diseases of the sclera. The action is probably due to the diffusion of the drug into the lymph vessels of the conjunctiva and thence into the corneal lymphatic spaces. Its principal action seemed to be exerted upon the cornea and its immediate neighborhood, the effect diminishing as the distance increased.

[8] Med. Chirurg. Centralbl., Feb. 13, 1903.
[9] Monatbl. f. Augenh., October, 1902.

VASOMOTOR DISTURBANCE OF THE EYE.

Lodge,[10] as a result of the examination of the eyes of patients in whom there were undoubted signs of vasomotor disturbance in other parts of the body, has noticed spasmodic contraction of the central artery of the retina and its branches, and marked dilatation of the retinal veins, with, in some cases, palpitation. Visual fields were greatly contracted in the temporal and lower temporal portions, but not so on the nasal side. Whenever an ophthalmoscopic examination has disclosed contracted arteries and dilated veins, it is apt to be the case that such appearances and changes in the visual fields accompany vasomotor disturbances elsewhere in the body, although they may be very slight and not considered important enough for treatment, as would be in severe cases of the definite Reynaud type. Such patients complain of frontal and parietal headaches; their eyes ache after use, even though ametropia may be properly corrected. These patients are generally neurotic, and have an anxious expression; sometimes there is proptosis and occasionally edema of lids. Dilated episcleral veins, myosis and ciliary spasms may be present. The thyroid may be enlarged, but, with the exception of the proptosis, there are no signs of exophthalmic goiter. The diagnosis of vasomotor disturbances of the eye is unmistakable if a subconjunctivitis comes and goes while the patient is under observation. Without corroborative symptoms the diagnosis of the chronic form is difficult. The author suggests that the so-called "hot eye" of Hutchinson, the subconjunctivitis of Graefe and the periodic transient episcleritis of Fuchs is really a vasomotor affection of the eye. "Suprarenal liquid" locally is advised, together with the internal administration of the gland substance.

THE PRESENT STATUS OF SUBCONJUNCTIVAL INJECTIONS.

Charles Stedman Bull, M.D., in a paper read this summer before the American Ophthalmological Society, after reviewing the literature of the subject of subconjunctival injections and showing thereby how contradictory has been

[10] Brit. Med. Journ., Nov. 1, 1902.

the evidence offered as to their real value, concludes that "the efficiency of these various solutions injected beneath the ocular conjunctiva cannot be ascribed to the increased local acceleration of the lymph currents and so-called leucocytosis nor to the antiseptic action of the remedies employed, since the presence of these processes cannot be demonstrated in the eye after such injections. The chief change seems to be in the composition of the aqueous humor. This is said to become much richer in albuminoids, due to the irritating action of the injected substances upon the blood vessels." As the protective substances in the blood are always in combination with the albuminoids of the blood, any increase of the serum albumen in the aqueous humor would coincide with an increase in protective substances. After an injection of sublimate or sodium chloride, the aqueous humor becomes markedly hemolytic. Although during the last three years he has treated various diseases of the eye by this method, making use of a number of different solutions, Dr. Bull has not been able to determine any important difference in the mode of action or their effect between salt solution and a solution of mercuric cyanide extolled by Darier, neither has he had the success claimed by Haitz in central choroiditis and vitreous opacities by use of solutions of mercuric cyanide, and he has found the solution to be very painful. Hetol injections were less painful, and seemed to influence favorably herpes, interstitial keratitis and acute uveitis. This good effect was noticed in superficial cases but not in the chronic, notably failing in scleritis. Persistent use in tubercular disease of the iris and choroid was apparently without the slightest effect.

BROMIDE OF METHYL-ATROPINE AS A MYDRIATIC.

Darier[11] recommends this new mydriatic, in that it lacks certain inconveniences of atropine and possesses certain good qualities. In the larger and repeated doses it is said to have the same action on the iris and ciliary muscle as the sulphate of atropine. When used in solutions of one per cent strength, the dilatation of the pupil only lasts about one day, while the cycloplegia lasts but a few hours. In solutions of one half of one per cent with one per cent of cocaine, mydriasis alone is produced.

ELECTRIC HEAT AND DIONIN IN RHEUMATIC AFFECTIONS OF THE EYE.

Maddox[12] has found it convenient, when applying artificial heat to the eye, to use a one-half or seven-tenths strength ampère current passed through very fine wire which has been wrapped in canton flannel. This current may be taken from an ordinary lighting wire and controlled by a transformer. He considers this form of dry heat to be especially indicated in rheumatic affections of the eye and certain forms of glaucoma. As a rule, he thinks dionin may be used when heat is indicated, but advises adrenalin when cold is more applicable.

[12] La Clinique Ophtalmologique, Dec. 10, 1902.

THE ORIGIN OF THE VITREOUS BODY IN VERTEBRATES.

Tornatola,[13] as a result of his investigations upon this subject, believes to have demonstrated the normal vitreous as being always composed of fibrillæ that have no granule; that pseudocells are not to be made out at the intersections of these fibrillæ; that when there exists a rosary-like arrangement of fibers it is of pathological origin; that there is no hyaloid membrane; that there is no true internal limiting membrane of the retina; that it comes from cells without nuclei, which form the base of the pars ciliaris retinæ and from elements which in the differentiated retina constitute neuroglia.

DIAGNOSIS OF INTRAVAGINAL HEMORRHAGE OF THE OPTIC NERVE WITH THE OPHTHALMOSCOPE.

Gonin[14] concludes his article as follows: A papillomacular haze with ischemia of the retinal arteries in a suddenly blind eye does not warrant this diagnosis. Profuse hemorrhages on the borders of the disk or in the vitreous do not necessarily signify an apoplexy of the sheath. They are in no way characteristic. A slight degree of papillary stasis is the only ophthalmoscopic appearance which the facts warrant considering an indication of retrobulbar effusion. The absence of all fundus changes does not exclude even an abundant hemorrhage into the sheath of the nerve. We are still ignorant of visual disturbances which are caused by hematoma of the nerve sheath, unless this hematoma is complicated by a more serious lesion, as, for example, fracture of the base or cerebral hemorrhage.

A PERIPATETIC EYE CLINIC.[15]

It is stated in the *Lancet* that Sir Ernest Cassel has given a large sum of money to the Egyptian government for the relief of ophthalmia in Egypt. It has been decided to send traveling dispensaries into the country for the relief of those who are unable to attend the already existing hospitals. There will be at first one of these dispensaries or ambulance hospitals, which will have a couple of tents with beds for patients who have to be operated upon, and for the treatment of the more serious cases. This will travel about from place to place under the direction of an ophthalmic surgeon. The system will be organized by a chief clinical assistant of the Royal Ophthalmic Hospital (Moorfields).

UNDER WATER FIVE MINUTES. — According to the *Medical News*, to settle a dispute, George Kistler, swimming instructor at the University of Pennsylvania, recently remained under water five minutes and five seconds without injury.

Reports of Societies.

AMERICAN GYNECOLOGICAL SOCIETY.

PROCEEDINGS OF THE TWENTY-EIGHTH ANNUAL MEETING, HELD IN WASHINGTON, D. C., MAY 12, 13 AND 14, 1903.

Joseph E. Janvrin, M.D., of New York, President.

An address of welcome was delivered by Dr. I. S. Stone of Washington, D. C., which was responded to by the President.

There was a symposium on the subject of

WHAT SHALL BE THE TREATMENT IN CASES OF PREGNANCY COMPLICATED BY FIBROID TUMOR?

The first paper with this title was read by Dr. Henry C. Coe of New York City, who stated that fibroid tumors complicate pregnancy because they interfere with the normal development of the pregnant uterus; they cause distressing symptoms, or they jeopardize the life of the fetus or of the mother. Each case must be studied separately, and the decision as to the treatment will vary with the patient, the tumor, the experience and bias of the surgeon. He spoke of the influence of the tumor on pregnancy, and of pregnancy on the tumor — increased growth, degenerative changes, environment, etc. He mentioned three "semesters" of pregnancy:

(1) Up to the fourth month. (*a*) Empty the uterus in the case of large interstitial or broad ligament tumors, or where they are situated in the lower uterine segment; also in cases of impacted intrapelvic growths. Cases were cited in point. (*b*) Small tumors should be enucleated *per vaginam*, if possible, though pregnancy will usually be interrupted. Intrauterine polypi should be removed, if accessible. (*c*) Enucleation should be done by the abdominal route. Subperitoneal pedunculated growths should be removed. (*d*) Impacted growths should be liberated under anesthesia, when no adhesions are present, and they should be kept out of the pelvic cavity until they are kept out of the way by the growing fetus. The wishes of the patient should be followed so far as this can be done with safety.

(2) Fourth to seventh month. The location of the tumor is important, as well as its size and variety. Pain and pressure symptoms furnish indications for treatment. (*a*) Large interstitial growths. The uterus may be emptied, although the danger of hemorrhage from such a course is greater. (*b*) He advises enucleation by the abdominal route, and spoke of the propriety of removing multiple small tumors which do not encroach on the uterine cavity. (*c*) The patient should be kept under observation. The patient may go to full term and be delivered normally. (*d*) Impacted tumors, pressing on the bladder, bowel, ureter, may call for radical operation. (*e*) Twisted pedicle, degeneration of tumor, disease of the adnexa, peritonitis, etc., may require interference without reference to pregnancy.

(3.) After sixth month. Viability of the fetus should be obtained if the life of the mother is not actually jeopardized. Can the woman be delivered at term? Yes, (*a*) with subperitoneal growths, if they are not too large and favorably situated. (*b*) Small interstitial fibroids, if they are not in the lower uterine segment. (*c*) Polypi presenting at the os can be easily removed at any time. After the eighth month the Porro-Cæsarean operation, suprapubic amputation or hysterectomy should be performed, preferably by election, that is, before full term.

Conservatism should be practiced here, as in other gynecological operations, but not carried to extremes.

The author discussed the question of marriage and subsequent risks of pregnancy in women with fibroids. He said the time for conservative surgery is often before there is a chance of conception. In general, if a fibroid is to be regarded as a menace to life before pregnancy, the condition must be still more grave after conception occurs. Is it not the duty of the gynecologist to ward off this danger?

Dr. Joseph Taber Johnson of Washington, D. C., read a paper on

MYOMECTOMY OR HYSTERECTOMY.

He said the treatment depended on the size, variety and location of the tumor, as well as the size of the pregnancy. Myomectomy in favorable cases should be the operation of election. However, cases occasionally present themselves with such urgent symptoms as to require supravaginal hysterectomy as a life-saving operation. He described briefly successful operations of both varieties. He discussed the quesions of abdominal and pelvic operations during pregnancy; also the propriety of inducing premature labor, as well as the policy of trusting to the *vis medicatrix naturæ*.

Dr. George Tucker Harrison of New York followed with a paper on

PREGNANCY AND LABOR COMPLICATED BY MYOMATA.

No general rules can be laid down with reference to the treatment, as each case must be carefully studied in all its circumstances before recourse is had to operative intervention. The dangers of this complication of pregnancy as a cause of dystocia were formerly overestimated. The plan of treatment during pregnancy, as a rule, is an expectant one.

Dr. Edward Reynolds of Boston spoke of the treatment of large incarcerated fibroids at or near term in advance of the fetal head. He had seen ten such cases. No one of these tumors was smaller than the seventh-month fetal head. In each instance the woman was delivered either normally or by forceps.

Dr. J. Duncan Emmet of New York City said there is no question but that certain myomata must be removed either by myomectomy or by

the radical removal of the uterus, while there are other cases in which the tumors do not interfere with the course of pregnancy. He was glad one of the essayists had emphasized a preference for myomectomy rather than the removal of the uterus, for the reason that the latter is such a serious procedure in its after effects, etc.

DR. WM. R. PRYOR of New York City expressed himself in favor of conservatism in the treatment of fibroids associated with or complicating pregnancy. If the tumors are situated in the anterior wall of the uterus, and are very small, they would slide up over the pubes without much trouble. Even before the seventh month, while some of these tumors may seem to be an actual bar to delivery, they accommodate themselves by their softness to the situation. Subperitoneal fibroid tumors complicating pregnancy demand operation as a rule.

DR. HENRY D. FRY of Washington, D. C., in referring to Dr. Coe's paper, spoke of emptying the uterus, saying he thought the cases are rare where this procedure is called for. The treatment is either expectant or radical. Those tumors which indicate emptying the uterus are necessarily located in the lower uterine segment, and yet some of these occasionally rise in the pelvis and give very little or no trouble.

DR. WALTER P. MANTON of Detroit, Mich., looked upon cases of fibroid tumors complicating pregnancy as very rare. Personally, he has seen but six such cases out of approximately five or six thousand cases of labor in both private and hospital practice. In the majority of cases of interstitial submucous fibroids, abortion almost inevitably occurs between the third and fifth months.

DR. REUBEN PETERSON of Ann Arbor, Mich., spoke of a case on which he had operated. The tumor was located in the lower uterine segment, and was of the interstitial variety. He did a myomectomy, the woman went on to full term, and was delivered of a child.

DR. GEORGE J. ENGELMANN of Boston had twice seen the disappearance of fibroids following confinement.

The subject was further discussed by DRS. CHARLES M. GREEN of Boston, ARTHUR W. JOHNSTONE of Cincinnati, JAMES CLIFTON EDGAR of New York, and the discussion closed by the writers.

DR. GEORGE H. NOBLE of Atlanta, Ga., read a paper entitled

COMBINED BISECTION OF TUMORS AND UTERUS, WITH ENUCLEATION OF THE FORMER, IN ABDOMINAL HYSTERECTOMY FOR LARGE FIBROID TUMORS.

In case of large fibroid tumors in the body of the uterus, the author recommends bisecting the tumor, bisecting the uterus and then enucleating the bisected tumor. In intraligamentous tumors the uterus should be bisected, the capsule of the tumor brought out from the cavity of the uterus and the tumor enucleated from its capsule.

The advantages of this method are: Saving of time, prevention of hemorrhage, increased working space, easy manipulation, accessibility to the blood supply in the deep pelvis and freedom from liability of injury to the ureters and uterine arteries.

DR. NOBLE then discussed

THE ENUCLEATION OF INTRALIGAMENTOUS AND POSTPERITONEAL FIBROID TUMORS IN THE DEEP PELVIS.

He stated that he had received a reprint from Dr. Pryor, in which he, Pryor, anticipated him in the treatment of intraligamentous tumors or postperitoneal fibroids in the deep pelvis. As the principle is the same, and the difference is merely in technique, the essayist endorses it. Intraligamentous tumors are partially enucleated by penetrating their capsules from the cavity of the uterus after bisecting the organ. They should be turned out with the fingers and morcellation forceps, then drawn up and rotated outward as described. The portion of the tumor attached to the capsule everted the latter as it is drawn out of the abdominal incision, and often to such a surprising extent that it may be included in the ligature placed around the upper border of the broad ligament. In this way the capsule in some cases may be entirely removed, and in others only cut away, and if within the ligature of the pedicle, avoided the necessity of suturing the edges of the capsule. He said that Dr. Pryor did complete enucleation of the tumor and sutured the capsule, while he partially enucleated the tumor, utilizing its attached portion to pull up the capsule, transfix and tie off, in part or entire, with the ligature of the broad ligament.

DR. CHAUNCEY D. PALMER of Cincinnati, Ohio, discussed

THE RELATION AND CORRELATION OF GYNECOLOGICAL AND NERVOUS AFFECTIONS.

He spoke of this relationship from two standpoints: (1) What influence do female pelvic diseases have in the induction of nervous disorders? (2) What affections of the female pelvic organs arise from nervous derangements?

He ruled out any thought of the occurrence of any organic, so-called structural lesions of the nervous system as resulting, unless indirectly and quite remotely, from pelvic diseases. The morbid changes to which reference was made were hysteria, neurasthenia, neuralgia, chorea, epilepsy, hystero-epilepsy, certain paralyses, migraine, convulsions of certain kinds, including tetanus, also mental aberrations and vasomotor changes.

While many hysterical women have no anomaly of the sexual organs, a certain proportion of them have some imperfection in the development of their sexual apparatus, especially the uterus. Hence the justifiability of an oöphorectomy in some such cases. Should the sexual organs be diseased in hysterical women, one could not say that the hysteria was secondary.

Psychical causes are at work, which are more potent than the local disease.

Errors in diet, in general hygiene, in lack of rest and in various indulgences of the mind and body in girlhood lead to physical anomalies and give rise to abnormal mobilities of the nervous system. The functions of ovulation and menstruation play more than the ordinary rôle in the inauguration of nervous phenomena.

The author spoke of cases of insanity having been promptly relieved by gynecological operations. Likewise insanity had immediately followed operations. Such sequelæ were probably more common than after other operations.

In the treatment of women for the special diseases of their sex, there is too much of a tendency to place undue stress on real or supposed lesions of their reproductive organs. This is particularly true in reference to some so-called ovarian affections. Gynecology of to-day would not amount to much without an appropriate surgery, but indiscreet surgery, like over-medication, may be an abuse. Every theory in medicine must be the outgrowth of an extended experience. "Knowledge comes, but wisdom lingers."

(To be continued.)

Recent Literature.

Handatlas der Anatomie des Menschen. Mit Unterstützung von Wilhelm His, bearbeitet von Werner Spalteholz, Professor an der Universität Leipzig. Dritte Band, Zweite Theil. Leipzig: S. Hirzel. 1903.

The second and concluding part of the third volume is at length before us. It is a worthy conclusion of a very excellent work. We have praised the previous parts as they appeared successively and we are glad now to praise the work as a whole. The part just issued deals with the nervous system and the organs of sense. The figures of the brain are very good, and will be welcome to both student and practitioner. There are among them many of Held's more or less diagrammatic figures with distinctive coloring. All parts are satisfactory. We may venture to regret that there is not a representation of an actual section through the eyelid instead of a borrowed diagram. Among the illustrations of the ear is a very ingenious one of the base of the skull seen from above and treated as transparent, while a copy of a cast of the internal ear shows the labyrinth in position. It is impossible to criticise such a work in detail; and it is the less necessary because we can heartily recommend it.

Spectacles and Eyeglasses. By R. J. Phillips, M.D. Third edition, revised, with 52 illustrations. Philadelphia: P. Blakiston's Son & Co. 1902.

This little book of one hundred and nine pages is the third edition of a publication which appeared about ten years ago as the outcome of systematic instruction given by Dr. Phillips to successive classes at the Philadelphia Polyclinic. Its pages are well worth careful consideration by general practitioner and optician, as they contain information of much practical value to both. That which relates to bifocal lenses and prisms has been carefully rewritten. The presswork is of excellent quality, the illustrations frequent and to the point.

Handbook of Climatology. By Dr. Julius Hann, Professor of Cosmical Physics in the University of Vienna and Editor of the *Meteorologische Zeitschrift.* Part I: General Climatology. Translated with the author's permission from the second revised and enlarged German edition, with additional references and notes, by Robert De Courcy Ward, Assistant Professor of Climatology in Harvard University. New York: The Macmillan Company. 1903.

The increasing attention paid of late to the therapeutic use of climatic surroundings has disclosed even in the writings of many excellent clinicians a surprising lack not only of accurate knowledge, but of some of the simpler principles of meteorology and climatology. Mr. Ward, therefore, has done a most welcome service in placing within the reach of the large number of our profession to whom the reading of German works is sufficiently difficult to prevent free study, this standard work of Hann's upon climatology.

The volume itself needs little review. It is without doubt the standard treatise upon the subject at the present time. Its scientific fullness has not lifted it above the level of practical medical use, and many of the sections should be studied hard by those who wish to write of climatic conditions in new health resorts. The comments upon irregular variations of temperature and variability of the monthly means are especially pertinent.

Mr. Ward's additional references to recent literature are numerous and extensive, so that it is a surprise that in Chapter V no reference is made to the numerous phenological data collected and analyzed by Professor Herrera and Dr. Vergara Lope in their volume "La Vie sur les Hauts Plateaux."

Great praise is due Mr. Ward for his work. The translation, in marked contrast to many recent medical books, is into such smooth, clear English that the reader forgets the double authorship and wonders why this or that example is chosen from German or Austrian fields rather than from nearer home; and then, only, recalls that the book is a translation.

The book should be in the library of every physician interested in the subject, and will do much to fulfill the translator's hope and "lead to the extension and improvement of the teaching of scientific climatology in the United States."

THE BOSTON

Medical and Surgical Journal

THURSDAY, OCTOBER 1, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

STOKES-ADAMS DISEASE.

THE subject of the so-called Stokes-Adams disease, which in recent years has excited a very considerable degree of interest, has received renewed attention at the hands of Dr. William Osler, who discusses the whole subject in a recent number of the *Lancet*. In 1895 Dr. Osler referred briefly to the condition in his lectures on angina pectoris, and later, in 1901, Dr. R. T. Edes reported a series of cases and discussed at length the literature of the subject. The condition is now likely to receive a definite place in textbooks of medicine.

Dr. Osler writes a concise and highly satisfactory account of the disease, giving his own very considerable personal experience. He defines the condition commonly known as Stokes-Adams disease as characterized by a profound disturbance in the automatic mechanism of the heart, a true bradycardia; by various nervous symptoms simulating often severe organic disease; and by secondary symptoms, among which may be mentioned Cheyne-Stokes breathing, cardiac asthma and vasomotor accompaniments of heart shock.

The condition which has been naturally much more adequately studied within the last years dates back to Adams' description in 1827, and it is rather remarkable that during the long intervening time relatively little interest has been excited on the subject either on the Continent or in England, although various authors allude to the symptom-complex, among whom may be mentioned Charcot. Dr. Osler discusses the conditions under which slow pulse may be met as physiological, neurotic, toxic and due to cardiac and cardio-vascular lesions, and lays stress upon the fact that Stokes-Adams disease is rather to be regarded as a syndrome than a disease in the proper acceptation of that term.

He finds that the cases may be arranged in three general categories: First, a post-febrile group; secondly, a neurotic group; and thirdly, an arterio-sclerotic group. His own experience has been confined almost wholly to the third group. He has had twelve cases, all in males, most of whom were above fifty years of age, and several above seventy-five. The histories of these cases are appended in systematic form, and serve to show the very great variety in symptomatology in cases which have a certain common resemblance. Vertigo, faintness, cardiac weakness, syncopal attacks, epileptiform attacks, discrepancy between heart and slow pulse rate, pseudo-apoplectic attacks, convulsions, anginal attacks, cardiac dyspnea, loss of consciousness, are some of the symptoms associated always with an extremely slow pulse, which these various cases present. It will be seen that many of these symptoms are on the part of the nervous system, and might most easily lead to grave errors in diagnosis.

Dr. Osler refers particularly to a case of this sort in which he felt confident that the patient was suffering from an apoplectic attack, which subsequently, however, proved to be an attack of syncope without grave significance. It occurs to us that not infrequently the unusual disturbances of consciousness in the form of attacks which are often perhaps rather loosely included under the general heading of epilepsy may find a possible explanation in this too much negelected symptom-complex of which we are speaking. Particularly is this true in the case of elderly persons who, without apparent cause, develop attacks simulating but frequently not identical with a typical epileptic seizure. The same may be said of the not infrequent apoplectiform attacks which one meets with in elderly men.

One lesson at least, therefore, which this careful résumé of Dr. Osler teaches is that we should give renewed attention to the cardio-vascular system in patients developing symptoms such as we have alluded to late in life. The combination of slow pulse with one or another of these nervous symptoms should at least lead to the suspicion of this Stokes-Adams syndrome, or one closely allied to it.

Dr. Osler finds the pathological anatomy of the condition altogether obscure, and, although arteriosclerosis is a very constant accompaniment of

many of the cases, he declines to commit himself as to the fundamental alterations producing the condition. The prognosis on the whole he finds bad, although life may be prolonged for many years with more or less serious periodic attacks. When the severer nervous symptoms have begun, however, there appears to be little prospect of complete relief, and sudden death is the usual outcome. With so uncertain a knowledge of the etiology and pathology of the condition, it is clear that treatment must usually be unavailing. There appears to be no remedy which will accelerate a permanently slow pulse, and the resort must be, particularly in elderly persons, to general hygiene and treatment of symptoms as they arise. In general, we hope that the clinical work which has recently been done upon this apparently important subject will conduce to an increase in our knowledge, and perhaps thereby to a clearer comprehension of the manifold and subtle disorders which attack the individual in his declining years.

THE WATER SUPPLY OF NEW YORK.

The expert commission appointed by the Mayor of New York has just sent in the preliminary report in regard to the water supply of the city, reference to which was recently made in the Journal. The estimate of $50,000,000 is declared by the commission to be sufficient to cover the completion of the necessary dams, reservoirs, aqueducts, tunnels and filters, and to acquire the necessary lands and rights sufficient for a daily supply of upward of 200,000,000 gallons. The summary of work to date has been submitted at the request of the commissioner of water supply, and includes several general conclusions, although the final conclusions on many details must depend upon surveys, estimates, etc., not yet completed. The main conclusion is that, notwithstanding the most favorable anticipations regarding the prevention of waste, the immediate construction of an additional supply is urgent. They find that it is possible to obtain such an adequate additional supply of excellent water from streams lying wholly within the state of New York. It is possible also to secure an additional supply larger than the present Croton and Bronx supply, plus the present Brooklyn supply, and capable of gradual development up to 500,000,000 gallons per day, from the following sources: (*a*) From certain of the eastern tributaries of the Hudson (the names of these are given). (*b*) From a portion of those just named in combination with the head waters of Esopus Creek on the easterly side of the Catskill Mountains. (*c*) By pumping and filtering water taken from the Hudson River, six miles or more above Poughkeepsie; the flow in time of drought to be reinforced from storage reservoirs in the Adirondacks, for the purpose of preventing the upflow of salt water to the intake.

The members are unanimous in a preference for the upland water to that of the Hudson, although the latter may be made pure and palatable by filtration, and should be regarded as in reserve for the more remote future. They recommend that the next aqueduct be built of a capacity of 500,000,000 per twenty-four hours, and also that the city should at once begin the construction of filters, both for the Croton water and for all other waters taken from surface streams. They consider that the surface streams which form so large a part of Brooklyn's present supply should either be filtered (as already in progress), taking the most polluted first, or that the ground water, being naturally filtered, should be taken, so far as practicable, by means of carefully planned wells or intercepting galleries of a design yet to be perfected. It is stated that the one great natural obstacle which limits the date of the early introduction of an additional supply from any and every adequate source within the state of New York is found in the long and deep tunnel which must be constructed for the aqueduct under the mountains and hills north and east of Peekskill. There are also some high dams needed in some of the projects, and it would appear that under the most prompt action, and with the best management, fully five years will be needed before the water of any up-country supply can be delivered in New York.

OPIUM TRADE IN THE PHILIPPINES.

The controversy going on in the Philippines over the bill proposing to place the whole opium trade in the hands of a single concessionaire has waxed so bitter that the whole matter has been indefinitely tabled and a committee appointed to investigate and report upon the results of the use of opium in other Oriental countries, and the methods in vogue in dealing with the opium traffic in those countries. The committee appointed will consist of Major E. C. Carter, Surgeon U. S. Army, the commissioner of health; the Reverend Dr. Brent, bishop of the Protestant Episcopal Church in the Philippines; and Commissioner

Lagarda, representing the Filipinos. The committee is directed to proceed to Japan, Formosa, Hong Kong and China, Burmah, the Straits Settlements and Java, for the purpose of making the necessary investigation, and is given four months in which to render its report. The committee left Manila early in August, and will be absent until the last of November, utilizing the last few weeks of the period allowed to prepare its report.

The Philippine Commission was apparently desirous of selling the opium concession to a syndicate, but this was opposed by a political alliance of the church people, represented by the Evangelical Alliance and the Chinese. The church people opposed the bill because they thought that opium should not be admitted to the islands, and the Chinese objected because they felt that under a concession it would be difficult to obtain an unlimited supply of opium at a price within reach of the humble coolie. The Filipinos, Spaniards, physicians, business men and Catholic clergy apparently took no interest in the matter. The commission desired to sell the concession, so as to realize a reasonable sum for the insular revenues, as opium can be so readily smuggled that probably only a small part of that which enters the islands pays the heavy custom duties demanded. Whatever may be the report of the Committee of Investigation, it is safe to say that the bill is dead and that the unholy alliance of American church people and Asiatic opium smokers — like the banding of the W. C. T. U. and saloonkeepers against the army canteen — will win. The church people can then sit down in the proud consciousness of having won an ethical victory, while the wily Celestial, as he smokes more smuggled opium at a less price and under less restriction, can smile to himself at the easy way the white man can be fooled when he looks at a practical subject through the glasses of sentiment. The fight was not without its amusing features. The would-be concessionaires claimed that opium smoking prolonged life, and was an absolute preventive and cure for most of the ills that flesh is heir to. The Evangelical Alliance made much of a petition presented against the bill by the Chinese Chamber of Commerce, "containing ten thousand Chinese signatures," which on examination proved to consist to a considerable extent of fictitious signatures and bits of Chinese humor. One signature was that of a Chinese general long since dead, and another purported to be that of a monkey famous in Chinese history.

EYESTRAIN.

IN this issue of the JOURNAL we complete the publication of an explanation of the ill-health of Francis Parkman. The author of this entertaining paper, Dr. George M. Gould, has recently come before the profession as an advocate of the important rôle of eyestrain in the production of various nervous disorders and in the consequent modification of character. That Dr. Gould carries his theory to an extreme, no one who has read his paper can for a moment doubt; that he is absolutely sincere in his own convictions is as little open to doubt; and it must also be said that relatively few will be able to follow him to the ultimate conclusions of his theory. Whether he be right or wrong as to the all-important rôle of eyestrain in the modification of character, and the indirect influence on genius, we may certainly admit that he has done distinct service in the attempt to analyze closely, even from the point of view of a somewhat overworked theory, the peculiarities of certain distinguished men. We are so apt to regard exceptional talent or unusual idiosyncrasy as an inevitable consequence of the lives of our ancestors that it is a positive relief to find a writer who is willing to trace with minuteness peculiarities and eccentricities to a rational or at least understandable physical source. Without endorsing Dr. Gould's extremely radical attitude toward the influence of eyestrain, we commend his method as scientific and conducive to a far juster appreciation of the influence of apparently minor events in the development of the man of genius. Anything tangible and definite as a basis of study is preferable to the vagaries and pseudo-science of some of the recent writers on genius.

MEDICAL NOTES.

BRITISH PHYSIQUE. — Owing to the widely-disseminated discussion regarding the physical deterioration of certain classes in England, a committee has been appointed by the Duke of Devonshire to make a preliminary inquiry into the facts. Until such an investigation is made it is certainly premature to draw conclusions.

MEDICAL SCHOOL BUILDINGS AT THE UNIVERSITY OF CHICAGO. — The University of Chicago has recently been negotiating for a large tract of land upon which it is rumored that medical school buildings are to be erected. The nucleus will be the Rush Medical College, supplemented

later by a memorial institute for infectious diseases and possibly by a hospital.

Probable Reappointment of Health Commissioner Reynolds of Chicago. — It seems altogether probable that Arthur R. Reynolds, present Health Commissioner of Chicago, whose energy in matters of health and hygiene has been constant and efficient, will be reappointed to his present office. Should this be the case, he will be publicly vindicated for the course he has pursued in administering his duties, which in the past has not been free at times from aspersions.

Chair of Experimental Pathology and Bacteriology. — It is announced that the Cornell University Medical College has made provision for a chair of experimental pathology and bacteriology, the work to be carried on at the Loomis Laboratory in New York. Dr. Bertram H. Buxton, assisted by Dr. Victor C. Vaughan, Jr., will be in charge of the work of this professorship.

Oral Hygiene in Medical Schools. — At a recent meeting of the National Dental Association it was "Resolved, that it is the sense of the 'National Dental Association' that each medical college in the United States should include in its curriculum a lectureship on 'Oral Hygiene, Prophylaxis and Dental Pathology.'"

The dental profession feels with the introduction of the teaching of oral hygiene in the public schools, which it is striving to accomplish, and the co-operation of medical men who have been specially instructed on this subject, that a great stride will have been made toward the prevention of caries of the teeth, not to mention many other good results to the general system, which would surely follow a better care of the oral cavity.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Sept. 30, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 36, scarlatina 26, typhoid fever 17, measles 20, smallpox 0.

Bequest to Hospital. — By the will of the late Richard W. Foster of Clinton, Mass., the Clinton Hospital Association receives the sum of $10,000.

New Harvard Medical School Buildings. — Work on the group of new buildings for the Harvard Medical School has begun.

Experimental Studies in Nutrition. — It is announced that the War Department will co-operate with Professor Chittenden of the Sheffield Scientific School at New Haven, in a physiological investigation of the minimum quantity of food required to maintain health and strength under ordinary conditions. For the purpose of the experiments twenty volunteers have been detailed from the army, who will live in New Haven during the progress of the investigation. The special object to be attained is a determination of the character of a physiologically economical diet.

A Case of Smallpox in Cambridge, Mass. — A case of smallpox is reported from Cambridge, Mass., the first which has appeared in that city for several months. No fear is entertained of a spread of the disease.

Evening Lectures on Nursing. — A course of training in emergency surgical work and nursing is to be given this winter at the Charlestown, Mass., evening high school. Lectures will also be given in advanced physiology.

NEW YORK.

New Building for St. Mary's Hospital. — The corner stone of the new building of St. Mary's Hospital in Jamaica, Borough of Queens, which when completed will accommodate about three hundred patients, was laid with religious ceremonies on Sept. 20. The present rather contracted quarters of the hospital, which is under the charge of the Little Sisters of the Order of St. Dominic, have proved inadequate for its growing work.

Sale of Hospital Property. — The property of the Memorial Hospital for Women and Children in Brooklyn has been sold at public auction for $96,500, which includes a mortgage of $50,000, and it is understood that the purchaser was the Jewish Hospital Society of Brooklyn, which will occupy the premises for its own work. The Memorial Hospital is one of the best-equipped institutions of its kind in the borough, but the managers were unable to support any longer the burden of the heavy mortgage, on which the holder brought foreclosure proceedings.

Department Store Pharmacy. — Through the serious consequences suffered by a lady who used one of the tablets for a nasal douche, it was recently ascertained that at one of the large New York department stores they were selling for Seiler's tablets, tablets of mercuric bichloride

for making antiseptic solutions. Each tablet had the word "poison" stamped on it, and the intelligent person who had put them in the bottles for sale had evidently "mixed the babies up." The label on the bottle purchased by the lady was marked Seiler's tablets, and contained directions for using these.

GIFT TO AMHERST PHYSICAL EDUCATION DEPARTMENT. — A daughter of the late Charles Pratt of Brooklyn has made a gift to the Department of Physical Education of Amherst College, by which the department is to receive an additional annual income of $1,500. Under the conditions of the gift a graduate of the college, complying with certain requirements, may by a year or more of work in the theory and practice of physical education, fit himself to become a teacher in this branch, while in the meanwhile assisting in the work of the department at Amherst. From members of the same family the college has during the last fifteen years received the present fine gymnasium and athletic field and various other generous gifts, includng the college "health-cottage," which is stated to combine sanitarium facilities with those of a hospital.

Miscellany.

COMPULSORY VACCINATION IN FRANCE.

THE lawmakers of France, after enduring for several years the irritating thrusts which had annually been published by the German health authorities, showing the great advantages enjoyed by the German cities as compared with those of France in the matter of immunity from smallpox, enacted a compulsory law in 1902, which in some of its provisions is preferable to that of Germany. This law became operative in February, 1903. By the terms of the act primary vaccination is required during the first year of life, and revaccination during the eleventh and the twenty-first years. The parents and guardians are held personally responsible for the execution of the provisions of the statute.

The French Academy of Medicine and the Consulting Committee of Public Hygiene were charged with the duty of recommending the methods of procedure for carrying out the provisions of this act.

The following is a digest of the recommendations as now published:[1]

(1) Vaccination to be exclusively performed with bovine lymph. Vaccination direct from the heifer to arm to be preferred in those cities where it is practicable, otherwise with glycerinated pulp.

(2) The preparation of lymph to be in charge of the government.

[1] Revue d'Hygiène, Feb. 20, 1903 p. 109.

Vaccine not to be used when over three months old.

Vaccinating physicians to keep registers, to be used, and all items of importance properly entered at each vaccination.

(3) The vaccinal service to be organized upon a uniform plan throughout the country.

(4) The Academy of Medicine which has for many years performed a worthy voluntary service, to have charge:

(*a*) Of the maintenance of investigations relating to the best vaccinal stocks, and the distribution of the same.

(*b*) Of the improvement of the modes of production, and of vaccination.

(*c*) Of the examination of the vaccine offered for sale.

The academy is to submit an annual report upon the vaccinal service, and upon the number of cases of smallpox occurring in the country.

(5) One or more *seances* are to be held annually in each commune for the purpose of affording gratuitous vaccination. Parents to be required to furnish information as to their children who are subject to vaccination and revaccination under the act.

(6) Vaccinators to be appointed by proper authority. Private physicians may be employed when preferred.

(7) Vaccinations not to be performed in a district where an infectious disease (other than smallpox) is prevailing, or threatens to become epidemic. Subjects for vaccination living in a house in which an infectious disease exists are to be vaccinated separately and not at the regular vaccinal *séance*.

(8) Lists of persons subject to vaccination to be made.

(9) These lists to contain dates and results of vaccination.

(10) Provision made for postponement on account of condition of health of subject.

(11) Investigations to be made when an unusual number of vaccinations prove unsuccessful.

(12) Provision made for repeated vaccinations in case of non-success.

(13) Provision made for inspection of issue of certificates.

(14) The lists of persons subject to vaccination comprise:

For primary vaccinations.— (*a*) All children born in the commune and entered upon the civil registration lists who are between three months and one year old on the day of the *séance*.

(*b*) Infants of the same age, born elsewhere but residing in the commune.

(*c*) Older children who for some reason have escaped vaccination.

(*d*) Those who have been vaccinated without success.

For the first revaccination.— The list comprises all children according to lists furnished by public and private school authorities who are enrolled in the schools and are eleven years old, and those of any ages who have neither submitted to vaccination nor revaccination.

Children who receive instruction at home are embraced in the same conditions.

For the second revaccination.—This list embraces all persons who have attained their twentieth year and are living in the commune.

(15) Provides for the publication of bulletins of information.

(16) Relates to the sanitary condition of the room or hall used for vaccination.

(17) Children to be brought for vaccination and kept afterward in a scrupulously clean condition.

(18) Children to be carefully examined, and their parents questioned as to their health before vaccination is performed.

(19) The operation to be considered a surgical one, and great care taken to avoid infection.

(20) Inspection to be made on the seventh day after vaccination. Provision for exceptions.

(21) Treats of the responsibility of parents, guardians and others.

(22) Reports to be made of vaccinations and of violations of the law.

(23) Foreigners and their children to be subject to the law.

THE MEDICAL PROFESSION IN AUSTRIA.

According to the *British Medical Journal* there appears to be one country in Europe which is not overstocked with doctors, namely, Austria-Hungary; nevertheless our Austrian brethren are not happy. At a congress recently held in Vienna it was stated that 20,000 communes of the Austro-Hungarian Empire, that is to say, 86% of the total number, are too poor to pay for a medical officer, and 30% — or taking Galicia alone 75% — of persons who die are buried without a medical certificate. The number of medical students is also steadily decreasing. Only 32% of the students of the Austrian universities belong to the medical faculty. The total number of medical students this year is 2,120, whereas in 1888–9 it was 5,277, showing a decrease of some 60% in about twelve years. The causes of the growing unpopularity of the medical profession is said to be the legislation which has made assurance against sickness compulsory among the working classes. About one-third of the population of Vienna is now so assured. It is further stated that, owing to the progress of hygiene, the number of cases of sickness has diminished one-half.

Correspondence.

A POSSIBLE USE FOR SPODUMENE IN MEDICAL DIAGNOSIS. — FURTHER PRECAUTIONS IN USING X-LIGHT IN DIAGNOSIS.

Whiteface, N. H., Sept. 28, 1903.

Mr. Editor: Recently there has been found in California a new variety of spodumene, which has been named Kunzite. It has been examined by Dr. Kunz and Professor Baskerville, and found to absorb energy when exposed to x-light, afterward continuing to radiate short ether waves for some minutes. If in a finely divided state, the mineral retains these properties. It will be of use in taking rapid x-light photographs, as the action of the fluorescent light on the photographic plate will continue, thus enabling the exposure to be much shorter than at present. This would be of great advantage, especially in instantaneous x-light photography of the heart.

In former notes attempts were made (by describing experiments on animals) to show that x-light was a dangerous agent, and to discover methods of diminishing the risk to the patient and physician. Some of these methods have already been sufficiently described. In the present note the matter is further considered. As x-light is a dangerous agent it should be allowed only to shine through the tissues under examination. The total amount striking these tissues during a given time should be the smallest which will allow an accurate diagnosis to be made. The time will come when physicians will realize that no examination of the chest is adequate unless the organs are seen by x-light. Then with these examinations advantage must be taken of the time during which a fluorescent screen gives light and of the persistence of vision to reduce the total amount of x-light required to make the diagnosis. The best way to do this is the one already recommended in earlier notes for prolonging the life of the tube used in such examinations — namely, sending the electric current in surges, each of very short duration, producing pulses of x-light that persist as fluorescent light on the screen and in the eyes, thus allowing intervals between the surges, during which, though the light appears continuous to the eye, no x-light is shining on the tissues.

Truly yours,

William Rollins.

RECORD OF MORTALITY

For the Week ending Saturday, Sept. 19, 1903.

Cities.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 2,978; under five years of age, 1,066; principal infectious diseases (smallpox, measles, scarlet fever, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 968, acute lung diseases 218, consumption 329, scarlet fever 18, whooping cough 21, cerebrospinal meningitis 9, smallpox 7, erysipelas 5, measles 7, typhoid fever 84, diarrheal diseases 432, diphtheria and croup 62.

From whooping cough, New York 6, Chicago 4, Philadelphia 6, Baltimore 1, Pittsburg 2, Boston 1, Chelsea 1. From erysipelas, New York 2, Philadelphia 1, Taunton 1, Clinton 1. From smallpox, Chicago 1, Philadelphia 1, Pittsburg 5. From scarlet fever, New York 6, Chicago 1, Philadelphia 6, Baltimore 3, Providence 1, New Bedford 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Sept. 5 the death-rate was 15.7. Deaths reported, 4,548; acute diseases of the respiratory organs (London) 123, whooping cough 61, diphtheria 51, measles 51, smallpox 7, scarlet fever 30.

The death-rate ranged from 3.3 in King's Norton to 25.2 in Middlesbrough; London 14.1, West Ham 14.8, Brighton 15.0, Portsmouth 16.8, Southampton 16.6, Plymouth 13.5, Bristol 12.2, Birmingham 17.8, Leicester 16.8, Nottingham 15.9, Bolton 18.0, Manchester 19.9, Salford 19.6, Bradford 15.6, Leeds 15.5, Hull 24.4, Newcastle-on-Tyne 20.6, Cardiff 14.2, Rhondda 13.9, Liverpool 21.9, Devonport 14.1, Bootle 22.3.

METEOROLOGICAL RECORD.

For the week ending Sept. 19, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING SEPT. 17, 1903.

GLENNAN, A.H., assistant surgeon-general. To proceed to Wilmington, Del., for special temporary duty, upon completion of which to rejoin station. Sept. 11, 1903.

VAUGHAN, G. T., assistant surgeon-general. Granted leave of absence for fifteen days from Sept. 18, 1903.

PECKHAM, C. T., surgeon. Granted leave of absence for one and one-half months, from Sept. 16, 1903.

GREENE, JOSEPH B., passed assistant surgeon. Granted leave of absence for one day, Sept. 16, 1903. Sept. 15, 1903.

VON EZDORF, R. H., passed assistant surgeon. To proceed to New Orleans, La., and wire arrival. To proceed to Laredo, Texas, for special duty. Sept. 16, 1903.

RICHARDSON, T. F., assistant surgeon. Relieved from duty at Tampico, Mexico, and directed to rejoin his station at New Orleans, and inspect en route Linares, Monterey and Victoria, Mexico, and Laredo and Eagle Pass, Texas. Sept. 14, 1903.

RICHARDSON, T. F., assistant surgeon. Bureau order Sept. 14 amended so that Assistant Surgeon Richardson will return direct to Laredo, Texas, and inspect service en route to New Orleans. Sept. 16, 1903.

BEAN, L. C., acting assistant surgeon. Granted leave of absence for four days from Sept. 15. Sept. 15, 1903.

GOLDSBOROUGH, B. W., acting assistant surgeon. Granted three weeks' leave of absence from Sept. 10. Sept. 10, 1903.

MARSH, W. H., acting assistant surgeon. Granted leave of absence for three days from Sept. 18, 1903. Sept. 16, 1903.

SMYTH, F.R., acting assistant surgeon. Granted two weeks' leave of absence from Sept. 10, 1903.

WALKLEY, W. S., acting assistant surgeon. Granted leave of absence Sept. 14 to 18, inclusive. Sept. 11, 1903.

ECHEMENDIA, D. M., acting assistant surgeon. Granted leave of absence for seven days from Aug. 27, 1903, on account of sickness. Sept. 9, 1903.

GOODMAN, F. S., pharmacist first class. Granted leave of absence five days from Sept. 5, 1903, under provisions of paragraph 210, Regulations P. H. and M. H. S.

RICHARDSON, S. W., pharmacist first class. Relieved from duty at Portland, Me., and directed to report at Bureau for temporary duty. Sept. 15, 1903.

MCBRIDE, CHARLES R., pharmacist third class. Relieved from duty at Stapleton, N. Y., and directed to proceed to Manila, P. I., and report to Passed Assistant Surgeon V. G. Heiser, Chief Quarantine Officer, Philippine Islands, for assignment to duty. Sept. 16, 1903.

BIERMAN, C. H., pharmacist third class. Directed to report at bureau for duty. Sept. 12, 1903.

VAN NESS, GEORGE I., pharmacist third class. Directed to proceed from McLean, Ill., to Stapleton, N. Y., and report to medical officer in command for duty and assignment to quarters. Sept. 12, 1903.

BOARDS CONVENED.

Board convened to meet at San Francisco, Cal., Sept. 25, 1903, for purpose of making physical examination of applicant for position in Revenue Cutter Service. Detail for Board: Passed Assistant Surgeon W. G. Stimpson, Chairman; Assistant Surgeon Carl Bemus, Recorder. Sept. 16, 1903.

Board convened to meet in Boston, Mass., Sept. 15, 1903, for the physical examination of First Lieut. George M. Daniels, Revenue Cutter Service. Detail for the Board: Surgeon R. M. Woodward, Chairman; Assistant Surgeon W. C. Rucker, Recorder.

APPOINTMENTS.

Clarence H. Bierman, pharmacist third class.
George I. Van Ness, Jr., pharmacist third class.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING SEPT. 26, 1903.

H. C. CURL, passed assistant surgeon. Detached from the "New York" and ordered to the "Boston."

E. R. STITT, surgeon. Detached from duty as a member and recorder of the Naval and Medical Examining Boards, Washington, D. C., and ordered to resume usual duties.

C. F. STOKES, surgeon. Detached from the Bureau of Medicine and Surgery, Navy Department, and ordered to the Naval Museum of Hygiene and Medical School, Washington, D. C.

A. STUART, assistant surgeon. Ordered to the Naval Hospital, Naval Home, Philadelphia, Pa.

J. L. TAYLOR, acting assistant surgeon. Appointed acting assistant surgeon from Sept. 16, 1903.

F. W. TYREE, acting assistant surgeon. Detached from the Naval Hospital, Port Royal, S. C., and ordered home to wait orders.

J. M. STEELE, surgeon. Ordered to the Naval Hospital, Port Royal, S. C.

SOCIETY NOTICE.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The semi-annual meeting of the society will be held at Hosack Hall, New York Academy of Medicine, 17 West 43d Street, on Oct. 13 and 14, 1903. The first afternoon session will be given to a symposium on the Röntgen Ray. The second afternoon session to a symposium on typhoid fever.

RECENT DEATHS.

GEORGE HAVEN, M.D., M.M.S.S., died in Boston, Sept. 27, 1903.

CALVIN SKINNER, M.D., a well-known physician, and one of the most prominent citizens in the northern part of the state, died at his home in Malone, Franklin County, N. Y., on Sept. 24. He was born in Royalton, Vt., May 29, 1818, and was graduated from the University of Vermont in 1836, and from Dartmouth Medical College in 1840. He was a close personal friend of the late Vice-President William A. Wheeler, and was a delegate to the Chicago Convention that nominated Abraham Lincoln for President. In the Civil War he served as surgeon of the 106th Regiment, New York Volunteers. In 1884 he took a prominent part in the founding of the Northern New York Institution for Deaf Mutes, and for ten years he was a trustee and medical officer of the institution.

BOOKS AND PAMPHLETS RECEIVED.

The Negro Problem from the Physician's Point of View. By W. T. English, A.M., M.D., of Pittsburg, Pa.

Circumcision and Flagellation among the Filipinos. By Lieut. Charles N. Barney, M.D., U. S. N. Reprint. 1903.

Traumatic Pneumonia. By W. T. English, A.M., M.D., of Pittsburg, Pa. Reprint. 1903.

Perichondritis of the Larynx, with Report of a Case. By Emil Mayer, M.D., of New York. Reprint. 1903.

The Cause and Specific Treatment of Hay Fever. By Emil Mayer, M.D., of New York. Reprint. 1903.

A Text-Book of Diseases of Women. By Barton Cooke Hirst, M.D. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

A System of Physiologic Therapeutics, a Practical Exposition of the Methods, other than Drug-giving, useful for the Prevention of Disease and in the Treatment of the Sick. Edited by Solomon Solis Cohen, A.M., M.D. Vol. VIII. Philadelphia: P. Blakiston's Son & Co. 1903.

King's College Hospital Reports; being the Annual Report of King's College Hospital and the Medical Department of King's College. Edited by Norman Dalton, M.D., F.R.C.P.; Albert Carless, M.S., F.R.C.S.; John Phillips, M.A., M.D., F.R.C.P.; W. D. Halliburton, M.D., F.R.S. Vol. VIII (Jan. 1—Dec. 31, 1901). London: Adlard & Son. 1903.

Rational Home Gymnastics. For the "Well" and the "Sick," with Health-points on Walking and Bicycling, and the use of Water and Massage. By Hartvig Nissen. With illustrations of Exercises for Women contributed by Baroness Rose Posse. Revised and Enlarged Edition. Boston: E. H. Bacon & Co. 1903.

Addresses.

MEMORIAL MEETING TO JOHN HOMANS, M.D.

ADDRESSES READ BEFORE THE BOSTON SOCIETY OF MEDICAL IMPROVEMENT, MARCH 30, 1903.

MAURICE H. RICHARDSON, M.D., BOSTON.

Dr. Homans' work in abdominal surgery began with his first ovariotomy in 1872. I had the good fortune to assist, though usually in a subordinate capacity, both at the Carney Hospital and at St. Margaret's. Many of the young men who received at his hands their earliest and best training in abdominal surgery have arrived at middle age in the practice of that great branch of general surgery. In their work at the present time one can detect the deep and lasting impression which Dr. Homans' teaching made upon them. Stimulated by his zeal and emulating his example, they have carried the pursuit of abdominal surgery from the narrow field of ovariotomy to the remotest areas of the abdomen. In all their work they have been aided by their early training more perhaps than they can fully realize, glad as they are to acknowledge their great indebtedness to Dr. Homans. In many respects the methods practiced when they were assistants are carried out to-day.

Take, for example, the operation of ovariotomy. In every respect, save in some minor details, the methods of Dr. Homans are still followed. His teachings as to diagnosis, as to indications for and against operation, as to technical details, after-treatment and prognosis, are as fresh in my mind, through constant application during the past fifteen or twenty years, as when they were spoken. I find myself repeating daily what he said in regard to this or that thing; what he did under certain conditions; what he said as to certain unfavorable symptoms; what made him think one kind of case unfavorable for operation, and another kind favorable; why one should always do this and never do that; why the neglect of a certain detail might be fatal; why he never had repeated a certain apparently promising procedure; why under certain disastrous complications he blamed himself first of all, and why he blamed himself alone.

One remark about the necessity of care in cutting across the uterine canal, lest the peritoneal cavity be dangerously infected, has influenced my technique in hysterectomy up to this very day. The rigid insistence upon the possibilities of contamination from the uterine cavity has, I fully believe, been the means of making the operation of hysterectomy one of practically no mortality.

His belief that ovarian tumors are frequently malignant when apparently benign has been justified time and again by deaths from disseminated abdominal cancer after the removal of a simple ovarian cyst. This disastrous sequel to a brilliantly successful ovariotomy has led me whenever possible to deliver ovarian tumors whole, lest the ovarian contents, possibly malignant, should infect the peritoneum. On the other hand, no matter how evil the tumor might look, he believed an effort should be made to remove it, unless the case was absolutely hopeless; for some of the tumors that are apparently malignant may prove benign, or at least their removal may result in a long period of health before recurrence.

In the through-and-through suture of the abdominal wall, Dr. Homans insisted upon the greatest care in passing the needle, lest there should be hemorrhage from the deep epigastric vessels; and he gave up entirely the cutting needle for the round and smooth. I have never sewed up an abdominal wound without calling to mind this precaution, especially after seeing a death from hemorrhage caused by the cutting of the deep epigastric artery by a glover's needle.

The extraordinary thing about his teaching and example is that as time goes by the wisdom of the former and the soundness of the latter have been demonstrated in hundreds and hundreds of cases. It is fitting, therefore, that those of us who were his assistants should recall some of the things which Dr. Homans, in the intimacy of our relations and in the privacy of his daily work, taught us; and to which, from his failure to recognize the weight and importance of his words, he never gave public utterance.

Dr. Homans' first work in abdominal surgery was confined chiefly to ovarian tumors. The investigation and removal of ovarian tumors naturally led him in certain instances to other tumors of the lower abdomen, through the impossibility of making accurate diagnoses. Questions therefore came before him regarding uterine tumors, tumors of the tubes, of the peritoneum, of the intestine, of the abdominal wall, of the retroperitoneal areas, — in a word, questions regarding all sorts of diseased conditions affecting the lower abdominal viscera. Through accidents of technique, through environment, through extension of ovarian and other diseases, — he was brought gradually to face lesions of great diversity and extent. As each new procedure was understood and mastered, his work began to include all sorts and conditions of disease throughout the abdominal cavity, until he himself realized — what after-comers are taught in the beginning — that he who opens the abdomen for some little, simple thing may suddenly and unexpectedly be confronted by those grave emergencies which tax the knowledge and skill of the most experienced.

Dr. Homans' first ovariotomy, performed in 1872, was fatal; the second, in 1873, the third and fourth, in 1874, and the fifth, in 1875, were all fatal. The first four were all serious and unpromising cases. Of the fifth he said in 1887, "I think I could easily cure a similar one now." The first four were adherent; the fifth was not.

His first successful ovariotomy was performed on Feb. 27, 1877. At this operation he used, for the first time, the carbolic spray. The next four patients recovered. Five consecutive operations, successful under antiseptic con-

ditions, following five consecutive unsuccessful operations performed without antiseptics, naturally made a profound and favorable impression upon Dr. Homans. It is no wonder that this great change was attributed entirely to the carbolic spray, for the cysts in these successful operations were all adherent and most of them multilocular. Indeed, in later years, when the spray was being generally given up, and when aseptic methods were supplanting the antiseptic, Dr. Homans was one of the last to abandon this cumbersome and now worse than useless detail. The regret with which he gave up the spray was characteristic of one who in other things was always faithful to a friend that had served him well.

The cases of ovariotomy rapidly increased in number: in 1878 there were 6; in 1879, 8; in 1880, 26; in 1881, 32; in 1882, 45. As his experience increased, his results became better and better. Up to 1887 there had been a run of 38 consecutive recoveries.

Though the results of operations gradually improve with experience in performing them, that improvement is too generally attributed entirely to increased experience and better technique — the most important factor being forgotten: that the early operations were regarded as justifiable only under urgent conditions. Dr. Homans' experience in the removal of ovarian tumors, as well as in that of uterine, shows the truth of this statement. Of his first seventeen ovariotomies, sixteen were of the adherent variety. What that word *adherent* meant, only those who saw the operations of those days can understand. The tumors were old, large and usually multilocular; they had been the seat of localized inflammations, ruptures, tappings. Their removal meant digging and tearing; escape of contents; a blood-oozing and slimy field; wounds of bladder and intestine — in a word, operations of the most difficult and formidable nature, which it required courage of the highest order to meet, especially after repeated failures. No wonder that the mortality was great; the wonder is rather that recoveries took place at all. The greatest element in the fatalities was the forbidding nature of the lesion itself, with its invariable accompaniment of a constitution enfeebled by long suffering.

So, too, in Dr. Homans' earlier hysterectomies — of which he had, up to 1887, twenty-seven; and of the treatment of which he modestly said, "My success has not been great;" but of which he said further, "I never do the operation unless the patient seems in danger of her life from hemorrhage, mechanical pressure or exhaustion, or else suffers such pain that life is not worth living." And yet of the 27 hysterectomies performed under these unfavorable conditions 17 recovered — 63 %. Twenty-seven hysterectomies at the present time are frequently performed without a death; and yet there may not be, and often is not, a single case among them in which there is either "hemorrhage, mechanical pressure, exhaustion or pain." The pioneers like John Homans led the way along the difficult and dangerous path by which uterine surgery has been brought to the brilliant possibilities of the present day.

The earliest operations of Dr. Homans which I remember seeing were performed at the Carney Hospital. The work was done in a high-studded room in the Chapel building — a room with a southern exposure, well ventilated and clean. Besides an etherizer there were two assistants and one or two Sisters. Sister Mary-Michael, who after operation was in charge of the patient, and in whom Dr. Homans had implicit confidence, was an efficient and faithful nurse. She shared in the enthusiasm of the times. To her untiring devotion in the after-care of his patients Dr. Homans attributed, in no small measure, the success of his earlier efforts.

No preparations of the patient were made until the time of operation, when the skin was washed with 1-20 carbolic acid solution, after the pubic hair had been shaved and the skin thoroughly scrubbed with soap and water. The instruments were immersed in 1-20 carbolic just before the operation. The same solution served for dipping the instruments prior to their use. The field was in a spray of 1-20 carbolic acid, produced by the elaborate and powerful sterilizers of that time. The sea sponges, then used exclusively, had been prepared by two or more days' immersion in 1-1000 corrosive sublimate. They were then kept in 1-20 carbolic until ready for use, when they were dried by being wrung out in an ordinary clothes wringer.

The first assistant stood opposite Dr. Homans; the second at his left hand. The first assistant did the direct assisting; the second, the heavy work of lifting the patient, compressing the abdomen, and the like. The operator stood on the right of the horizontal patient, the Trendelenburg position not being then in use. Incision, grasping of cyst, plunge of trocar, separation of adhesions, delivery of tumor — were rapidly accomplished. In non-adherent tumors the incision was about two inches in length. When necessary, the cut was carried upward; when extending above the umbilicus, it was always to the left of it. The pedicle was grasped with a clamp, — usually called "Mr. Dawson," — and tied with silk in a Staffordshire knot. The silk was passed through the pedicle upon a round needle, grasped by a peculiar holder. The escape of fluid was hastened by the second assistant, who squeezed the lateral and posterior walls of the abdomen. Who can forget the remarks made from time to time during the operation? If things went well they were abundant, cheery, humorous; if ill, not a word of any kind except quick, decisive, imperative words of command; or if the case was unfavorable, the outlook grave, the decision doubtful, the hopeful, "Let us make an effort!"

Before, during and after the operations we were treated to remarks which have proved of the greatest value under numerous similar conditions. How many times I have regretted that I have not followed the common-sense advice of

those days! I would almost say: "As many times as I have failed to follow that advice."

As to diagnosis, he would say: "Never fail to percuss the abdomen; always auscult when the tumor is large; never fail to consider the commonest tumor of women,— pregnancy,— no matter what the social life may have been, provided the patient is of child-bearing age; never tap an ovarian tumor through the abdominal wall; never use an aspirator in abdominal tumors; never fail carefully to examine both externally and internally when the patient is etherized, and before making your incision."

As to operative technique: "Look out for the bladder in making your incision, even if that incision is remote from the usual position of the bladder; be sure not to cut too boldly, lest you go through abdominal wall, tumor and all, or wound the intestine; separate adhesions carefully, lest you tear intestines; look out for ureters, especially if the tumor lies deep in the pelvis; beware of a slipping pedicle; use round needles in closing the abdomen, lest you cut the epigastric artery; be sure you have left no sponges or instruments in the abdominal cavity; do not burn your patient with hot water bottles."

Not long after Dr. Homans' work was well begun at the Carney Hospital, and when patients from all sides were flocking to that institution, he felt compelled to go elsewhere. The time and enthusiasm which Dr. Homans devoted to ovariotomy at the Carney Hospital were transferred to St. Margaret's. The Sisters of St. Margaret in Louisburg Square were asked to extend their charitable work to the care of the sick. Nos. 15 and 17 Louisburg Square were fitted up as a private hospital. Transferred to St. Margaret's, his untiring zeal soon made the name of that hospital known wherever his own was known. Other surgeons were allowed the privilege of treating their patients there; and St. Margaret's soon became the home of private surgery in Boston. The accommodations were gradually enlarged; more houses were transformed into hospitals, until now there are four separate establishments, all sprung from the small beginnings of the early eighties.

Though a private hospital, St. Margaret's received then, and has ever since, many poor patients, either at a very small rate or for nothing. Dr. Homans' enthusiasm for abdominal surgery, before he was appointed to the Massachusetts General Hospital, led him not only to take without fee all patients who could pay their board, but even to take some and pay their board himself!

Early in his abdominal work Dr. Homans was appointed surgeon to out-patients at the Massachusetts General Hospital. Not long after this he entered the house as visiting surgeon. At that time abdominal surgery was looked upon as a specialty. By long-established precedent the introduction of specialties into the hospital was not looked upon with favor. For this reason the introduction of abdominal surgery into a general hospital met with some opposition. It is hard to realize that within twenty years abdominal surgery was regarded at the Massachusetts General Hospital as a specialty — a hospital in which more than one thousand abdominal operations were performed in 1901 and 1,155 in 1902!

I do not know that there was ever any definite rule regarding the introduction of abdominal surgery into the Massachusetts General Hospital. My recollection of what Dr. Homans said at the time is that a friend on the staff advised him not to perform ovariotomies there — or, at least, not to bring abdominal surgery into undue prominence. Be that as it may, abdominal surgery had already gained in the surgical world an impetus before which all conservative objections to its introduction into the hospital vanished. What had been perhaps a branch of special knowledge on the part of Dr. Homans was soon transmitted to his colleagues upon the staff, all of whom, though they had not been his assistants, were quick to profit by his example and teaching in the amphitheater. Within a very few years, abdominal surgery, in regard to the introduction of which into the hospital so many fears had been expressed, was so fully recognized as a most important, if not the most important branch of general surgery, that the Bradley Ward and operating theater were especially constructed for abdominal and cerebral cases.

Though Dr. Homans regarded abdominal surgery as a branch of general surgery, he did much to debar from this dangerous field those whose environment was such that they could never become either skillful or experienced. He realized then, as all surgeons experienced in abdominal work cannot but realize now, that he who opens the abdomen must — by skill, education and experience — be prepared to meet the most formidable complications; and that he who without such qualifications opens it, but too often subjects his patient to unnecessary and formidable risks.

Dr. Homans continued to serve the Massachusetts General Hospital with his customary fire and devotion until he reached the age limit, in 1899. His retirement was the occasion for sincere regret on the part of staff and of trustees.

The words used by Dr. Homans to express himself during the excitement of operating hours clung to the operation of ovariotomy, and even entered into other operations. There were the *snaps* — small spring forceps which were applied to bleeding vessels of the abdominal wall, and which were prevented from slipping into the peritoneal cavity by means of thread and weight. There were the *sweeps* — sponges grasped with long-handled forceps to sweep out the blood from the depths of the pelvis. There were also *Mr. Spencer Wells* (trocar), as well as *Mr. Dawson* (clamp), *half-lengths* and *full-lengths* (hemostatic clamps). The abdominal wound was covered with gauze tightly bound down by a single wide strip of sticking plaster, after being closed by interrupted through-and-through sutures of

silk, *double-headers*, introduced from within, a separate needle for each side, the silk being threaded at each end. The abdominal dressing was tightly applied by means of a single long and broad swathe.

An early realization of the danger of leaving sponges and instruments in the abdominal cavity led to great precautions to prevent this disaster. Many methods were used. In the beginning it was the sole duty of a nurse to keep an account of all the sponges that were put in and all that were taken out — tally being kept of each act. Later, long tapes were used, with a weight attached; and, finally, the sponges were counted, both before and after the operation. Even this method was not absolutely safe; for mistakes might occur in counting, either before or after the operation. No greater disquietude could be caused than by the report of a missing sponge. Even after the abdomen had been closed, Dr. Homans would re-open at once if a sponge was unaccounted for. It was, of course, absolutely essential that the initial count be correct, and that no sponge be taken from the room. Dr. Homans found, as many of us have since under similar conditions, that the greatest danger of leaving sponges in the abdominal cavity existed when the count was correct. When a sponge was missed, and when after the most careful search it could not be found, it was pretty certain that the error was in the counting or in unnoticed abstraction from the room. In one instance the missing sponge was concealed in one of the numerous sacs of a multilocular cyst; in another it was found later in the day stuck on the bottom of an assistant's boot! Dr. Homans' insistence and extreme care against leaving sponges in the peritoneal cavity made a great impression upon me; and I have followed absolutely his methods in this respect.

Another point about which he was very insistent was the security of the ligature and precautions against its slipping. The pedicle was tightly compressed by the clamp; and in this sulcus a strong silk ligature was tightly drawn by means of the Staffordshire knot. The pedicle was then severed with the Paquelin cautery, which gave additional security against hemorrhage.

With reference to the diagnosis of ovarian tumors, or tumors simulating them, I recall many remarks of his, the truth of which I have had ample means of testing. Rapidly growing tumors are always indicative of malignancy; so, too, bloody serum. Malignancy is indicated by solid masses lying below the abdominal wall in an abdomen distended with fluid, — in which the tumor presents features the opposite of uterine balottement, — the finger receiving the impression of descending through fluid upon a submerged solid.

The prognosis after operation was illustrated by many examples which have been to me, in after years, the source of hope under distressing anxiety — as well as a source of anxiety in apparently hopeful conditions. Of the latter, I remember Dr. Homans' grave anxieties when vomiting was continuous and persistent, even if other signs were favorable; on the other hand, the insignificance of temperature and pulse, in his opinion, when abdominal conditions were favorable and there was no vomiting.

The results of Dr. Homans' operations constantly improved with increasing experience. Some of his early cases were extraordinary, even for those days. In two cases, both successful, the tumor weighed over a hundred pounds; in several the patients were of advanced years.

The disasters which occasionally occurred he attributed to faults of his own, when he could find them. Of 248 ovariotomies, performed up to 1887, 34 were fatal. Of these "about one-quarter, probably, are to be attributed to some error or carelessness of mine." Other fatalities were beyond his knowledge or his power of prevention. Whenever a death was owing to any preventable cause, that fact was always emphasized, both to his assistants privately and in his publications. In studying the latter, one is impressed by his unqualified self-condemnation. It is the single quality of unswerving love of the truth that has given Dr. Homans' words their impressive weight.

Another quality strongly emphasized in his conduct of abdominal cases was that of common sense. His diagnosis, treatment and prognosis were illustrative of this rare attribute. It led him to a proper estimation of the weight to be given to symptoms, to a wise selection of methods of operation and of after-care and to an accurate prognostication of coming events.

His skill in diagnosis of abdominal tumors was unrivalled in this community. Left to himself, without advice or prejudice, his early conception of a case was almost invariably accurate; and yet he was, he maintained, easily thrown off the track by the suggestions of others.

During the performance of operations he insisted that there should be no suggestions from any one. He had his operation planned beforehand, "often waking in the night and arranging in his mind its details;" and he objected to off-hand remarks which might interfere with his prearranged plans. Many of his followers, to the present day, sympathize fully with him in this respect. They learned from him how and when to hold their tongues. Not that Dr. Homans wished us to remain silent if some serious error of technique was imminent — quite the contrary. He wished, as we all do, to be warned if he was evidently mistaking an important for an unimportant structure. It was the interference with a plan well thought out by himself, — the interference made upon the spur of the moment by one who before that instant had given the matter no thought at all, — it was this kind of a suggestion that he objected to; and all operators will agree that he was right.

Dr. Homans was always pleased and encouraged by a long series of recoveries; and yet he would say when everything was going well, "A man must not be too much set up by an unbroken

series of successes. The first he knows, he will meet with one or two disasters which will make him think that he is not such an extraordinary fellow after all!"

Time does not permit me to mention, even briefly, the many reminiscences which Dr. Homans' name suggests. They are all interesting and all valuable. I find hardly a topic connected with abdominal surgery which some act or saying of his does not serve aptly to illustrate. Valuable as his later contributions have been to surgery, it is his earlier work — during the ten years following 1877 — which contributed most effectively to the wonderful advancement of abdominal surgery.

A. T. CABOT, M.D., BOSTON.

My close acquaintance with Dr. Homans began soon after my return from Europe in 1877. He asked me to act as his assistant in a case of ovariotomy, [1] and I worked with him in this capacity in something like one hundred operations.

One cannot stand opposite an operator and follow, as an assistant must, his every move in as many abdominal operations as that without getting a pretty clear insight into the workings of the operator's mind. Thus I came to know Dr. John Homans, the surgeon. His most striking and characteristic quality was his courage. This he showed not only by light-heartedly undertaking difficult feats of surgery, but also much more by the persistent pluck with which he put through a seemingly hopeless task in which he had met unexpected difficulties. One was constantly reminded of his training in the army, for he approached a surgical operation as if he were going into battle. He made his dispositions carefully beforehand, and then went ahead with no idea of retreat or failure.

In those early days of abdominal surgery when the proper technique was being learned by hard experience, the unforeseen was constantly happening, and the determination "to fight it out on that line if it took all summer" was a heroic trait, most valuable to a surgeon. This Dr. Homans possessed in fullest degree.

Another quality that he had —not so generally known, perhaps—was the spirit of investigation—the desire to learn the truth. Some of you may not know that for many years Dr. Homans interested himself in pathology, he made many autopsies, and, while not specially trained as a pathologist, he sought to learn all he could by his examinations. After he devoted himself to surgery, this investigating habit did not leave him. If a patient of his died, he insisted on knowing why, and was happy if he learned any fault in technique that he could rectify. It was this fearlessness in facing unfortunate results that enabled him to constantly improve his methods. I have often heard him say after a hard operation, "Well, we have done our best," and with that consciousness he was always ready to examine that best to see if he could not make it better.

[1] Dr. Homans' first successful laparotomy.

The man who is cheerful in the midst of difficulties gets better work on that account, both out of himself and out of those who are helping him. Dr. Homans' unfailing fund of humor often came to the rescue of an unfortunate or difficult situation. Every one who worked with him will remember some of his amusing sayings: "Hullo, what's that? Let's cut it and find out." The action followed the word, and the dissection proceeded after perhaps tying the vessel that had been divided. Thus jokingly, but always earnestly and with good sense and good judgment, he put through an enormous amount of surgical work and gained that experience which made him constantly a better and better surgeon.

His interest in his patient did not cease with the operation. He attended to the after care with untiring watchfulness and energy. In his zeal for having things efficiently done, he attended with great care to the details of the nursing of his patients. One visiting the private hospital at No. 15 Louisburg Square in the morning hours would often find him in his shirt sleeves hoisting a patient on the Crosby bed while the sheets were changed, or otherwise assisting in some delicate or laborious nursing maneuvre.

He once said to me that the best way to get patients was to take good care of those you had. He certainly carried out this plan faithfully, and achieved great success.

Such are some of the impressions of Dr. Homans gleaned beside the operating table. Another place where one saw a delightful side of his character was at the dining table. Here his charming *bonhomie*, assisted by a wit and humor that were all his own, made him the best of good company. That table was never dull at which he sat. His tales of men and things were good-humored, and always amusing. I am sorry for any of you who never heard him tell his army and navy experiences. Even if you had heard the tale before, it was sure to have some new turn of humor that made it fresh. One could read between the lines of his stories, and see how the same qualities with which I became acquainted in his surgery stood by him in the army, and made him a jovial comrade, always ready for fun or work.

I have dwelt at some length upon the two qualities which seemed to me to do the most for his surgical success. Another most marked quality was his energy, which went straight to its object, and was so much a part of him that it seemed perfectly natural for him to take a poor patient with ovarian tumor out of bed and take her in his own buggy to the Carney Hospital where he could operate upon her.

His frankness and outspokenness seemed to be almost beyond his control. If he could find any reason for criticism of one of his operations, he was the first to tell it to the patient. This transparent honesty was so winning a trait that it strengthened greatly the hold he had on his people. Such is the recollection I shall always keep of John Homans: courageous, a seeker after truth, squarely facing the situation, whatever it

was, and doing his best in it; constantly examining his works and frankly criticising himself when he could see possibility of correction; thus steadily advancing, cheerily, brightening every occasion and working steadily to the end.

GEORGE B. SHATTUCK, M.D., BOSTON.

Dr. Homans had begun an autobiography, but had only carried it through the first part of his army service. It is written in a simple, straightforward, humorous style, characteristic of the man. I am permitted to make some extracts from it which I feel sure will appeal to those who knew him and serve to give others an idea of his individuality.

He mentions having performed an autopsy about the year 1860, when in the medical school, on the body of a lady who died from the growth and enormous enlargement of two ovarian tumors. She had suffered terribly from pressure and dropsy for several years, and he was then impressed with the feeling that the death might have been avoided, and certainly the suffering might have been mitigated. It was this autopsy, he says, which turned his attention to ovariotomy; but the breaking out of the war put an end to all such thoughts for four years, and later the prejudices of the profession and the reluctance of women to submit to an operation the success of which had not been demonstrated postponed any action on his part many years longer.

Whilst still a house officer in the Massachusetts Hospital, in 1861 he passed the examinations for the medical service of the U. S. Navy, choosing this branch of the service "because he had been fond of yachting." He was ordered to join the *Aroostook* in February, 1862, and served on this vessel for six months. The extracts from Dr. Homans' autobiography here submitted begin at the time when he resigned from the navy to enter the army.

I had been much impressed by the care and method of the naval service, but a confinement on a small ship for six months, with no professional interests and with absolutely no surgery, had become very irksome and almost unendurable. I went to the Douglas Hospital, which was in charge of my friend Warren Webster, U. S. A. Surgeon Webster was a relation of Daniel Webster, the great orator and statesman, and was a very able man. In the Harvard Medical School he was one of two men, as I recalled, who could enumerate all the muscles of the back, with their origins and insertions. At the Douglas Hospital I was at home again, with a ward full of patients under my care and all the surgery that I could well handle. I remember doing an excision of the shoulder, an operation I had never seen done, and the result was very good.

The thought of going back to the *Aroostook* and being shut up again became more and more abhorrent and unendurable, and I determined to try hard to get my resignation accepted in the navy and to enter the regular army. In order to effect my purpose, I was directed by somebody to call on Mrs. Douglas, the widow of Senator Douglas of Illinois, and also on the family of Mr. Riggs, the banker. I think whoever advised me was putting up a joke on me. However, I called and spent an evening with Mr. Riggs and his daughters. I had never seen them before, had no letter of introduction and what they thought of me I do not know, but I would have gone through fire and water to get my resignation accepted, and certainly an evening spent with these agreeable young ladies was not a hardship.

I think I also called on Mrs. Douglas. She was a fine-looking, middle-aged woman of great ability and influence. I then pleaded with Assistant Secretary Fox to accept my resignation. I told him that I did not want to go home, I wanted to serve in the field with the army, where I should have some scope for my surgical abilities, and I finally said: "If it was your own son, would you not allow him to resign if he was going to enter the army at once?" My resignation was accepted, and I went at once before the Army Medical Board in Philadelphia. Surgeon Asch was president of the board, I think. I was in pretty poor shape as to health and strength. I had had chronic diarrhea for some months, and I required nearly a teaspoonful of laudanum in the morning to keep me going all day, and I had but little appetite.

The examination was very fair, except that in one instance the examiner did not know the answer to his own question. Dr. Asch asked me what the urine of serpents and birds was composed of. I told him "uric acid." He said it was urea. I told him that I had analyzed these secretions from serpents many times and that the urine was composed of uric acid, but he said I was mistaken. I replied that there could be no question about a matter of fact. I hope this was not set down against me. At this examination I formed the acquaintance of Dr. C. C. Lee, who entered the service at the same time, and our friendship lasted till his death in New York. He became one of the surgeons to the Woman's Hospital in New York.

I went home about the first of October, 1862, awaiting news in regard to the verdict of the medical board. I was taken with jaundice, and was in bed for some weeks. Dr. James Jackson attended me, and applied eighteen leeches along the border of my right costal cartilages. Whether it was the effect of the leeches or whether it was coincident with their application I know not, but the bile began to run within forty-eight hours and I was soon well, although weak. I received my appointment from Mr. Lincoln as an assistant surgeon in the U. S. Army (regular), and my orders to join the remainder of the Banks Expedition and to report for orders to Brig.-Gen. George L. Andrews at New York.

Here I was assigned to the duty of inspecting army transports and reporting upon how many troops could properly be carried on each vessel. I found that the U. S. immigrant inspection required that each immigrant should be allowed

one thousand square feet of air, consequently I measured the ships and reported the number of soldiers I thought could be taken on this plan. I found that where I recommended the transportation of about two hundred and fifty men the authorities had decided to take twelve hundred and fifty, and so it was throughout the fleet. I also suggested that if there was a fatal fire on a vessel there would not be boats enough to hold one-third of the number of soldiers, but I was told that the soldiers would have to be burned or drowned, for the government would never get the troops to the scene of action if my plans were followed. This last remark I thought very true and reasonable, and that some risk must be run if we were to transport large bodies of troops.

At length everything being ready, the expedition sailed. I went in the steamship *Illinois*, on board of which was the 49th Mass. Vol. Infantry, commanded by Col. Frank Bartlett, who had lost his leg in the trenches before Yorktown while an officer in the 20th Mass. Gen. George L. Andrews, commanding the whole of the "Remainder of the Banks Expedition," was also on board. I remember little about the voyage, except that the steamer had oscillating cylinder engines and had formerly been on the line between New York and the Isthmus, also that Bartlett used to keep our hearts in our mouths by walking up and down the deck unassisted when the ship was rolling. We had to lay off the bar at the mouth of the Mississippi because the water was low. I should say we remained several days, perhaps a week. When the water is high in the river, it is low on the bar, because the high water and swift current bring down great quantities of mud and sand, and pile it up on the bar.

The authorities had asked me in New York what would be the consequences of crowding the ships as they were doing, and I had answered: "The probable prevalence on the ships of ship-fever and dysentery;" and this proved to be the case, and many cases of these diseases were left at quarantine. On arriving at New Orleans, about the 10th of February, 1863, I reported at Major-General Banks' headquarters, and was assigned by Surgeon Richard H. Alexander, medical director, to the St. James Hospital. This was formerly the St. James Hotel, and was on Magazine Street. Surgeon William R. Brownell was in charge of the hospital, which contained about three hundred and fifty beds.

My duties at the St. James Hospital were very congenial. I had several wards under my care. The cases were mostly affections of the bowels or chills and fever, or malaria in some form, with debility, homesickness and feebleness from age, the sufferers having understated their age when enlisting. Almost all the members of a Rhode Island battery that came to the hospital were over sixty.

Sometime in the spring of 1863, Dr. Brownell was ordered to his regiment in the field and I was placed in charge of the hospital. I remember that Dr. J. V. C. Smith, formerly mayor of Boston, came to the hospital as a contract surgeon and an agent of the Christian Commission; he was quiet and attended to his duties; he did not practice surgery, but turned those cases over to me. There was not much surgery, as there was not much fighting until the two assaults on the works at Port Hudson on the 27th of May and the 14th of June. The wounded were mostly sent to Baton Rouge. I got a short leave of absence from my hospital and went to the army at Port Hudson. I went to General Auger's headquarters and was very kindly received by his staff, among whom were Major Cutting and others. They gave me a hammock to sleep in and took me into their mess. On the 27th of May a general assault was made on the rebel works. It was intended to be simultaneous, but it was not. Some of the troops assaulted at the early hour agreed upon and other assaulted later. They were beaten in detail. The colored troops assaulted, I was told, as well as the others, but all were repulsed, one after another. I was called by Dr. Winsor, surgeon of the 49th Mass. Infantry, to see Col. Frank Bartlett. As I have already mentioned, the colonel had suffered amputation of his right leg, I think, above the knee, at Yorktown in the late spring of 1862. He was the only mounted officer, I believe, in the assault. He could not walk over the felled trees and other obstructions with his artificial leg, and so he rode and jumped his pony. He was shot in the ankle and through the left wrist. He begged me to amputate the hand, but I declined and told him that I thought he would save his hand. When he insisted, I told him he must get some one else to amputate, as I would not. I attended him for a few days in Baton Rouge and wanted to take him to New Orleans with me, but I was not allowed to. Before I left him he said, "Now I shall lose my arm near the shoulder." I told him I did not think so.

I saw him again in the winter of 1865–66 in Rome, Italy. I inquired how his wrist was. He said it was first rate — "I drove a four-in-hand with it this morning." In Frank Palfrey's life of Bartlett it is said that the general's arm would have been amputated if the surgeon had not been too drunk to operate. This must have been after I left him at Baton Rouge. I think such stories are generally untrue, and I hope this one is. I remember seeing a surgeon trying to tie the common carotid going in behind the sterno-mastoid. I watched him for some time, but he had not found it when I left. I remember a soldier wounded in the vertex of the skull. He followed me round all day, pointing down at the top of his head with his forefinger. I found on examination that he had an abscess in the brain, and that the bullet was probably in his skull. I passed a knife into the brain and opened a large abscess, but did not find the bullet. I presume that he died, but as I left for New Orleans the next day, I did not learn his subsequent fate.

At New Orleans I found that a few wounded had arrived at the St. James Hospital during my absence, among others, Captain Russell of the 38th Mass. Infantry, who had been shot through the right leg, the bullet splintering the tibia at a

point about six inches below the knee. The wound was suppurating freely and the captain wanted the leg amputated, but I persuaded him to be patient, and he subsequently recovered perfectly, with a good limb. He subsequently entered the regular service after the war, and served till about 1898 or 99, when he was retired, more than thirty years after he was wounded.

Among other incidents, I remember that among several wounded Confederate prisoners was one boy of fifteen who had lost his leg. In a few days his mother came to see me and asked if I could employ her in any capacity without any pay so that she could be near her boy. She was very gentle and sensible, and very different from most of the Confederate women I had seen. I employed her as a nurse in the ward where her boy was lying, and she was one of the best nurses I had, and did her duty to the Yankee soldiers readily and with good sense and sympathy. The men all liked her, and when the boy had wholly recovered I gave him and her a pass and advised them to go out of the hospital and not to return. They were very grateful, and I never saw them again.

I remember I also had a visit one day from a lady who had the Confederate rosette in her bonnet: a red, white and red rose. She said that I had one of her servants who was working in the hospital. I asked her the woman's name and she said it was Rose. Now Rose was a mulatto woman and waited on my table, and one day she showed me her back, which was marked with pigment lines, the result of whipping with a lash; it was the only back of any one I ever saw who had been whipped. This lady asked me if I would give her her servant, and I replied, "Certainly." So I called Rose and asked her if she would return to her former mistress, and she replied with decision that she would not. The lady asked if I was not going to send a guard of soldiers to take Rose to her house. I told her, "No," that the soldiers were not here for that purpose, but that Rose could go if she pleased. The lady said of course she would not go unless she were made to, and she flounced out of my office in great indignation.

This lady came in again some time later and asked me if I would allow her to send some blankets to the rebel officers who were prisoners and who were confined in the custom house. I was at that time detailed, in addition to my other duties, to attend sick and wounded Confederate prisoners. She sent the blankets to the prison, and a few days later I saw them in the form of a long rope, made by tearing them in strips and tying them together. The officers descended at night by means of the rope to the ground, and were received in the arms of the guards, who had learned of the projected effort at escape. When the lady next called to see me, I asked her to go to the custom house to see her blankets. She said she never would have sent the blankets if she had supposed they would tear them up. I presume that the plan of escape was arranged with her, but of course I never knew.

I also learnt, while in charge of the St. James Hospital, the power of starvation as a taming and humbling process. Under Captain Beaumont on the *Aroostook*, the discipline of the ship was carried on by Lieutenant Spencer, the first lieutenant. His plan was to gag and trice up a refractory sailor. This was done by tying a wooden gag in his mouth, then tying his hands, which had been handcuffed behind his back, to a sufficiently long piece of rope. The end of this rope was then thrown over a boom and drawn tight until the prisoner stood on his tiptoes. The strain was great and the punishment was very severe. Another means of bringing the culprit to a proper state of mind was to shut him up in the coal bunker, or in the "brig." The latter was a closet with lattice work in the upper half of the door. The closet was just deep enough to receive the man standing up, but he could not lie down when the door was shut. Here he was imprisoned as long as was thought necessary to bring him to a proper state of mind. For my part I could not see that these punishments did any particular good, and the same men were punished over and over again. There were only a few bad fellows in the ship; many of the men were from Aroostook County, Me., who had seen the ship built and who had helped build her and had enlisted from patriotic motives.

When Captain Franklin relieved Captain Beaumont, he put a stop to these punishments and devised another. He had a part of the quarterdeck partitioned off by handspikes and canvas, and in this space the prisoner was shut up and fed on a few biscuits a day. I observed that this plan worked excellently. One Sunday evening I came home and was informed that two of the patients had been allowed to go out into the city and had returned very drunk, noisy and obstreperous. I told them to go with the sergeant-at-arms to the guard room, but they swore that they would cut my heart out and do all sorts of things. However, I got them shut up in the guard room and told the sergeant to give them three biscuits a day. The next morning I went to see them and told them to clean up the room. No, they wouldn't do it, they would see me damned first, etc. They said they wanted more food. I told them that when they had cleaned the room to my satisfaction, I would consider the question of food, but that for the present they could only have three biscuits a day.

On Wednesday they sent me word that the room was clean, but I told the sergeant that I would not go up till Saturday. On Saturday the room was as clean as a pin, you could have eaten off the floor anywhere, both the men were on their knees trying to kiss my hands, and they promised that they would behave perfectly and be civil and respectful. They were sailors, and I soon sent them to their ship.

I had watched another middle-aged man, who had been hobbling about the hospital, bent over and leaning on a stick, for about three months. He said he had the rheumatism in his back and that he could not stand up straight or do any duty. It seemed to me that the man had better

be cured and returned to duty, or discharged. There was no reason why the government should be paying for a man who was of no use. One morning I sent for the sergeant of the guard and told him to send me a strong, sensible man, who could use some judgment in a case for which I should detail him. He sent me a tall Yankee belonging to a New Hampshire regiment.

I instructed the man to take the afflicted one on to the veranda, to take away his stick and to order him to walk up and down the veranda — if he stopped to prod him with his bayonet. I explained to the patient that I was anxious for his good and wanted to see if I could not cure him. He agreed that it was a sensible plan. In about ten minutes the soldier reported that the patient was walking on the veranda, but was sweating profusely and seemed quite tired. I said, "Let him up for a few minutes and then keep him going according to your judgment till dinner time, and then take him out again an hour or so after dinner." In the afternoon the soldier and the patient reported. The sick man was walking perfectly well and the next day was returned to his regiment. I thought if the man was malingering he would soon repeat the process and get into another hospital. In the autumn of 1864, while surgeon-in-chief of the first division of the 19th Army Corps in the Shenandoah Valley in Virginia, I was hailed by a man on a mule, driving an army wagon. "God bless your honor, I hope you are well." "Very well," said I, "and who are you?" "I am the man you cured of rheumatism in New Orleans, God bless you."

Another case was a man who walked with two crutches and said he could not walk without them. I studied him for a long time and then ordered him sent to the convalescent camp and to walk all the way; it was about three miles. I sent two guards with him: one carried the crutches and I told them to give the man the crutches if they thought he could not get along without them, but to start him on the road without them, even if they had to carry him. They started, each of the men supporting one shoulder more or less. After about half a mile the man asked what the doctor had said about the crutches. "He said you were not to have them." "Very well," said the man, "then I will walk along;" and he walked perfectly well to the camp.

Another case was that of a boy who used to be seized with intense pain in his stomach quite frequently. Any doctor who saw him in one of these attacks would rush to the dispensary and get a dose of morphine and give it to him. Having had success with other cases, I thought I would try and cure this one. So I told him that the next time he had an attack it would be necessary to do an operation on him. He did not have an attack for some time. When he did, I got out my largest knives and made preparations before him for an operation, and told him that we could not give him ether or chloroform on account of the nature of the operation. He was much frightened and promised to go to his regiment and behave right for the future.

The Charity Hospital, the large public city hospital of New Orleans, was at that time presided over by Dr. Smith, who at this time tied the innominate artery for a subclavian aneurism. I saw the case. Dr. Smith ingeniously stopped a secondary hemorrhage by pouring shot into the wound. The man, a negro, recovered. Now there were certain taxes levied for the support of the hospital. One was a charge for nightly performances at the theaters and other places of amusement; another was a tax of five dollars on every bale of cotton exported. Cotton was then a dollar and ninety cents a pound, so that a bale of cotton was worth nearly a thousand dollars. I was directed by Gen. J. J. Reynolds, of the regular army, in command of the city of New Orleans, to find out where these moneys went. I started on my investigation and reported to General Reynolds that it seemed to me that some persons of high rank and prominence might be involved, and he told me that he was not likely to be supported in his action and that I had better cease my investigations. I ought to have said that what started General Reynolds in his inquiry was the fact that rations were being issued to the Charity Hospital for all the patients as if they were soldiers, and this seemed unnecessary if the taxes on the theaters and cotton had been honestly handed over to the hospital.

E. H. BRADFORD, M.D., BOSTON.

Sound traditions are of inestimable value to all communities and institutions in their gifts of dignity and stability, and it would appear that the medical profession of New England has reaped an especial benefit from the bequests of her strong medical families.

Dr. Holmes called to our notice the fact that for one hundred and fifty years there was a Dr. John Clarke, father and son, ready to administer to the medical needs of the community in its earliest days. The portrait of the original John Clarke in the hall of our library shows him a man of good sense. He was apparently skilled in the use of the formidable surgical implement at his hand. Rumor says that besides being a good physician he was a good judge and a breeder of horseflesh, probably a valuable accomplishment for the doctors of the time. From that time until now there have been a number of prominent families in our New England communities engaged in the practice of medicine, furnishing to each generation a man of mark. The names of many are almost household words among us — Warren, Jeffries, Holyoke, Jackson, Bigelow, Ware, Shattuck, Cheever, Bowditch. In equal rank among them stands the name of Homans, with, as was the case with some, the added dignity of what seems now a medical patent of nobility, a surgeon's commission in the army of the Revolution, signed by the commanding general, George Washington.

Why it is that the profession of medicine rather than of law or theology was transmitted in this way is perhaps an evidence of the stronger inter-

est of our calling among its votaries. It would have been thought that in early New England the hierarchy of the clergy would have been kept in families. It is for the student of history to explain this permanence of medical families, which have survived not merely in names to be respected, but in each generation a position of prominence has been won in our profession through an apparent inherited aptitude.

That there were three of the Homans family practicing medicine at the same time in Boston with success is a demonstration of the medical vitality of the family. To the youngest, Dr. John Homans, 2d, whose recent death cut off too soon a career of great usefulness, we owe in large measure our new medical library building. His father, Dr. Charles Homans, seemed (to one whose service as a colleague with him on the staff of the City Hospital was a great pleasure) a surgeon of unusual good sense, a practitioner of unfailing judgment and a rare gentleman. Dr. John Homans, the younger brother of Dr. Charles, was the last to die; he had inherited his father's name and added to its ancestral value, making it well known among surgeons throughout the land. It is a cause of gratification that the chain has not been broken and that in the rising generation there remains a young John Homans with a promise of professional achievement.

It is often said that it is difficult to measure exactly the worth of a man. The Napoleonic test, "What has he done?" is a practical one, but hardly just. A man's aims, his early attempts, his failures and how he bears them all are of value for the estimate of the height of his aspirations, the breadth of his scope, the depth of his convictions. A junior colleague on a surgical staff often has an opportunity to judge of his senior's worth more fairly than his patients or the general community. At the Carney Hospital at the beginning of his career of surgical prominence, Dr. John Homans showed to his juniors unusual characteristics. He was not a surgeon of the anatomical type who knew his anatomy with precision and was hampered or emboldened by the exactness of his knowledge; he was not a surgical student who was familiar with surgical literature or statistics; he lacked the judicial calmness of judgment of his brother. He was a man of a strong personality and energy, and possessed one of the traits which, as Emerson says, helps to make greatness — he reminded us of no one else; his mind was an original one and he followed his own lead. He had as a most valuable possession the splendid heart of a boy, which loves venture, is ready for an opportunity, enjoys achievement, meets defeat not only with serenity but with gayety, and is eager for another chance. He enjoyed large responsibilities; he liked surgery as the most attractive of endeavors, the most magnificent of games — the sport of splendid attempts. A true New Englander, he was a thorough self-critic, but this sharpened and never dulled his efforts.

With all the spirit of the adventurer, which was pronounced in him, he possessed a strong vein of conservatism. He was not a seeker after new things. He was slow in the acceptance of antisepsis in surgery and was slow in giving up the idea of the necessity of carbolic spray after he had adopted it. He was, in fact, with all his lack of conventionality, imbued to a degree with the spirit of what Dr. Holmes calls the New England Brahmin, who measures men and events by the standards which have met the approval of generations of worthies with lives centered about the Hub of the Universe, the dome of the Boston State House.

It was owing to this conservatism no less than his spirit of almost reckless venture that Dr. John Homans was able to accomplish in this community what he did. Time has done honor to the bold efforts of the pioneers in abdominal surgery and their successes, but it has laid the gentle hand of oblivion on the failures of that time, the ghastly failures of many of the early and injudicious followers in the movement. If the truth were told it would not seem strange that the conservative surgeons of the pre-antiseptic days hesitated in giving their sanction of approval to the rashness which was usually death dealing.

Owing to his conservative traditions, Dr. John Homans was not cast out among the outer barbarians in surgery, who injured their calling by their recklessness, and who seemed to the calmer members of the profession surgical buccaneers without skilled training, but armed with rash audacity, licensed thugs cajoling the public and boasting of their few successes, oblivious of their many failures. It is fortunate that this feature of surgical practice is now forgotten, only a few remembering its menace to the credit of our profession. It is to the lasting credit of Dr. John Homans, that while he was foremost in the movement which advanced surgery, he avoided this rash excess of operative zeal, and learned and taught the lesson of careful preparation and thoughtful undertaking.

Surgery was at that time in transition. Dr. Homans was brought up in a school which regarded a surgical procedure as a personal feat; the surgeon like a toreador matched his courage, energy and dexterity in an event. It was largely an attempt of the amphitheater in the mind of the surgeon, even if the spectators were few.

Dr. Homans lived to see surgery developed into a science of careful painstaking, often wearisome to the spectators, rarely spectacular, as beneficial as it is laborious.

Before Dr. Homans' time there were with us no professional surgeons. In our community there were general practitioners, who attended to surgery with skill and success, but they often gained their livelihood chiefly as general practitioners. Some even prided themselves on their reputation as family practitioners who avoided the narrowness of specialism. Dr. Homans himself for many years practiced general medicine until the public and his reputation forced him to make his practice purely surgical. It is largely through his efforts and to his example that our community has been led to demand special skill

in surgery, and to now give its support to so many surgeons of admirable skill.

Sir Frederick Treves in a recent address said that he regarded a community as fortunate where there was an unusual surgeon, but that that community was even more fortunate which contained a large number of well-trained and skillful surgeons.

It may be said to be in a degree to Dr. John Homans that Boston owes its great good surgical fortune.

ROBERT T. EDES, M.D., BOSTON.

I was invited to say something about Homans in the navy, but although we were indeed both in that branch of the service at the same time, one was in the Gulf and Mississippi, the other on the Atlantic coast, so that my acquaintance with him both before and after that time was a much more intimate one, and it is of this that I am very greatly obliged to you for giving me the opportunity to speak.

As medical students Homans and I were together a good deal, in anatomical study, both human and comparative, and in chemistry, at both of which subjects he worked with the zeal that characterized him throughout life. His quaint and shrewd remarks dwell in the recollection of his old companions.

It has been remarked by one of the gentlemen who preceded me that he was not a trained pathologist. Perhaps not in the present methods of training, — no one was, — but he was eager to grasp all the training there was to be had in those days, seizing every opportunity for autopsies and working diligently with the microscope. Dr. J. B. S. Jackson, the professor (in those days there were very few professors of pathological anatomy) was not indeed a lover of the microscope, but of what could be seen without it little escaped his eye, and there was no more enthusiastic teacher. Calvin Ellis was the volunteer leader as to anything approaching modern pathology, and of him Homans was a favorite pupil. We visited Spectacle Island and got specimens of anchylosed bones and intestinal calculi, which I dare say are still in the museum. When the Civil War began, the four internes of the Massachusetts General Hospital all entered the navy, prompted by what special inclination I do not know.

One of these four, " Billy " Gibson, a particular friend of Homans, died in the service, of yellow fever. The other two, Dr. Clarke, still in the navy, and Dr. Park of Groton, survive. The next I saw of him was in New Orleans, where I was with the vessels under my charge in the river, meeting him at the St. Charles Hotel, just after his arrival, and several times later; on one occasion making the rounds with him at his hospital, where it was pleasant to see the patients brighten under his cheerful address and humorous remarks. I heard that he had left the navy, for reasons very obvious to one who knew his vigor and ambition and who was aware of the tedium of attending a hundred healthy men; and that he had gone through the regular army examination, of which I heard several funny stories, of how he did not hesitate to express his independent opinions, although knowing that they were not likely to be officially acceptable.

One of these, but I cannot say whether he told me himself or whether it came more indirectly, was to the effect that when he was asked whether he would not, under certain conditions, shave the patient's head and paint it with nitric acid, replied, with characteristic independence and promptness, " By no means."

There seemed to me to be some connection between this story and a favorite expression of his in regard to a certain professor of very mild demeanor, " You might pour nitric acid on his head and he wouldn't say anything."

Later, to my great pleasure, I received a short visit from him, accompanied by the younger brother of a distinguished military family, on my vessel up the Red River, where he accompanied General Banks' army and did great service at Pleasant Hill. Of his army service, however, I knew nothing, except in this incidental way. Our acquaintance was renewed after the war was over, just before I left the service, by a visit at the Chelsea Hospital from him, accompanied by his nephew, then a small boy, but later the distinguished John Homans, 2d. As a consequence of this visit, we sailed for Hamburg in August, and with no very long delay reached Vienna, where we got to work as rapidly as possible.

There were there many Americans, some of whom, like ourselves, had been in the service, and who wanted either to carry on their general or special studies further, or who wished to supplement army practice by instruction in branches, such as obstetrics and gynecology, where the clinical instruction was in our colleges at that time practically *nil*.

Surgery, singularly enough, attracted neither of us much in Vienna. From the little I took occasion to observe I should suppose Homans, and perhaps many others, might have taught the Austrian surgeons at least as much as they would have learned. Such instruction as he obtained in that department of surgery in which he afterwards became so eminent, which was then in its early infancy, if not actually in embryo, he must have got later.

During these few months that we were together taking courses in various specialties, — obstetrical diagnosis clinically, with a few perfunctory lectures on gynecology under Meyerhofer; or pathology with Scheuthauer, with an occasional glance from the eye of the great Rokitansky; or Störck, the laryngologist, who had just risen to eminence by his treatment of a well-known singer, to whom he had restored not merely his normal voice, but a much superior first tenor; enlivened by excursions and visits on the Sundays and holidays, too numerous to suit our thirst for instruction, — Homans always displayed the same zeal for his profession, the

same determination to know all that would make him practically useful, and above all, the same independence of thought, the same utter candor and frankness, and yet all this without thinking of himself in the least as having arrived at the end or completeness of development.

Once he said to me, "I suppose by the time I get to be a pretty good doctor, I shall die." Fortunately not true, for so far as my less intimate acquaintance of later years would enable me to judge, the same absolute honesty distinguished him for long years beyond the time when he had become a "pretty good doctor," and when he was just as quick to confess the errors of judgment which may come to the wisest.

THE OPERATIVE TREATMENT OF UMBILICAL HERNIA.

BY J. COLLINS WARREN, M.D., BOSTON.

UMBILICAL hernia is an affection to which a distinct class of individuals is liable. It is seen often in infancy and childhood, but the surgeon is rarely consulted for such cases, at least in private practice, for care and the use of a suitable belt usually suffices to keep the hernia within the abdominal cavity until, with the growth of the child, the opening in the abdominal wall disappears and a cure is effected.

FIG. 1. — Lipomatosis dolorosa and hernia.

The typical case which comes under the surgeon's care is that of a woman in middle or advanced life, of corpulent habit and the mother of a large family. The etiology of this form of hernia appears to consist partly in changes occurring in the abdominal wall during pregnancy, after which the parietes are left in a more or less relaxed condition, and partly in the accumulation of adipose tissue external to the true abdominal wall. The force of gravity and the pressure of clothing — notably the corset — gradually produce a pendulous fold which, in extreme cases, results in an apronlike mass of integument, which covers the genitals. This is always well marked in cases of diffuse lipomatosis, and is well shown in Fig. I (Case XIII), a male, in whom we have a double fold, the second covering completely the genitalia. The umbilicus is composed of cicatricial tissue, uniting the skin of the abdominal wall to the peritoneum and the fetal remains, which have become intimately associated with it. As the adipose tissue accumulates, this cicatricial tissue is placed upon the stretch and drags a funnel-shaped fold of peritoneum through the true abdominal wall. In this way the old congenital tract is gradually re-opened and dilated, and forms the ring of the hernial tumor, which is now found in the upper part of the pendulous fold of adipose tissue. The contents of the hernia are in the early stages invariably omentum. This readily becomes adherent, and at each adherent point the lobule of omentum forms a pouch for itself, so that in large and old hernias the sac is honeycombed with pouches containing separate lobes of the omentum. When the hernia is well developed, it is liable to occasional inflammation, and the adhesions of the omentum become partly intra-abdominal. This gives rise to frequent attacks of pain radiating over the abdominal cavity and causing more or less invalidism. An escape of a knuckle of intestine may give rise to sharper attacks of colicky pain, or even to strangulation (Case XII). In a case seen by me with the late Dr. Foster of Charlestown many years ago, there was gangrene of over twelve inches of intestine, with spontaneous recovery.

Although the mother of the present Princess of Wales was said to have died of a strangulated umbilical hernia, wealthy patients as a rule get along fairly well with a suitable truss; but, inasmuch as the affection prevails chiefly among elderly and obese subjects, it is only by the aid of skilled assistance that an apparatus can be adjusted so as to guarantee a fair degree of security (Case XIV). Patients are thus able to lead a much more comfortable existence, but the danger of a strangulation is always present.

Modern experience shows that obesity and even the glycosuria which frequently accompanies it is not a contraindication to operation, and improvement of surgical technique is always bringing about better results.

This form of hernia has generally been considered by surgeons as more liable to relapse than inguinal or femoral hernia, and with truth; but the percentage of recurrences is constantly growing smaller. This does not seem to me to be due to the invention of new methods of closing the neck of the sac, as has been the object of many recently described operations, but rather to attention to an accurate suture of the different layers in a manner that will bring them into close contact without too much tension.

The hernial sac should be exposed by two slightly curved incisions on the median line, which should meet and blend above and below into an incision sufficiently long to expose the outer walls of the sac as far as the neck of the sac and the surrounding aponeurosis. The sac should then be opened and the contents freed from adhesions and returned into the abdominal cavity. If the omentum is much matted together it had better be excised at a point below the portion which usually occupies the sac. The sac itself should then be carefully excised, care being taken to secure such vessels as may be divided. The shape of the opening in the abdominal wall is now obvious, and is found to represent an oval with the long diameter lying at right angles to the linea alba.

The peritoneum should, if possible, be separated from the fascia and sutured with fine sutures. The edges of the hernial ring consist of the tendinous raphé formed by the blending of the aponeuroses of the abdominal muscles. The accurate coaptation of these edges is of the greatest importance. The anatomical closure of this opening would apparently be effected by bringing the right and left edges together, but this cannot be done without great tension in the center of the line of suture, making a wound with depressed and tense center and raised and relaxed ends. The vertical diameter of this opening is always the shorter of the two, and if the lower and upper margins of the ring are brought together by forceps they can easily be held in that position without exercise of any appreciable degree of force. The parts seem to fall naturally together if the opening is closed transversely. Indeed, lateral strain closes this opening in the linea alba, while vertical strain tends to open it. The material used for suturing the peritoneum is fine silk (No. 8). It is not necessary to select the finest grades, such as are used for intestinal sutures, for this purpose. A No. 12 silk is the size used for suturing the aponeurosis. Enough tissue of this layer should be taken up to hold the suture securely and prevent retraction of the edges of the ring. It does not seem to me necessary to use quilted or other complicated forms of suture, or to expose the edges of the recti muscles (except in the rare cases of wide separation of the recti muscles) in order to obtain a perfect union. In an aseptic wound attention to the points mentioned above is sufficient. The adipose layer and outer integuments should be trimmed with the knife so as to fall easily into apposition. This involves excision of the umbilicus and a certain amount of skin on either side. The adipose layer is then caught together by several medium silk sutures, and the skin is united by silkworm gut.

A new feature in the surgical treatment of these cases is the excision of the thick layer of adipose tissue. This is thickest in the "double-chin"-like fold already referred to, but it covers the abdominal walls from the epigastrium to the pubes, and is sometimes several inches in thick-

FIG. III. — Case IX before operation — front view.

ness on the median line, tapering off to normal dimension on a line erected from the anterior-superior spinous process. To remove this layer the median incision should be extended through the skin and subcutaneous adipose tissue from a point about two inches below the ensiform cartilage to the transverse fold defining the upper limit of the mons Veneris. The skin with the adipose layer still attached is then dissected away from the aponeurosis of the abdominal muscles by long sweeps of the knife until the integuments have been freed as far as the loins. In doing this many vessels of considerable size

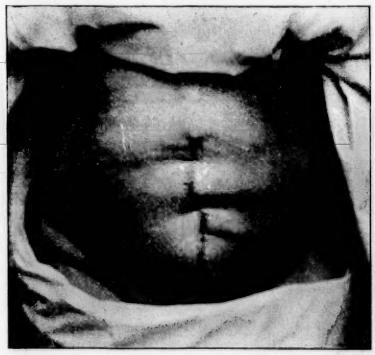

FIG. IV. — Case IX after operation for umbilical hernia and removal of abdominal fat — front view.

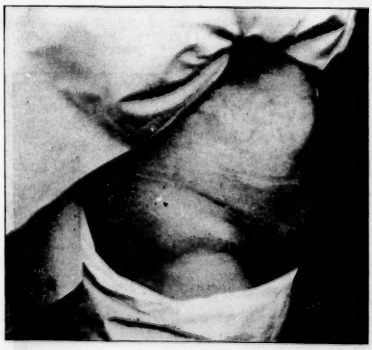

FIG. V. — Case IX after removal of adipose layer — side view.

are divided, but are easily secured. After both sides have been freed in this way, each half of the adipose layer can be removed from the skin with a long-bladed knife. After hemorrhage has been arrested the skin should be attached to the aponeurosis by two or three catgut sutures to prevent dead spaces, and the edges of the skin should be united in the usual way with silkworm gut. The cicatrix is at first unusually long for an abdominal scar, but, being superficial, contracts considerably with time. This method of obliterating the "double-chin" fold seems more effective than the employment of a long transverse or crescentic-shaped incision, by which the fold itself might be excised. Such an incision would, however, leave a scar at a point likely to cause irritation, as it would come directly at the point of constriction of the clothing.

I have tried this operation in two cases (Cases VIII and IX) with very satisfactory results. There was no shock from the operation nor was the convalescence in any way delayed by the extensive dissection of the flaps.

The following cases are taken partly from hospital and partly from private practice, and represent fairly well the type one has to deal with surgically:

CASE I. A. R., forty-six years old; married; very obese, but an active and strong woman, doing general housework. Was operated upon for the recurrence of an umbilical hernia, which was originally the size of an adult head with numerous pouches and adhesions. The dissection had been so prolonged at the first operation that the sac was not entirely removed, and recurrence had taken place eighteen months later. The second operation was performed December, 1890, and consisted in careful dissection and removal of the sac, and suture of the peritoneum as a separate layer. The aponeurosis was sutured transversely with silk stitches. In spite of some fat necrosis in the edges of the wound, good union was obtained, and there has been no recurrence. She was examined by me in 1900, and result proved to be perfect. The patient wears an abdominal belt, and is in active work.

Writing April, 1903, patient states: "I have had no return of the rupture. I am as well and free from any pain as though I was never in that condition."

CASE II. Harry U., fourteen months old, was sent to hospital November, 1894, with a congenital umbilical hernia the size of a walnut. The sac was dissected out, the peritoneum sewed with silk, and the aponeurosis brought together transversely with silk stitches. The vertical skin incision was united with silkworm gut. Examined by me in March, 1900, and the result found to be perfect. No truss.

CASE III. Mrs. R. J. R., forty-five years old; has had eight children and is very fat. Entered hospital November, 1897, with an umbilical hernia the size of a baby's head. It was operated upon in the same manner as above stated. The external wound was brought together in λ-shape. It healed by first intention. The patient reported eighteen months later a relapse, but preferred to get along with a truss instead of undergoing another operation.

CASE IV. Mrs. L. F., thirty-eight years old; five children. Entered the hospital November, 1897, with an umbilical hernia the size of a fist, produced after a fall down a bulkhead. The ring at time of operation admitted three fingers. The sac was excised and the wound sewed in separate layers — fine silk being used for the peritoneum and braided silk for the aponeurosis. The skin was united by silkworm gut. The wound healed by first intention. The patient has since worn an abdominal belt, and the result when examined in January, 1903, was found to be perfect.

CASE V. Mrs. M. C., sixty-seven years old; very fat, has five children; had been suffering for eight years with an umbilical hernia. Although she had worn a truss, the hernia was enlarging. At present the size of walnut. The operation was performed in December, 1898. A longitudinal incision opened the sac. Adherent omentum was excised, and the sac also. The material used in stitching the different layers was silk. Union by first intention. The patient was seen in March, 1900, when there had been no return of the hernia. Writing April, 1903, patient states that the operation was entirely successful, and she has had no trouble since.

Case VI. J. G., thirty-nine years old; a very obese Jewess, with five children, entered the Hospital October, 1900. The hernia had existed for eleven years at the time of entrance, the size of a cocoanut. It was reducible. After opening the sac the omentum which it contained was excised and silk sutures were used in the usual manner, the aponeurosis being brought together transversely. The wound united by first intention. In April, 1903, the patient was reported as having no recurrence of the hernia. She wears no belt.

Case VII. Mrs. Bridget W., twenty-eight years, medium-sized woman, with five children. In this case the hernia was about the size of a small apple. The patient also had a floating kidney, but preferred to have the hernia relieved first. The usual operation was performed November, 1902, and the wound healed by first intention. No reply was received to a letter of inquiry recently sent.

Case VIII. Mrs. C., fifty-one years of age. Operation Jan. 10, 1903. Has but one child, twenty-one years of age. Patient's weight is 209 pounds. Has an umbilical hernia about size of small orange which has existed for six years, but has never been strangulated.

Patient was particularly anxious to have the fat removed from her abdomen. The abdomen is pendulous, and the adipose tissue forms a deep fold below the umbilicus. An incision about nine inches in length was made in the median line, and the sac was carefully dissected out. An opening was then made in it, and the omentum being found adherent to several pouches in the sac could not be reduced. It was accordingly tied and excised. The peritoneum and the edges of the ring were united horizontally by separate rows of silk sutures. The skin and subcutaneous fat were now dissected off from the fascia of the rectus and the external oblique as far as the loins on either side. The hemorrhage (which was slight) was controlled by the ligature of several large vessels emerging from the aponeurosis. The adipose tissue was next dissected away from the skin on each side by large sweeps of the knife, and was removed in a large wedge-shaped mass. The skin was caught down firmly upon the aponeurosis by buried catgut sutures on either side, and the median incision was closed with silkworm gut suture. The wound healed throughout by first intention, and the patient left the hospital on Feb. 2. In August, 1903, she writes that her "health is good, no return of rupture; the abdominal fat is about the same as before operation."

Case IX. Mrs. S. A. J., age forty, was sent to me at the hospital by Dr. George Francis. Patient is a large and stout woman, and has had three children, nine years, four and a half years and fourteen months old. There is a large amount of fat in the abdominal wall, forming a pendulous mass below the umbilicus, where a hernia about size of an orange exists.[1] The hernia was first noticed six months ago after stepping out of a bath; three weeks ago began to be troubled with sharp pain in the umbilical region. There had been a slight swelling at this point ever since the birth of last child. The hernia can be easily reduced, and the ring admits the forefinger.

Operation Jan. 13, 1903. An incision was made on the median line about ten inches in length, with the umbilicus at its center. The sac was first carefully dissected out from the surrounding tissues without opening it. The sac was then opened and the omentum returned into the abdominal cavity and the sac excised. Silk sutures were taken in the cut edges of the peritoneum and the edges of the ring were brought together transversely by braided silk sutures. The skin and subcutaneous adipose tissue were now dissected away from the abdominal parietes, exposing the aponeurosis for about ten inches on either side. In this way the thick layer of adipose tissue which constitutes the fatty layer of the abdominal wall was separated from its attachments. After arresting bleeding from several arterial branches which emerged from the aponeurosis, the adipose tissue was carefully sliced off from the skin on either side. In this way two wedge-shaped masses of fat were removed, each measuring about three and a half inches in thickness and six inches in width. Their combined weight was about two pounds. After thoroughly arresting all hemorrhage the skin was caught down upon the aponeurosis on either side by two buried catgut sutures to prevent the existence of a dead space. The median incision was then brought together by silkworm gut sutures, some of them being deep enough to catch the underlying aponeurosis and hold the skin firmly in apposition with it.

The wound healed throughout by first intention, and the patient, eight months later, expressed much satisfaction with the result of the operation. There was no return of the rupture and no increase in the abdominal fat, since leaving the hospital.

Case X. Mrs. H., sixty-five years of age, was referred to me by Dr. George Francis in December, 1900. Her weight was 325 pounds. She has had five children. Has suffered from umbilical hernia since her last confinement. The hernia is about the size of a fist. Although it has not been strangulated, it has often been the seat of severe attacks of pain. Owing to great weight of patient it was decided to operate upon the bed upon which she was to lie after the operation. An incision four inches long laid open the sac. A mass of adherent omentum was tied off in sections with silk. The ring was large enough to admit the tips of three fingers. The sac was dissected out. The peritoneum was united with fine "intestinal" silk sutures. The edges of the ring were brought together transversely with silk sutures. The subcutaneous fat was also caught together with fine silk sutures so as to leave no dead spaces. The skin was stitched with silkworm gut.

In October, 1903, her nurse reports a perfect result (in spite of recent fall down stairs) — patient has derived much benefit from operation.

Case XI. Mrs. C., sixty-five years of age; weighs about 250 pounds; two children; was referred to me by Dr. E. G. Cutler. The hernia is of long standing and is about the size of an orange. It has never been strangulated. Was operated upon in March, 1901. A mass of omentum which was found adherent was tied off and excised. The application of sutures was the same as in Case X. Some skin was excised in this case, including the umbilicus. Union by first intention. In October, 1903, patient reports the scar to be perfect. No recurrence of the hernia. Wears an abdominal supporter.

Case XII. Mr. B., sixty-six years of age; weight 260 pounds; was referred to me by Dr. E. G. Cutler for an incarcerated umbilical hernia. There was pain and vomiting, and the hernia had been irreducible for twenty-four hours. It was reduced by taxis without ether, and held in place by adhesive straps. The operation for radical cure was performed a few days later, as the hernia (which for several years had been under control) now came down on getting out of bed and could not be reduced by the patient. The umbilicus was included between two slightly curved incisions, and its skin (which was excoriated and could not be thoroughly disinfected) was removed. The omentum was found adherent and covered with fresh exudation, and a portion which could not be returned easily was tied off and removed. Silk was used for the different layers as in previous cases. Owing to skin infection from abrasions the wound did not heal by first intention, and most of the buried sutures came away. The healing of the wound was, however, firm, and there was no hernia. About six months later, in March, owing to an attack of bronchitis, there was a slight recurrence of hernia, which, however, was held easily by an abdominal belt.

Case XIII. This case is introduced to illustrate the typical condition of lipomatosis associated with this form of hernia. The patient is a male, aged fifty-nine; a janitor by occupation. I was called to see him by Dr. F. G. Hersey for an acute pain in the left loin, emanating from a large subcutaneous tumor, probably lipoma (lipomatosis dolorosa?).[2] Owing to the existence of a skin affection no operation was advised. The fold of abdominal skin is double in this case — a second and smaller fold lying between the usual one and the mons Veneris, and entirely concealing the genitalia. The attack of pain was of a few days' duration, and its cause purely traumatic.

Case XIV. Mrs. F. In 1891 I reduced an umbilical hernia and fitted the patient, who was a very stout woman of fifty-eight, to an abdominal supporter. The rupture had existed twenty-two years, appearing at the time of her first confinement. By the constant attention of a

[1] Figs. II and III.

[2] Trans. Col. Phys., vol. xxiv, p. 17.

skilled attendant, a large share of whose time is devoted to the adjustment of the belt and care of the skin, the patient has suffered little pain or inconvenience from the hernia during the last twelve years.

Summarizing the data furnished by the above cases, we find two in which no operation has been performed. The contraindications in Case XIII were the presence of a chronic skin affection combined with lipomatosis and diabetes. In Case XIV the careful adjustment of a truss, advised many years ago (when the modern technique was not what it is now), has enabled the patient, aided by a skilled attendant, to overcome the tendency to strangulation which had previously existed. This case furnishes an example of one whose surroundings enables her to get along without an operation with a fair degree of safety.

Case XII, being a case of operation following closely upon a reduction of a strangulated hernia, furnished conditions unfavorable to strict asepsis, and recurrence in this case may therefore be ascribed to sepsis rather than the method adopted.

There remain eleven cases operated upon by the method advised in this paper. In only one of these cases has a recurrence been reported during periods varying from one to thirteen years.

In the case in which a recurrence took place the hernia was as large as a child's head.

This gives a record of about 9% of recurrence after operation — a record, which although it does not quite equal the very satisfactory results of operation for inguinal and femoral hernia, shows that this method of operating for umbilical hernia bids fair in time to rival them.

VESICO-INTESTINAL FISTULA.

BY JOSHUA C. HUBBARD, M.D., BOSTON.

Assistant in Surgery, Harvard Medical School; Third Assistant Visiting Surgeon, Boston City Hospital; Assistant Surgeon to Out-Patients, Free Hospital for Women.

A. B., fifty-four years of age, married, cigar-maker, entered the Boston City Hospital, June 29, 1902. The previous history was unimportant except that he had never had any venereal disease. The present trouble began about three months previous to entrance, and had the following symptoms: distress and belching of gas after meals, cramps in the stomach occuring four or five times a day and lasting three or four minutes, occasional nausea and a constant sour taste in his mouth, attacks of dizziness two or three times a week. There was no edema, palpitation or shortness of breath, and no cough. Bowels constipated. Has the desire for a movement, but unable to get a satisfactory one. For the last few days troubled by the sudden stoppage in the flow of urine while micturating. Has pain before and after passing water. Nervous. Loss of strength and weight.

Physical examination. — Both pulse and temperature were slightly elevated. The examination was negative except for the urine. Urine analysis: neutral reaction, specific gravity 1,016, slight trace of albumen, no sugar. Sediment, few small caudate and small round cells, some fatty. Few large round cells. Considerable blood, normal and abnormal. Much pus, free and in clumps. Few squamous cells and at a later examination much mucus.

During his stay in the hospital it was noted that he complained of pain, most marked about and below the umbilicus and at times in the perineum. Micturition was at more frequent intervals than normal. A sample of urine drawn by catheter was cloudy and contained small masses of thick material. The patient was then discharged at his own request.

He entered the hospital again Jan. 28, 1903. The history of his condition since he left the hosptial was as follows: Last July had an attack of pain referred from the hypogastrium to the tip of the penis. Could not retain urine. Micturition caused a burning pain, and what seemed to be pus was passed. During the following December had an attack of sharp, cutting pain in the left lumbar region, shooting down toward the bladder. The attack was so severe that the patient was doubled up by the pain. Passed a stone of about the size of the end of the index finger. Since then the pain has continued unchanged. The stream of urine shuts off suddenly at times. Pain at the tip of the penis. Passes no blood, but a thick greenish-yellow urine which at times takes the form of casts. Has six or seven stools a day and the material passed looks like that which comes from the bladder.

The urine anyalsis was essentially the same as at the first examination. Examination with the fluoroscope was negative. Cystoscopic examination under ether was as follows: Motor power fair. No blood in washings. Bladder wall uniformly dark red in color (congestion with exudate), with pieces of mucous adherent. Rugæ not distinct. Trigone fairly distinct. Both ureteral orifices normal in size and functioning. Just inside left ureter and about 1 cm. above it is a circular spot about 1 cm. in diameter which is yellowish-white in color. Edges clearly defined and but little if any below the bladder surface. Posterior bar about 1.5 cm. Prostate outline normal. No growths or foreign bodies in bladder. Bladder wall about normal thickness.

Treated with daily irrigations of the bladder, and discharged improved to the Out-Patient Department, where the bladder washing was continued. The condition of the bladder became worse, and the patient was sent back into the hospital for a suprapubic cystotomy for drainage.

He was admitted to the service of Dr. Bolles, who kindly allowed me to operate. On March 30 the bladder was opened above the pubes.

Ether. — Bladder filled with boracic acid solution. Incision made in the median line. As bladder did not dilate well the peritoneum was accidentally opened but immediately closed with a suture. More solution was then injected into the bladder,which was opened between stay sutures. Mucous membrane of the bladder sutured to the muscles of the abdominal incision. Catheter fastened in the suprapubic opening, which was closed tightly about it.

Immediately after the operation feces began to come out of the suprapubic opening. On April 5 under ether the scrotum and surrounding areas were incised, because of the extravasation of urine and feces, under the skin, around the suprapubic opening. The rectum was examined at this opportunity under ether,but no fistulous opening was seen. During the next few days attempts were made to locate the position of the fistula. Methylene blue was injected into the rectum and almost immediately found in the bladder, while methylene blue injected into the bladder did not appear in the rectum.

The patient was slowly and steadily losing ground and was suffering severe pain from the irritation of the feces in the bladder. An immediate attempt to close the fistula was decided on. Inasmuch as the intestinal opening could not be seen in the rectum, it was thought best to first do an exploratory laparotomy to determine the site of the fistula. If it was then found to be too low down to reach comfortably through the abdomen the plan was to turn the patient over on his face and reach the fistula from below by turning back a bone flap from the sacrum.

Ether.— April 13. Suprapubic opening closed temporarily by continuous silk suture. Incision made through the left rectus, the lower end of this cut being on a level with the upper end of the suprapubic incision. The omentum was found adherent to the bladder. Adhesions broken up. Omentum very much thickened and indurated along its attachment to the bladder. Sigmoid found adherent to the upper part of the bladder about two inches from where it was adherent to the abdominal wall at the suprapubic opening. Adhesions between bladder and sigmoid broken up. Small hole found in the sigmoid with everted edges. Corresponding hole in the bladder about the size of a lead pencil. Purse-string suture of catgut around the opening

in the bowel. As this was tied the mucous membrane was inverted. Peritoneum then drawn as well as possible over this by intestinal silk suture. This was found rather difficult, as the stitches tore easily out. Hole in the bladder closed in a similar way by a purse-string suture, with the peritoneum then pulled over it. Wicks were left to separate the bladder and intestine, and the abdominal incision partially closed. To prevent the foul discharge from the suprapubic opening in the bladder from reaching the abdominal wound, oiled silk was sewed to the skin to separate the two dressings. Drainage of the bladder by catheter through the penis was unsatisfactory, so the suprapubic catheter was put in place. Instead of bringing it directly up from the opening in the bladder, it was carried through one of the sinuses made at the time of the urinary extravasation, so that it came out well down in the groin, and the skin at the suprapubic opening was drawn together over the catheter by adhesive plaster to minimize the leakage.

Immediately after the operation the patient developed a post-operative delirium which could not be controlled by drugs. Four days after operation the wicks were changed and a little fecal matter was noticed on them The delirium allowed him almost no rest at all, and gradully wore his strength out so that on April 19 he died. At this time there was a fecal fistula at the site of the abdominal incision, but the opening in the bladder had apparently remained closed.

Résumé of the case. — This, then, was a case of vesico-intestinal fistula without evidences of carcinoma or tuberculosis of the inflammatory type, with a stone of apparently secondary origin. The fistula was situated so high in the bladder that fluid would not pass readily from the bladder into the intestine, but freely the other way. The adhesions between the bladder and the intestine prevented a satisfactory dilatation of the bladder. The cystoscopic examination was misleading.

The first reference to a fistulous opening between the bladder and a portion of the intestine has been found in a report by Praxagorus. Since his time to 1900 Pascal[1] was able to collect accounts of 287 such fistulæ. Nevertheless, in spite of this comparatively large total, very few have been reported since modern surgical methods have been in use.

Vesico-intestinal fistulæ occur more often in men than women, 75% of the cases being found in men and 25% in women (Pascal). This is due in part to the anatomical position of the vagina between the bladder and the rectum, so that vesico-vaginal and recto-vaginal fistulæ are much more common than vesico-rectal. and in part to the greater liability of man to trauma, many of the reported cases having been due to gunshot wounds and sword-thrusts. The immediate cause of the fistula may occur in either the bladder or the intestine, or outside of both. The causes of the nontraumatic cases are cancer, tuberculosis and nontubercular inflammation, the last class being due to a great variety of diseases: cystitis, pericystitis, vesicle calculus, toxic enteritis, typhoid, dysentery, appendicitis, intestinal obstruction, stricture of the intestine, syphilis, actinomycosis. The simple inflammatory lesions cause the greatest number of fistulæ — 30.52% of 95 cases analyzed by Chavannaz.[2] Tubercular inflammation, with its primary focus in the intestine or the prostate, or less commonly in the bladder or seminal vesicles, furnishes 7.36% and cancer originating usually in the rectum, 20%. Pascal found the cause of the cases analyzed primary in the bladder in 18% and in the intestine in 35%. The causes of vesico-intestinal fistulæ, originating outside of either urinary or intestinal tract, are inflammation of the peritoneum or inflammation of new growth of the uterus and its adnexa. In these cases the primary focus secondarily invades both bladder and intestine, thus forming a fistulous connection between them. The infrequency of cancer of the bladder as the origin of the fistula is shown by a series of 4,774 autopsies done by Heiborn (Pascal), among which were only 37 cases of vesicle cancer and of these only 7 were primary. Of the 37, 9 had caused a vesico-intestinal fistulæ. As far as age is concerned the cases are fairly evenly distributed from early adult life till old age. The fistula may be formed by an agglutination of the bladder and intestinal walls with a direct connection at this point, or there may be a small canal between the two (Chavannaz, in 22.10% of the cases), or a cavity may exist independent of either intestine or bladder, and be connected with both by a fistulous tract. The fistula may be single or multiple, or single in the bladder and multiple in the intestine, or multiple in the bladder and single in the intestine. Ordinarily it is single in the bladder, in but 5 out of 95 (Chavannaz) cases were there several openings in the bladder. When there are several openings into the intestine they are usually into the same portion of it, though cases have been reported where they connected with distinctly separate areas. In 100 autopsies or operations tabulated by Pascal the orifice in the bladder was situated on the anterior face in 1 case, on the side 9 times, on the summit 13, in the base 17 and on the posterior surface 23 times, 19 of which were near the ureters. The connection with the intestine is in the great majority of cases with the rectum. Of 195 cases (Pascal) the connection was with the rectum in 113, with the colon and especially the sigmoid 42, and with the ileum 26 times. The opening of the fistula may form a valve which prevents the passage of material in one direction. The bladder itself is usually diminished in size, and eventually, with the urethra, becomes chronically inflamed, though it may withstand for a surprisingly long time the presence of the fecal matter. Infection ascending through the ureters and to the kidneys is rare. In 100 autopsies (Pascal) definite mention was made of the kidneys and ureters in 25 cases, in 7 of which they were healthy and in the remaining 18 showed the lesions of an ascending inflammation. Secondary stones may form in the bladder about a nucleus of fecal matter and be composed of either largely fecal material or phosphates. When a stone is found in the bladder the inference cannot be immediately drawn that the calculus was formed before the fistula and caused it by ulceration. These cases with stone must be carefully analyzed before the etiological value of the stone can be determined. The intestine below the fistula becomes

[1] Des Fistules Vesico-Intestinales acquises chez l'Homme. 1900.
[2] Ann. d. Mal. d. Org. Genito-urin., Par., 1897, xv, 1176.

inflamed and irritable from the presence of the urine, or the rectum may dilate and form a pouch in which the urine collects to be passed only at intervals.

The cardinal symptoms of vesico-intestinal fistula are the passage of gas and fecal matter through the urethra and of urine through the rectum. These symptoms, however, are not always present at the same time and one perhaps may be entirely absent. Patients often suffer intense pain constantly, or only at the time of micturition, due then to the passage of fecal matter through the urethra, which may become plugged, causing retention and urinary extravasation. There is both vesical and rectal tenesmus. The urine is that of the condition of the urinary tract, cystitis, pyelitis, etc., caused by the presence of the fecal matter plus the fecal matter itself. The cystitis or the irritation of a stone, either primary or secondary, may be severe enough to cause secondary ulcerations which may eventually perforate and form additional vesico-intestinal fistulæ.

The passage of gas with the urine is the most constant symptom and ordinarily the first to indicate the presence of the fistula. In some cases this is the only symptom, and the case may advance no farther. Pousson [3] reports a case where the passage of gas was the only symptom for two years and Pascal mentions one where there were no other symptoms for nine years. The gas is usually passed at the end of micturition. Occasionally it comes in the middle of it, when the stream of urine ceases till the gas has all come out. The passage of the gas is accompanied by a noise more or less whistling in character. The gas may disappear for several days, only to reappear again, and may be in some cases dependent on the position taken during micturition.

The amount of fecal matter in the urine varies within large limits. There may be no feces in the urine at any time, or they appear only when the patient has a diarrhea. Some have thought that the readiness with which the feces passed into the bladder was dependent on their diet, the amount always increasing after the ingestion of a certain food. The region of the intestine with which the fistula connects may be told in a rough way by the character of the fecal material found in the urine. Pieces of well-formed feces indicate a connection low down, while undigested material shows that it is high up in the intestinal canal. The length of time after eating before the appearance of the fecal matter is also a guide to the situation of the fistula. A microscopic examination of the sediment in the urine may be necessary to determine its intestinal origin and its characteristics. The fecal material may form a calculus or serve as a nucleus for a phosphatic stone.

The passage of urine through the rectum is a lessconstant symptom, and depends on the situation of the opening in the bladder and its valvular action. Its presence causes eventually an inflammation of the mucous membrane of the intestine. Occasionally the passage of urine from the rectum is the first symptom noticed by the patient. The urine may leak away constantly through the anus or be retained for a variable length of time and be passed only when the patient micturates or defecates. Some patients have complete control over these discharges, except when they are in an upright position or attempt to urinate.

It would seem that the diagnosis of a connection between the bladder and the intestine could be made from the presence of any one of the three characteristic symptoms, gas or fecal matter in the urine and urine in the stools. There are, however, other conditions than vesico-intestinal fistulæ which may give rise to some of the above symptoms. Gas may appear in the urine after catheterization or litholapaxy. It is developed sometimes in diabetes mellitus, when a yeast fungus reaches in some way, perhaps by the catheter, the urine in the bladder and sets up fermentation. It may occur also when purulent cavities with gaseous contents develop near the bladder and break into it. Pneumaturia occurs without any apparent reason in certain neuropathies (Guirard).

The presence of fecal matter in the urine is proof of the existence of a fistula with the intestinal tract. It may connect, however, with the urinary apparatus below the bladder. In an urethro-rectal fistula there will be anal urination only at the times when urine is passed through the urethra. A physical examination will settle the question. An examination of the rectum alone may determine the point. If the fistulous opening in the rectum is found below the prostate, the connection is probably with the urethra, while a fistula above the prostate probably connects with the bladder.

Urine in the rectum other than that due to a vesico-intestinal or a urethro-rectal fistula may occur in an uretero-intestinal fistula. The differential diagnosis can be made by the absence of fecal material in the urine and by the physical examination.

The various methods of physical examination are employed to determine not only the presence of a vesico-intestinal fistula but its site. The cases of new growths and tuberculosis which give rise to this condition must be so far advanced as to make their diagnosis easy. As the simple inflammatory fistulæ are the most favorable for treatment, an early diagnosis is important. The examination of the bladder and rectum may be by cystoscope and proctoscope. Failure to find the opening, especially in the bladder, does not necessarily mean its non-existence, for it may be so small that it is hidden by a fold of mucous membrane. The injection of a colored fluid into the rectum and its recovery later from the bladder, or *vice versa*, is sure proof of the presence of a fistula. A negative result from the injection one way does not rule out the fistula. The passage of the fluid depends on the position and the character of the opening of the fistula, and while it will pass in one way it may not in the opposite, or an existing intermediate cavity may be large enough to hold it all. In place of a colored liquid some have

[3] Assoc. français de Chir., 1896, Vol. x, 536.

used a chemical, and then tested for its presence in the fluid recovered later. The bladder has been filled with a chemical, and then the rectum, which has been wiped with a second chemical, examined by the proctoscope. Where the two meet at the fistula a characteristic reaction takes place, and the site of a connection which had escaped notice discovered. It has also been suggested to inflate the rectum with hydrogen gas and burn it as it issues from the end of a catheter passed into the bladder.

The prognosis depends primarily on the cause of the fistula, and in cancer and tuberculosis on the primary disease rather than on this complication. In the simple inflammatory fistula it depends largely on its size. This determines the amount of fecal matter which runs into the bladder, and on this depends the condition of the bladder. The more inflamed the bladder, the greater is the liability of an infection ascending to the kidneys. The fistula once present, the course of the lesions due to it is steadily forward. However, Harrison Cripps[4] reports that a spontaneous cure has occurred. Although a moderately large number of cases has been collected, so few are reported in recent times that no attempt has been made to estimate the length of time before the fatal termination, which is ordinarily inevitable sooner or later unless the fistula is closed.

The treatment is dependent primarily on the cause of the fistula, and in cancer or tuberculosis would be rather different from that devoted to a fistula of simple inflammatory origin. The treatment has varied greatly in different periods from a course of "Bristol water and asses' milk" to laparotomy. The treatment is divided naturally into palliative and radical. Specific medication should be used in a syphilitic case.

The palliative treatment is devoted to keeping bladder and rectum clean by frequent irrigations or permanent drainage, or in some cases by the position of the patient. In order to prevent the passage of feces into the bladder, an artificial anus may be formed above the intestinal end of the fistula. In order to get the full benefit from this operation, no feces must get into that portion of the intestine distal to the artificial anus, for they will in time reach the bladder. To prevent this the anus is made with a large spur or the lower opening is permanently closed. To accomplish the same object an entero-anastomosis may be made, joining the part of the intestine above the fistula directly with that below.

Vesico-intestinal fistulæ from the point of view which has in mind their radical cure are divided clinically into those accessible from the rectum, or vesico-rectal, and those inaccessible from the rectum, or vesico-intestinal, even though the fistula connects anatomically with the upper part of the rectum. Various procedures have been suggested for their radical cure, the more important of which I will briefly indicate:

Rectal route. — The anus is stretched and the edges of the fistula from inside the rectum are freshened and sutured in layers. Division of the sphincter ensures the free discharge of the feces and lessens the likelihood of the stitches tearing.

Perineal route. — Transverse incision in the perineum. The rectum is separated from the prostate and urethra in front. The peritoneum is pushed up out of the way if the fistula is high, and the fistula directly sutured. Drainage is advisable. It has been suggested that at the end of the operation the rectum be turned a little so that the repaired opening in the bladder may come against a healthy intestinal wall.

Sacral route. — Incision is made from the anus along the side of the coccyx and sacrum, and a bone flap turned back. The fistula may be reached by pulling the rectum to one side.

Vesical route. — Pousson[5] attacked the fistula through a suprapubic incision into the bladder. The mechanical difficulties of this method are great.

Abdominal route. — Separation of the intestine from the bladder and direct repair of the opening in each. Drainage.

Pascal gives the following results:

Rectal or perineal route with or without sphincterectomy, fourteen cases. Healing of the fistula in eight, failure in six.

Laparotomy seventeen times with nine failures, seven recoveries and one improvement.

The causes of death in the fatal cases were peritonitis and shock.

Reports of Societies.

AMERICAN GYNECOLOGICAL SOCIETY.

PROCEEDINGS OF THE TWENTY-EIGHTH ANNUAL MEETING, HELD IN WASHINGTON, D. C., MAY 12, 13 AND 14, 1903.

(Concluded from No. 14, page 381.)

Dr. Hiram N. Vineberg of New York City contributed a paper on

THE ETIOLOGY, PATHOLOGY AND TREATMENT OF PUERPERAL SEPSIS.

Severe sepsis may be caused by a variety of pathogenic germs. The variety of germs found in the uterine discharge in a given case is no criterion of the severity of the case, and forms no safe guide as to prognosis or as to the treatment to be adopted. Bacteriological examination of the blood is of little value, either from a prognostic or therapeutic standpoint. The treatment of puerperal sepsis must be based chiefly upon the clinical history and physical signs of each individual case. Wounds or infection in the perineum, vagina or cervix are to be treated on the general surgical principles of irrigation and drainage. Curettage is indicated where there are evidences of placental decidual residue in the uterus independent of the variety of bacteria that may be found in the uterine cavity. In those rare cases in which adherent and sloughing placental tissue cannot be removed, either

with the sharp curette or fingers, hysterectomy is indicated, provided the patient is not already moribund. Hysterectomy is also indicated in cases of septic endometritis or infection of the placental site, so long as the infection is still limited to the uterus, and when the symptoms steadily grow worse in spite of uterine irrigation with or without curettage, and appropriate hygienic stimulating treatment.

In abscess of the uterus, the abdomen should be opened, and, when feasible, the purulent foci should be drained and the uterus preserved. If the uterus be studded with small abscesses, hysterectomy is indicated. The abdominal is to be preferred to the vaginal route for hysterectomy. If the infection has passed from the uterus into one or other tube, and has set up a violent grade of inflammation, the abdomen should be opened and the infected tube removed before a general peritonitis develops. When the infection has passed through the uterus and has set up a general peritonitis, a case might occasionally be saved by a timely abdominal section and drainage. In cases of parametric exudates the treatment should be conservative, and surgical intervention is indicated only when there are evidences of pus formation. In obscure cases in which the pathological lesion cannot be determined, and the symptoms are steadily growing worse, it may be advisable to open the abdomen to search for a hidden purulent focus or for a circumscribed slough of the uterus. The procedure proposed by Trendelenburg and executed by him and others, of ligating the pelvic veins when they have become infected and thrombosed, is worthy of further trial.

DR. WM. R. PRYOR of New York City took issue with the essayist in regard to the significance of certain pathogenic germs. In mild cases of puerperal sepsis very rarely is the streptococcus present, while in the severe ones streptococci are found. In the mild forms of the disease many other kinds of germs are found, chiefly staphylococci and saprophytic bacteria. The form of puerperal sepsis which demands careful attention is due to the streptococcus.

DR. EDWIN B. CRAGIN of New York City related his experience at the Sloane Maternity. In this institution infection occasionally occurs, because cases are taken undelivered, no matter whether they have been handled by midwives or by beginners. Women are admitted whether they are just in labor or whether they have been in labor for several days. Occasionally a patient has been lost from puerperal infection, although pathologist and bacteriologist were unable to find the streptococcus. A number of severe cases have been observed in this maternity in which a variety of bacteria were found in the uterus. In the management of puerperal sepsis he emphasized two points: First, to make sure the uterus is emptied; second, in making sure that it is emptied, do just as little damage to the inside of the organ as possible.

DR. J. WHITRIDGE WILLIAMS of Baltimore laid stress on the value of bacteriological examinations of the uterine lochia and of the blood. In many cases there is no definite indication for treatment from such examinations, yet there is no doubt in his mind that important and valuable information as to the condition of the patient can be elicited in this way, more particularly by examining the blood. He has seen but two cases of puerperal sepsis in which he feels operation was distinctly called for.

DR. MATTHEW D. MANN of Buffalo, N. Y., spoke of gonorrheal infection in connection with the puerperium. Recently he saw a patient in consultation, who had been sick for more than a week when she was first observed by him. Her temperature reached 111° before death. She had been having a temperature of from 107° to 108° for a number of days. Pulse was 120. Examination of the discharges by competent bacteriologists showed a pure culture of the gonococcus. There was no other germ present in any of the secretions. He thought the infection would localize itself and the woman would recover; but the joints and heart became affected, and the patient died.

DR. G. GILL WYLIE of New York City said there can be no question but that surgical intervention is indicated in some of the severe cases of puerperal sepsis. Of his first nine cases, which were treated at the Bellevue Hospital some twenty years ago, seven were dealt with locally and two surgically. He believes the uterus should be emptied in every case of severe streptococcus infection.

DR. EDWARD P. DAVIS of Philadelphia, in speaking of hysterectomy in cases of puerperal sepsis, stated that this operation has nothing definite to support it except in rare cases of adherent placenta. A method which yields good results where irrigation has failed, consists in opening the abdomen and inspecting the uterus, tubes and ovaries, freeing adhesions, etc., and, if there is a collection of pus in the tubes, drainage by means of iodoform gauze carried through into the vagina, separating the organs from abnormal adhesions.

DR. MALCOLM MCLEAN of New York City referred to the curette as a dangerous instrument in cases of puerperal sepsis in the hands of the average general practitioner. Emptying of the uterus is an absolute necessity in some cases, especially where there is evidence of putrid absorption, with chill and sudden high temperature.

DR. HENRY D. FRY of Washington, D. C., said the practice at the Columbian Hospital, where a large number of maternity cases were observed, was first to thoroughly clean out the uterus, particularly if the patients were seen at the beginning of sepsis and it was confined to the uterine cavity. After having taken a culture, active treatment of the uterus is suspended until the result of the culture is made known. If there are retained pieces of placenta, blood clots, accompanied with a foul odor, producing infection, the indication for cleaning out the uterus is clear. On the contrary, if the cul-

ture showed streptococcus, staphylococcus, colon bacillus or gonococcus, the uterus was left alone. In cases of streptococcus infection he believes the use of the curette does a great deal of harm, in that it breaks down the protective zone of inflammatory tissue, which is thrown out by nature and which causes ultimately a general systemic infection.

Dr. Herman J. Boldt of New York City said experience has taught him, so far as the treatment of puerperal sepsis is concerned, that a bacteriological examination of the secretions from the vagina or from the uterus, or a bacteriological examination of the blood, furnishes no indication whatever for treatment, because there is usually a mixed infection, both streptococci and staphylococci being found in the secretions of the uterus and vagina. Such patients frequently manifest mild clinical symptoms, although operative intervention is not indicated. In all cases that come under his care, examinations of the secretions and of the blood are invariably made, and in patients who show bacteria in the blood, even a pure staphylococcus infection, the general condition of the patient does not seem to indicate the need of surgical intervention, consequently they are left alone and recover. On the other hand, many patients show absolutely no bacteria in the blood, yet they die, so that, as the result of accumulated experience, bacteriological examinations of the secretions and of the blood of such patients do not give a definite clue as to the indication for treatment.

Hysterectomy is of no avail in the severe cases of puerperal sepsis, as the patients die within a few days.

Dr. Seth C. Gordon of Portland, Me., thinks surgical treatment is undertaken too early in some cases of puerperal sepsis. If there are abscesses of the Fallopian tubes, they should not be opened until one is quite sure that he can make a straight incision from the vaginal vault into the abscess cavity, without having any doubt as to whether pus is limited to the top of the vaginal wall. Every time an abrasion is made in the uterus or vagina with the curette or knife, he thinks a new avenue of infection is opened up, and causes, in many cases, a great deal of harm.

Dr. H. G. Wetherill of Denver, Col., referred to the Carosso method of treatment of puerperal sepsis, saying its value was unquestionable. This method has been advocated particularly by Dr. Edward J. Ill of Newark, N. J.

Dr. Charles M. Green of Boston contributed a paper entitled

REPETITION OF CÆSAREAN SECTION ON THE SAME PATIENT; THE EXPERIENCE OF THE BOSTON LYING-IN HOSPITAL.

After a brief summary of the experience of the Boston Lying-in Hospital with repeated Cæsarean sections, the writer raises the question whether it is justifiable in performing Cæsarean section for either an absolute or an elective indication to remove normal organs, or to resort to other procedures with a view to preventing subsequent pregnancy and the risk of a repeated section. The writer seeks to answer this question in the negative, and invited discussion of his views. Reference was made to a paper read by Dr. Coe at a meeting of the society in New York in May, 1896, entitled "Cæsarean Section; Suture of the Uterus *versus* Total Extirpation."

Of nine repeated sections, all performed on a relative indication, four were done, one each by four members of the staff, and five by the author. Two were done after labor had been in progress for nine hours each, and seven at an elected date before labor began. One patient had her first section without the hospital; six had their first and second, and one her first, second and third sections within the hospital. In one case there were no adhesions; in seven cases there were more or less adhesions. The duration of operation was from thirty-nine and one-third minutes to one hour and twenty-four minutes. In the case that died of shock the duration was forty-eight minutes. In one case the utero-abdominal adhesions were so extensive that the fetus was delivered without opening the peritoneal cavity, and the time of operation was thirty-eight minutes. The nine infants were discharged well; and of the nine mothers one died, a maternal mortality of 11%.

These results were not reported as unique or remarkable, because repeated sections have resulted favorably in other clinics, but they are reported in the hope of influencing opinion that the time has come when the society should withhold its approval of the doctrine that women should be sterilized at their first Cæsarean section, in order that they may not be subjected to the risks of a repeated section.

(To be concluded.)

Recent Literature.

Journal of Proceedings of the Sixth Annual Convention of the National Association of State Dairy and Food Departments, held at Portland, Oregon. Published under the direction of the Association.

This volume of 500 pages contains the laws of each of the states of the Union, relative to food inspection which were in force as late as 1900, together with the proceedings of the convention held at Portland, Ore., in 1902. An examination of these laws shows that nearly all of the states have enacted statutes providing heavy penalties for the awful crime of coloring margarin so as to resemble yellow butter, while more serious offences under the food laws are visited with lighter penalties. In some states the use of salicylic acid or other preservatives in milk and other dairy products is prohibited, while it is permitted in other articles of food, provided that the fact of such use is made known by a distinctly printed label.

The addition of five or six dozen photographs of state food officials does not improve the qual-

ity of the work, but may be taken as a cheap method of appealing to personal vanity.

The following statement may be found in the introduction of the work: "The increased inquiry for pure food being expected as the result of business announcements in these pages, carrying with it the guarantee of the purity of the products offered the consuming public, will serve the double purpose of increased demand for pure food goods and restrict the sale of adulterated ones." Whatever this statement may mean, there are advertisements of many food preparations in the book which would not stand the test of some of the laws laid down in the same work.

A System of Physiologic Therapeutics. — A Practical Exposition of the Methods, other than Drug-giving, Useful for the Prevention of Disease and in the Treatment of the Sick. Edited by SOLOMON SOLIS COHEN, A.M., M.D. Vol. viii. Rest, Mental Therapeutics, Suggestion. By FRANCIS X. DERCUM, M.D., Ph.D. Philadelphia: P. Blakiston's Son & Co. 1903.

The eighth volume of this series has appeared under the authorship of Dr. F. X. Dercum of Philadelphia, on the subjects of Rest, Mental Therapeutics and Suggestion. Of these three therapeutic measures, Rest, or the so-called "rest-cure," is given the place of chief importance. In working out this important branch of his subject Dr. Dercum has gone rather far afield in considering etiological and pathological as well as clinical and diagnostic matters, all of which, however, add very materially to the comprehensiveness and value of the book. The final section concerns itself with Suggestion. This subject receives a skillful and rational treatment which should be appreciated not only by those concerned in diseases of the nervous system, but also by practitioners in every branch of medicine. A brief consideration is given of the curious and always interesting vagaries of the human mind, which have resulted in such methods of treatment as metallotherapy, mind cure, faith cure and Christian Science. We commend especially Dr. Dercum's views on the subject of Rest. There can be no question that this method of treatment has been overdone, frequently to the positive detriment of the patient's condition. What we need is a sane, rational presentation of this important therapeutic measure, taken in conjunction with other means of treatment. This Dr. Dercum has apparently given us. He believes in work and exercise as well as rest in many functional nervous disorders. "Partial rest" is a favorite expression with him, and this we think is usually indicated. Naturally in a book of this sort many topics slightly foreign to the subject under discussion, for example, the symptomatology of various diseases, are taken up, though not in detail. In general we are glad to say that this is a fitting continuation of the excellent series of volumes which have preceded it.

THE BOSTON

Medical and Surgical Journal

THURSDAY, OCTOBER 8, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

TYPHOID FEVER AND IMPURE ICE.

SINCE the usual source of infection in typhoid fever has been discovered, it has been natural that from time to time considerable attention should be paid to the possibility of the transmission of the disease through ice formed from contaminated water. It will no doubt be remembered by some of our readers that an investigation of the Boston ice supply, conducted under the auspices of the Board of Health, was published in this JOURNAL in 1901, with the general conclusion that ice more than three weeks old is practically as safe as a well-filtered water supply. Inasmuch as infection, if it occurs at all from ice, would naturally follow the cutting, it was held that after March the ice could not be held responsible for an outbreak of the disease, even were it known originally to have been infected. As a matter of fact, on analysis very few cases of the disease have been shown to be due to ice. This renders a careful piece of work on the subject by Dr. R. H. Hutchings and Dr. A. W. Wheeler of the St. Lawrence State Hospital at Odgensburg, N. Y., published in the current number of the *American Journal of the Medical Sciences*, worthy of comment.

The tracing of an epidemic of typhoid at the St. Lawrence Hospital by these investigators certainly seems to indicate that under favoring conditions ice may be the source of the disease. Formerly the hospital was supplied with drinking water through the St. Lawrence River, but this, having been definitely shown to be the source of very considerable epidemics of typhoid, was abandoned after various measures for purification had been investigated. Thereafter water was obtained from a small Adirondack stream, which supplies the city of Ogdensburg. This change led to a practical disappearance of the disease for

about two years, and during this time the water was not boiled and ice was freely used. In the latter part of 1902 typhoid fever again appeared, and after a careful investigation of the water and milk supplies it was determined that the ice used in the institution was the probable source of infection. This ice had been taken from the St. Lawrence River and had been stored more than seven months. It appears that when this particular ice was forming, three or four cases of typhoid fever had occurred in the city among users of well water. Ice cut from the same place had previously been used for upwards of ten years and had never before been suspected. Bacteriological investigations of specimens of drinking water and melting ice were undertaken by Dr. George Blumer of the Bender Laboratory in Albany, whose report led to the strong suspicion that the ice was at fault. Further careful investigation brought out the fact that the ice, which contained considerable extraneous matter, was contaminated with numerous organisms, many of which were motile. Cultures showed a rapid growth, and colonies of colon bacilli and typhoid bacilli were finally isolated. The tests applied in the case of the suspected typhoid organisms left no doubt in the minds of the observers that they were dealing with Bacillus typhosus. In three of the cases the disease was clinically identified by autopsies. In further support of the contention that ice was the source of the infection is the fact that with the discontinuance of the use of this ice the epidemic gradually subsided. There were in all thirty-nine cases. At present, with the exception of a different ice supply, the conditions are the same as at the beginning of the epidemic. The water used is not boiled.

This piece of careful work should be widely read. It is apparently a justification for the opinion, long theoretically held, that under certain favoring conditions ice may be a definite and dangerous source of typhoid fever, and should lead to definite precautions against the spread of the disease from this source. Although the work of the Boston Board of Health was apparently conclusive, so far as it went, this new experience at Ogdensburg should suggest further experiment in which the natural conditions are as closely simulated as it is possible to make them under artificial experimental conditions.

INTERNATIONAL CONGRESSES ON SCHOOL HEALTH.

We are in receipt of a circular printed in three languages designed to excite interest in the question of the establishment of international congresses on the health of school children. Attention is called to the fact that among the various branches of hygiene, public and school health are of the first importance; that many authorities on hygiene have attempted to arouse interest in these branches; that physicians, teachers and governments have done what they could to forward the work, recognizing the extreme importance of hygiene of the school in its influence on the development of healthy adult life.

It is now proposed to bring together persons interested in the general subject in congresses, to be held at various intervals. Societies on school hygiene have already been formed, both in English-speaking and Continental countries. The establishment of the formal congress is simply another step toward unifying the work on the general subject. It is proposed that this congress assemble every three years, and it is already announced that the first is to be held in Germany in the spring of 1904, at which papers may be read in any European language, with preference for English, German or French.

Membership in this congress is open to all who take interest in the promotion of improved school hygiene. Each member, by contributing a small yearly sum, receives all the privileges of membership in the congress. Some of the subjects which will be particularly discussed are hygiene of school buildings, hygienic instructions for masters and pupils, bodily training of pupils, illness, petty ailments and medical attendance in schools, questions concerning children of weak intellect, and, finally, hygiene of the faculty.

This movement is most certainly commendable, and that the existence of such an association, drawing its membership from all civilized countries, would do very much toward establishing schools everywhere on a far better basis as regards the health of the pupils is self-evident. It needs no comment from us to demonstrate the essential importance of work, beginning in the very earliest years of school life, toward the establishment of health

AMERICAN RESEARCH.

In an editorial comment *American Medicine* speaks of an editorial on "American Research and German Reviewers," which recently appeared in the *Journal of the American Medical Association*, as follows:

Under this title the *Journal of the American Medical Association*, in one of its recent issues, had an editorial to

the effect that American investigations did not receive full justice at the hands of German reviewers. To a certain extent there is undoubtedly some foundation for the assertion, but on the other hand it is only fair to admit that during the last few years special publications in Germany have honestly endeavored to cover their respective special fields as exhaustively as possible, which would naturally include the American contingent. Although these German reviews give the greatest prominence to those investigations which have originally been published in the German language, the American investigator, on the whole, does not fare any worse than his colleagues in any other non-German country. This is in so far a satisfactory feature, as it clearly proves that American research has successfully asserted its claim to international recognition and that the spirit of healthy, vigorous aspiration will not allow itself to be suppressed.

We are inclined to agree with this view of the situation. Although there is still apparently a certain lack of knowledge of the English language on the part of German reviewers, it is nevertheless true that this defect is growing less and that worthy American or English work is finding a more and more appreciative recognition at the hands of the Germans. Another ten years will no doubt complete the good work already begun by establishing once for all the claim of American research to universal recognition.

Following this very just statement of the situation *American Medicine* also makes the following comment:

> If American investigators desire to be fully and seriously recognized by European scientists they will have to furnish unmistakable evidence that their work is solely the outcome of a desire to further the true interests of science. There should exist among American medical authors a feeling of solidarity with an ever-ready willingness to give credit where credit is due. It will not do to laud to the skies for selfish motives European productions which cannot hold a candle to home researches. In other words, we must ourselves be convinced and be in a position to convince others of our scientific maturity and zeal, before we can reasonably expect to command the recognition of foreign nations. It is all very well to talk about "international science" — the weaker is perfectly willing to profit from internationality by taking from the stronger whatever good he can find, but where is there any adequate compensation for the stronger?

Here we cannot agree with our contemporary. So far as our observation has gone, there is no conspicuous lack on the part of American authors in giving due credit for work done, whether native or foreign. Possibly a few youthful students, fresh from the laboratories of Europe, are apt to overestimate the value of their foreign training and to minimize the good things at home, but after a few years' experience we are convinced that the American investigator, as a rule, takes a perfectly fair attitude toward investigation whereever it may appear. Possibly our experience in this matter may be small, but we are very sure that we have already reached that "scientific maturity" which is capable of taking a broad point of view.

MEDICAL NOTES.

AN HONOR FOR PROFESSOR VON BEHRING. — It is announced that Professor Von Behring has been made a member of the Prussian Privy Council with the title of "Excellenz." Medical men have rarely received this distinction, and the few who have up to this time have been surgeons.

PROFESSORSHIP IN THE HISTORY OF MEDICINE. — It is reported that the University of Maryland has established a chair in the history of medicine and that the first incumbent is to be Dr. Eugene F. Cordell of Baltimore. We hope this may pave the way to many more such professorships.

ACCIDENTS IN THE ALPS. — News from Geneva states, according to *American Medicine*, that never before in the history of the Alps have death and disaster been so common on the mountains as during the present season. Over 300 accidents have occurred, resulting in the loss of no fewer than 150 lives. Over half of this season's accidents have happened to Germans and Austrians, who, partly from bravado and partly from pecuniary reasons, almost invariably climb without guides.

MEDICAL UNION IN THE STATE OF NEW YORK. — A special meeting of the council and fellows of the New York State Medical Association was held Oct. 1 in New York, for the purpose of discussion of the question of medical union in New York State. The following resolutions were passed:

"*Whereas:* The members of the New York State Medical Association desire a union of the medical profession in the State of New York, and

"*Whereas:* It is deemed expedient for the attainment of this purpose to make further effort to bring together the New York State Medical Association and the Medical Society of the State of New York under the name of 'The Medical Society of the State of New York':

"*Resolved:* That a committee of five be appointed by the chair, and said committee is hereby empowered to do whatever is necessary and expedient to bring about such a union in a just and equitable manner, and

"*Resolved:* That the committee so empowered may confer, coöperate and unite with a committee

of the Medical Society of the State of New York for the purpose of forming said union of the two medical organizations, and

"*Resolved:* That a copy of these resolutions be transmitted to the secretary of the Medical Society of the State of New York, with a request that their Conference Committee be granted similar powers."

Confederation of Reciprocating, Examining and Licensing Medical Boards. — A meeting of the American Confederation of Reciprocating, Examining and Licensing Medical Boards will be held at St. Louis, Oct. 27. Reciprocity certificates are at this time being issued daily between several of the states, members of and in sympathy with the confederation; and the executive officers of such reciprocating boards will be present at the meeting and will severally give brief addresses upon "Reciprocity from the Standpoint of Experience in the Interchange of State Licenses." Several eminent medical men throughout the United States not directly connected with medical boards have been invited to attend the meeting and to take an informal part in the proceedings. Among others who have accepted are Dr. Frank Billings of Chicago, President of the A. M. A.; Dr. William E. Green, Little Rock, Ark., Member Committee on Medical Examining Boards, A. I. H.; Dr. Charles A. L. Reed, Cincinnati, Ex-President A. M. A.; and Dr. Frank J. Lutz, St. Louis, Secretary-General of the World's Congress of Medicine, 1904.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Oct. 7, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 49, scarlatina 28, typhoid fever 22, measles 18, smallpox 0.

Bequest to Melrose, Mass., Hospital. — By the will of the late Royal F. Barry the Melrose Hospital receives one thousand dollars.

A Decision in Favor of Christian Science. — A decision of the Supreme Court of New Hampshire in a case brought against a so-called Christian Science healer established the legality of the practice of Christian Science healing in that state by ruling in the defendant's favor. On a charge of fraud also brought against the "healer," the court sustained the plaintiff. We question whether this combination of decisions has before occurred in a single case.

NEW YORK.

Physicians and the Hall of Fame. — In the course of an address at the opening of the New York University and Bellevue Medical College on Sept. 30, Dr. MacCracken, the chancellor of the university, stated that he had received a letter from a physician, who is also editor of a medical journal, asking him for an article upon this question, How do physicians stand in relation to the electors of the Hall of Fame? He then went on to say: "The decision as to the names to be inscribed in the Hall of Fame belongs to a board of one hundred electors. What place have physicians had in this whole matter? Of the one hundred judges, four were doctors of medicine. There is no support for the position that has been taken by certain writers that the absence of physicians from the Hall of Fame is explained by the small percentage of physicians in the Electoral Board." At the time the official vote for names for the Hall of Fame was given out the number of votes cast for the names of Dr. Rush and other eminent medical men was announced, but in no instance was this number sufficiently large to secure a place among the immortals.

A Proposed Public Park. — At a meeting of the Board of Estimate and Apportionment held Sept. 30, Mr. De Forest, the tenement house commissioner, and others spoke in regard to a proposed public park at Monroe Market, Hamilton and Catherine streets, on the East Side. Mr. De Forest urged that a park should be established in this locality, but suggested that, instead of the block proposed, the board should take the adjoining block to the south, which is known in the district and in the Health Department records as the "lung block," because of the prevalence of consumption there. "Many of the houses in the block," he said, "are permanently infected with the germs of tubercular disease. Certain of these houses have had in the past five years as many as twenty-two cases of pulmonary tuberculosis in each house, as far as the records of the Board of Health go. It is probable that the actual number of cases of tuberculosis in each house is double this amount, as it is well known that only one-half the cases are reported to the Board of Health." Definite action in the matter will be taken next month.

Pollution of Passaic River. — On Oct. 2, Judge Mahlon Pitney, of the Supreme Court of New Jersey, set aside a verdict by which a local jury, in the face of the court's instructions, at-

tempted to aid Paterson in the fight which surrounding communities are making upon the city for its part in the pollution of the Passaic River. The suit in which this occurred was one brought by Catharine Simmons of Dundee Lake to recover $25,000 damages for the alleged destruction of her ice business by the sewage of Paterson. The court practically directed a verdict for the plaintiff at the close of the trial, but the jury, declining to follow the court's instructions, found that the plaintiff had no cause of action. The verdict is set down to an overzealous loyalty of the Paterson jurors to the interests of the city in a struggle in which it has been engaged for years with all the surrounding country. One of the purposes of the ten-million-dollar trunk-sewer which is about to be built on the Passaic River is to intercept the sewage which Paterson dumps into its waters. The owners of mills and other property along the river banks have long been in arms against the pollution of the stream, and the cities of Newark and Jersey City, which formerly drew their drinking water from it, were eventually obliged to abandon it and look elsewhere for their supplies.

Obituary.

GEORGE HAVEN, M. D.

DR. GEORGE HAVEN, whose death occurred on Sept. 27 last, was born in Portsmouth, N. H., July 13, 1861. He graduated from the Harvard Medical School in 1882. He served a year as house physician of the Children's Hospital in Boston. The next two years were spent abroad, where in the hospitals of Munich and Vienna he devoted himself to the study of obstetrics and gynecology. In 1887 he began practice in Boston. He was connected with the Boston Dispensary from 1887 until his death, at first as district physician, later as physician for diseases of women. He was assistant visiting physician in the Lying-In Hospital for ten years, resigning in 1900. Here he initiated a series of Cæsarian sections, the success of which had much influence in the community in establishing the value and safety of this operation. He was appointed to the Department of Diseases of Women at the Boston City Hospital in 1889, and at the time of his death was junior visiting physician.

He served for several years as assistant in Obstetrics at the Harvard Medical School and still held the position of instructor in gynecology.

Dr. Haven was a man of exceptional value in the community. Refined, well-balanced, straightforward, strong in mind and in body, he safeguarded at the same time the best interests of his patient and of the profession. He has added significance and dignity to the specialty of obstetrics and gynecology, during a period when the recognition of the necessity of such a specialty was doubted by a large number of the profession.

As a physician, wise in counsel, tireless in devotion, tactful and confident, with a strong personality and reassuring presence, he brought hope and comfort to the sick-room. His patients were his friends, whose trust and love he possessed in a remarkable degree, to whom his services were freely offered without thought of self. His sense of duty was well illustrated by his response to his last professional call. In the acute stage of the illness which three weeks later caused his death, he rose from bed to attend a patient during a grave attack of eclampsia. His own condition was forgotten, while he worked with the assistance of a younger colleague until compelled by exhaustion to stop, only to return again and again to the task of a difficult delivery, as momentary strength was regained. The patient's life was saved.

As an operator he showed unusual judgment and untiring patience. He was skillful, careful, resourceful and successful. Conservative, yet bold, he was willing to assume the largest measure of responsibility, but the interests of his patients were never forgotten.

As a consultant his practice constantly increased as his diagnostic ability and operative skill became more widely known. Inflexibly recognizing the welfare of the patient as his first duty, his tact and high sense of responsibility peculiarly qualified him for the exacting requirements of this relation. His professional success was already definite and assured. A longer life could have but enlarged its measure.

Miscellany.

THE SYSTEMATIZATION OF EFFORTS TO REDUCE INFANTILE MORTALITY.

THE failure of sanitary efforts to reduce infantile mortality is the most unfavorable fact in the history of Great Britain in the last twenty years. It was not altogether unreasonable to expect that public health administration would have a very great influence in reducing infantile mortality to what may, under present conditions, be regarded as a normal standard; namely, one death under one year of age out of every ten born. But although the removal of privies and cesspools and of other nuisances, the improved conditions of housing, the more cleanly habits of the people, must have had some influence in the right direction, various social factors have been at work which have at least counterbalanced the good effect of sanitary improvements. These are, in particular, the greatly increased urbanization of the population, the more

frequent non-domestic employment of married women, and the increasing tendency of mothers to neglect their primary duty of nourishing their infants. The last is the most serious evil of all, town-living by itself not necessarily implying a greatly-enhanced risk of death during the first year of life. Whether due to unwillingness of mothers to perform this duty or to the practical difficulties involved in the industrial employment of women, the fact remains that artificial feeding of infants is a main cause of infantile mortality.

In another column we publish a brief analysis of communications made to the International Congress of Hygiene at Brussels, describing the organized efforts made in France and Belgium to reduce infantile mortality. With regard to France, there is little to add to the full account of the system which was given in the series of articles on the milk supply of large towns published in our columns last spring, and it will be seen that in Belgium similar methods are followed. In both countries the importance of medical supervision is more fully recognized than in this country. Sterilized milk for infants is now supplied by several municipalities in Great Britain, but hitherto there has been, in connection with these efforts, so far as we are aware, no attempt to combine the provision of milk with a weekly medical consultation, involving a weekly physical examination and weighing of the infant and an adaptation of its food to the special requirements of each case. This would be difficult to manage in England without the consent of the family practitioner. But is it not of the essence of the experiment and is it not indispensable for its success, that such weekly observations should be made and that the use made of the sterilized milk should be checked at frequent intervals? We are of opinion that efforts should be made to overcome the difficulties in the way of weekly medical examination in connection with the supply of sterilized milk.

Stress also may be laid on the possibility of a supply of sterilized milk encouraging mothers not to suckle their infants. The particulars as to the means by which this danger is avoided in connection with the French maternity charities are particularly interesting. It is open to doubt whether similar inducements could be held out in England among any except the very lowest class without exercising a pauperizing influence. But in connection with the infants born in workhouses and those born in connection with maternity charities, some further efforts ought to be made and the methods adopted in France, although they should not be slavishly copied, are worthy of consideration and may at the least suggest methods of procedure which will be consistent with the retention of self-respect on the part of the mother, while giving her infant an improved prospect of surviving the first year of its life.

The subject is one deserving of further study, of careful experimental work, and the co-ordination of measures, already in operation or about to be adopted, should be borne in mind in any attempts at extended work. — *British Medical Journal.*

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, SEPT. 26, 1903.

Cities.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 3,014; under five years of age, 1,017; principal infectious diseases (smallpox, measles, scarlet fever, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 814, acute lung diseases 218, consumption 343, scarlet fever 11, whooping cough 27, cerebrospinal meningitis 15, smallpox 16, erysipelas 8, puerperal fever 4, measles 9, typhoid fever 43, diarrheal diseases 258, diphtheria and croup 80.

From whooping cough, New York 3, Chicago 5, Philadelphia 10, Baltimore 3, Pittsburg 3, Lawrence, Fitchburg and Quincy 1 each. From erysipelas, New York 2, Chicago 3, Philadelphia 1, Boston 2. From smallpox, Philadelphia 1, Pittsburg 15. From scarlet fever, New York 4, Chicago 2, Philadelphia 1, Baltimore 1, Pittsburg 1, New Bedford 1, North Adams 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Sept. 12 the death-rate was 15.8. Deaths reported, 4,575; acute diseases of the respiratory organs (London) 122, whooping cough 66, diphtheria 35, measles 28, smallpox 1, scarlet fever 36.

The death-rate ranged from 5.0 in Bournemouth to 27.7 in Wigan; London 15.2, West Ham 19.6, Brighton 14.6, Portsmouth 15.5, Southampton 17.0, Plymouth 19.1, Bristol 12.5, Birmingham 18.5, Leicester 13.7, Nottingham 16.3, Bolton 18.0, Manchester 17.6, Salford 16.1, Bradford 14.5, Leeds 11.8, Hull 20.9, Newcastle-on-Tyne 19.2, Cardiff 12.7, Rhondda 17.9, Liverpool 18.8, King's Norton 10.6, Middlesbrough 22.5.

METEOROLOGICAL RECORD.

For the week ending Sept. 26, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING OCT. 3, 1903.

S. W. DOUGLAS, pharmacist. Detached from Naval Proving Ground, Indian Head, Md., and ordered to Navy Yard, Portsmouth, N. H.

W. S. PUGH, Jr., assistant surgeon. Appointed an assistant surgeon, with the rank of lieutenant, junior grade, from Sept. 23, 1903.

M. V. STONE, assistant surgeon. When discharged from treatment at the Naval Hospital, New York, ordered home and granted sick leave until Dec. 31.

S. H. GRIFFITH, surgeon. Detached from the Marine Barracks, Washington, D. C., and ordered to the "Minneapolis" and to duty as fleet surgeon of the Atlantic Training Squadron.

R. B. WILLIAMS, assistant surgeon. Detached from the First Torpedo Flotilla, and ordered to the Naval Hospital, Norfolk, Va.

F. M. BOGAN, assistant surgeon. Detached from Navy Yard, Washington, D. C., and ordered to the "Chauncey" for duty with the First Torpedo Flotilla.

SOCIETY NOTICE.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — A regular meeting of the society will be held at Hotel Nottingham, Boston, Mass., on Thursday, Oct. 15, 1903, at 7.30 P.M. The meeting will be in charge of the Section on Dermatology, Dr. Edith R. Meek, chairman. Exhibition of patients treated with the X-ray. Papers: Dr. Edith R. Meek, "X-Ray Work from the Chemical Standpoint;" Dr. Mabel Austin, "Histological Changes Occurring in Tissues Subjected to the X-Ray," illustrated by microscopical sections; Dr. Antoinette Konikow, "Brief Résumé of Current X-Ray Literature." Discussion by Drs. Smith, Culbertson, Alexander and others.

DR. AGNES C. VIETOR, Secretary.

TRINITY COURT, BOSTON.

BOOKS AND PAMPHLETS RECEIVED.

A Narrative of Medicine in America. By James Gregory Mumford, M.D. Philadelphia and London: J. B. Lippincott Company. 1903.

Nurses' Guide to Surgical Bandaging and Dressings. By Wm. Johnson Smith, F.R.C.S. Illustrated. Philadelphia: J. B. Lippincott Company.

Intracranial Tumors among the Insane. A Study of Twenty-nine Intracranial Tumors found in Sixteen Hundred and Forty-two Autopsies in Cases of Mental Disease. By I. W. Blackburn, M.D. Illustrated. Washington: Government Printing Office. 1903.

The Boy's Venereal Peril. By F. C. V. Reprint. 1903.

Aids to Cystoscopic Practice. By Fred C. Valentine, M.D., of New York. Reprint. 1903.

A Contribution to the Study of Mouth Bacteria. By Samuel A. Hopkins, M.D., D.D.S., of Boston, Mass. Reprint. 1903.

Hypnotism: Its History, Practice and Theory. By Z. Milne Bramwell, M.B., C.M. London: Grant Richards. 1903.

Text-Book of Histology, including the Microscopic Technic. By Dr. Philipp Stöhr. Fifth American from the Tenth German Edition. Translated by Dr. Emma L. Bilstein. Edited, with additions by Dr. Alfred Schaper. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

Scheme for the Differential Testing of Nerves and Muscles for use in Diagnosis. By J. Montgomery Mosher, A.M., M.D. Illustrated. Albany, N. Y.: Brandow Printing Company, Fort Orange Press. 1903.

The Crusade against Tuberculosis. Consumption a Curable and Preventable Disease. What a Layman should Know about It. By Lawrence F. Flick, M.D. Philadelphia: David McKay. 1903.

A Manual of Operative Surgery. By Sir Frederick Treves, Bart., K.C.V.O., C.B., LL.D., F.R.C.S. New Edition, Revised by the author and Jonathan Hutchinson, Jr., F.R.C.S. In two volumes. Vol. I. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

The Principles and Practice of Hydrotherapy, a Guide to the Application of Water in Disease, for Students and Practitioners of Medicine. By Simon Baruch, M.D. Second Edition, revised and enlarged. Illustrated. New York: William Wood & Co. 1903.

A Laboratory Guide in Urinalysis and Toxicology. By R. A. Witthaus, A.M., M.D. Fifth Edition. New York: William Wood & Co. 1903.

American Pocket Medical Dictionary. Edited by W. A. Newman Dorland, A.M., M.D. Fourth Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders & Co. 1903.

Lippincott's New Medical Series. Edited by Francis R. Packard, M.D. The Principles and Practice of Surgery. Designed for Students and Practitioners. By George Tulley Vaughan, M.D. (Univ. of Va.). Illustrated. Philadelphia and London: J. B. Lippincott Co. 1903.

A Text-Book of Obstetrics. By Barton Cooke Hirst, M.D. Fourth Edition, revised and enlarged. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

The Practical Medicine Series of Year Books, comprising ten volumes on the year's progress in medicine and surgery. Under the general editorial charge of Gustavus P. Head, M.D. Vol. IX. Illustrated. Chicago: The Year Book Publishers. August, 1903.

Clinical Examination of the Urine and Urinary Diagnosis, a Clinical Guide for the Use of Practitioners and Students of Medicine and Surgery. By J. Bergen Ogden, M.D. Second Edition, thoroughly revised. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Nervous and Mental Diseases. By Archibald Church, M.D., and Frederick Peterson, M.D. Fourth Edition, thoroughly revised. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

A Text-Book upon the Pathogenic Bacteria for Students of Medicine and Physicians. By Joseph McFarland, M.D. Fourth Edition, rewritten and enlarged. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

A Text-Book of Pathology. By Alfred Stengel, M.D. Fourth Edition, thoroughly revised. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

An American Text-Book of Surgery for Practitioners and Students. By various writers. Edited by William W. Keen, M.D., LL.D., F.R.C.S. (Hon.), and J. William White, M.D., Ph.D. Fourth Edition, thoroughly revised and enlarged. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

A Text-Book of Comparative Surgery, covering the Surgical Anatomy and Operative Technic involved in the Operations of General Surgery. Written for Students and Practitioners. By Warren Stone Bickham, Phar. M., M.D. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

The American Illustrated Medical Dictionary. By W. A. Newman Dorland, A.M., M.D. Third Edition, revised and enlarged. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

A Text-Book of Clinical Anatomy for Students and Practitioners. By Daniel N. Eisendrath, A.B., M.D. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co., 1903.

A Text-Book of the Practice of Medicine. By James M. Anders, M.D., Ph.D., LL.D. Sixth Edition, thoroughly revised. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

A Text-Book of Obstetrics. By J. Clarence Webster, M.D. (Edin.), F.R.C.P.E., F.R.S.E. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

A Dictionary of Medical Science. By Robley Dunglison, M.D., LL.D. Twenty-third Edition. Revised by Thomas L. Stedman, A.M., M.D. Philadelphia and New York: Lea Brothers & Co. 1903.

PARASYPHILITIC AFFECTIONS,

OR REMOTE EFFECTS OF SYPHILIS.[1]

BY ABNER POST, M.D., BOSTON.

In the opinion of Professor Fournier, syphilis is responsible not only for a multitude of manifestations undeniably syphilitic both in origin and nature, but also for a number of other manifestations which are not at all syphilitic in nature but are nevertheless syphilitic in origin; that is, they are produced by syphilis or under its influence. For these manifestations Professor Fournier has proposed the name *para*syphilitic, which may be understood to mean proceeding from syphilis without being syphilitic. The term remote effects of syphilis is explanatory but not exactly synonymous.

These manifestations demand attention for two special reasons: First, they are very numerous, and second, they in great measure defy treatment.

Under the name of parasyphilitic affections we must include: The pigmentary syphilide; acute hystero-neurasthenia of the secondary period; divers neurasthenic manifestations of a more advanced stage; hystero-epilepsy; tabes; general paralysis; a special form of epilepsy; and a special form of muscular atrophy, and, for hereditary syphilis: Numerous general or partial atrophies; organic malformations, notably dental malformations; arrest or retardation of development, physical or mental; infantilism, perhaps dwarfism; congenital inaptitude for life; rickets; hydrocephalus; certain cases of meningitis; perhaps certain cases of true epilepsy; certainly juvenile tabes. These manifestations are not cured either by mercury or the iodides.

Two principal characteristics seem to establish a well-marked line of demarcation between the affections properly called syphilitic and the parasyphilitic affections. Firstly, the parasyphilitic affections are not referred necessarily to syphilis as a cause, while the purely syphilitic affections never exist without syphilis as a cause. No mucous patch or gumma exists without a pre-existing syphilis. On the other hand, general paralysis, rickets, infantilism, although so frequently the result of an antecedent syphilis, can be produced by other causes independent of all syphilitic antecedent. Secondly, parasyphilitic affections are not influenced by mercury and iodide of potassium, as are the true syphilitic affections. That is to say, these drugs do not exercise upon them a repressive or curative action so manifest that one may use it as a criterion of syphilitic character.

To explain the different conditions of these two results of syphilis, the doctrine of toxines may be invoked, and one may say that the usual accidents of syphilis are the product of a microbe, while other possible remote accidents of the same disease are the result of a toxine secreted by that microbe. Whether this explanation is correct or not, the future alone can determine.

There is a syphilitic lesion of the skin which is particularly adapted to illustrate the parasyphilitic affections. This is the manifestation known as the pigmentary syphilide or as syphilitic vitiligo or leucoderma. It is impossible to deny the syphilitic origin of this manifestation, and yet, except for its location, the same lesion may be produced by divers morbid or perhaps physiological causes totally unrelated to syphilis.

By this name of pigmentary syphilide is designated a syphilitic manifestation which consists of pigmented spots upon the skin which have been preceded by no other eruption and which occur in the great majority of cases upon the neck. They occur in the course of the first or second year, and with rare exceptions only upon females. They form without pain or the slightest local symptom, and reach their fullest development in the space of two or three weeks. At this period they consist of a series of pigmented marblings, disposed without order, anastomosing for the most part and enclosing islands of normal integument; forming a sort of network or lacework with large meshes upon the neck. These spots present no other abnormality than the hyperpigmentation; they show neither redness, swelling, thickening nor desquamation. As to color, they vary from the faintest yellow to a dark brown. Very often they show simply the tint common to necks which have not been recently washed. When the bearers of them first notice these spots, they believe that their necks need washing, and it is only after various trials that they become convinced that the discoloration is really in and not on the skin.

Usually the enclosed skin, although it appears from its position to be deprived of pigment, is normal. The network of pigmentation may surround the neck evenly or be more marked in spots. Usually it is more marked upon the lateral surfaces. Rarely it is seen upon the upper part of the thorax or even on the face. Its persistence is great — a year or two, or even longer. It persists usually after other symptoms have disappeared and the patient has ceased to visit the physician, but it finally disappears.

These abnormalities in pigmentation constitute lesions which, derived from syphilis, do not belong exclusively to syphilis and which are refractory to antisyphilitic remedies. They serve as a type of the curious pathological conditions which are grouped under the name of parasyphilitic affections. In the adult, these phenomena, which it is proposed to call parasyphilitic, are mostly concerned with the nervous system. In their consideration it is not the intention to intrude in the least on the ground of the neurologist, but simply to complete the catalogue of parasyphilitic affections.

The first of the series of nervous phenomena is

[1] This paper is practically a condensation of Professor Fournier's book — but a certain freedom in the use of the material and certain comments and quotations from other sources make it impossible to call it simply a condensation. It was prepared originally as a lecture to the Fourth Class in the Medical School of Harvard University.

neurasthenia. These cases differ in nothing from ordinary cases of neurasthenia, with which syphilis has nothing to do. How, then, connect them with syphilis? Simply that they occur too often to be simply a coincidence and because the condition is sufficient to provoke the result:

(1) By the debilitating, depressing, anemic action which it exercises upon the whole economy;

(2) By the profound influence which it exercises upon the nervous system;

(3) And also by its action upon the mind in the terror and despair which it brings to some individuals.

It must be remembered that syphilis shows a predilection towards the nervous system. Of the cases of late syphilis, cases which may properly be called tertiary rather than parasyphilitic, because they are due to distinctly syphilitic lesions and are amenable to treatment, fully one-third are lesions of the nervous system. It is unnecessary to enumerate all the forms which neurasthenia may take — one of the most important to recognize is that which simulates tabes and may be designated as neurasthenia-pseudo-tabes. In it the patellar reflex, the pupillary reflex and the functions of the bladder are unchanged.

Syphilophobia. — The chronic forms of syphilitic neurasthenia are sometimes complicated by a special symptom. This is a hypochondriacal preoccupation known under the name of syphilophobia or syphilomania. There is a class of syphilophobiacs who have never had syphilis but only the fear of it. Of course the latter class is not included in this account.

There are certain syphilitics whose whole mind is concentrated upon one single object, namely, syphilis. They exaggerate its dangers and its possible consequences. For them syphilis becomes a disease which is never cured whatever one does, a disease which ends necessarily in the most lamentable catastrophes, such as caries of the bones, the destruction of the nose or paralysis. It is a monster which combines all the sufferings which may affect the human race. In this condition they see syphilis everywhere. Everything which happens to them is syphilis. Some go so far that even anatomical peculiarities hitherto unnoticed arouse their suspicion. The papillæ of the tongue become syphilitic growths. The lacunæ of the tonsils are syphilitic ulcerations. It is fortunate if to syphilophobia is not added mercuriophobia. In that case the unfortunate finds himself between two foes, if he escapes the one he will be the victim of the other. But this combination is rare; usually the syphilophobiac believes in mercury. Such manifestations are temperamental in some measure, occurring in excitable and apprehensive individuals. Sometimes, however, they prove to be the initial symptoms of graver forms of disease.

Parasyphilitic hysteria is simply a hysteria which manifests itself under the influence of syphilis as an exciting cause, but which is simply a hysteria like other hysterias. Syphilis plays the same rôle as in other hysterias does a traumatism, or an infectious disease. Such a connection between syphilis and hysteria has been observed by others than Fournier. Taylor writes:

"In some exceptional cases in women, a mild and temporary aberration of mind is observed in the form of hysteria, emotional disturbances, hallucinations, delusions and morbid impulses. In men there may be present mild or severe stupor, delirium and even mania."

The really important — the most important members of the parasyphilitic group as sequels of acquired syphilis — are locomotor ataxia, general paralysis and epilepsy.

The question in regard to tabes is no longer whether syphilis may cause it, but whether other infections or intoxications can also produce it.

In the article on General Paralysis in the *Nouveau Dictionnaire*, published in 1885, the word syphilis is not even mentioned in the chapter on Etiology. Since then there has been described a pseudo-general paralysis due to syphilis. Without discussing the question whether this division is right or not, the present reference is to true general paralysis, characterized by a prodromic stage, marked by certain changes of character — afterwards by a stage in which two orders of symptoms occur:

First. Symptoms called somatic: muscular trembling of the tongue, face, hands; modification of the handwriting; slurring speech; alteration of pupils, reflexes and gait; apoplectiform and epileptiform attacks.

Second. Psychic troubles; progressive enfeeblement of the intellect; diminution of the memory; either melancholy, depression, hypochondria or exaggeration of the personality, personal satisfaction, delirium of grandeur.

Finally, a terminal period of dementia, physical and moral decline, and death.

Whether syphilis has or has not any causal relation with general paralysis is the first question. Considering the frequency of syphilis in the antecedents of general paralysis, very widely different statistics, varying from 4 to 5 in 100 to 80 or 85 in 100, have been produced. The proper way to consider such widely varying figures is not to take the mean, but to consider the reliability and value of the different sets. Statistics which give only 4 or 5 cases of syphilis in 100 persons can hardly be of value, as the proportion of syphilis in the general population is larger than that. In Professor Fournier's opinion, at least 15 cases of syphilis will be found in any 100 males taken at random.

Professor Fournier draws attention to the frequent association between tabes and general paralysis; to the multiplicity of symptoms common to the two maladies; to the frequent combination of the two morbid types; to their similarity in evolution, in termination, in resistance to therapeutic agents. Such reasons seem to indicate that tabes and general paralysis are two topographical manifestations of one and the same malady. When it locates itself exclusively or predominantly upon the cord, it constitutes tabes; when it locates itself upon the brain, it constitutes general paralysis; when it affects both cord and brain, it constitutes a hybrid type, to which the

name cerebro-spinal tabes would be applicable. If these two diseases are so closely related that they are sometimes confounded, that they bid fair to be at some time united as simply different manifestations of the same pathological entity, they must have the same relations to syphilis as a cause.

Epilepsy follows syphilis frequently, or at least epileptiform attacks are symptoms in the evolution of a cerebral syphilis — as such they are the direct results of syphilis and to be classed with other tertiary lesions, but occasionally there occurs an epilepsy not conjoined with other syphilitic lesions, which Fournier believes should, in our ignorance of its true nature, be classed with parasyphilitic affections.

A curious form of progressive muscular atrophy described in 1893 by Raymond [3] deserves a place in this category. Clinically it is a progressive muscular atrophy of spinal origin tending to become general and differing from the classical cases in two principal symptoms, accentuated pains and localized paresis serving as prelude to the involvement of each muscular group. In four cases described by Vulpian and Raymond an antecedent syphilis existed in each.

Antisyphilitic agents exercise no influence upon the disease. In the only autopsy there was nothing specific; nothing which might not be found in cases perfectly free from syphilitic taint.

One case mentioned may be briefly summarized as follows: A young man of twenty-five contracted syphilis in 1874. He apparently recovered, but in 1883 was attacked by an ulcerating syphilide. In 1885 his nervous affection began under the form of lancinating pains in the right shoulder, which were taken for rheumatism. Soon afterwards appeared cramps and intermittent contractions in the fingers and hand of the right side. The action of writing became painful, difficult, almost impossible. In 1889 a new symptom, diplopia, appeared suddenly and persisted for two months. From that time the nervous affection was marked by two sets of symptoms: painful phenomena, consisting of lancinating pains in the posterior cervical region, the right arm and the shoulders; and paresis, almost paralysis, affecting divers localities; successive paralysis of all the fingers of the right hand, which began to grow thin; paralysis of the right vocal chord and a muscular atrophy gradually involving additional parts up to generalization. For a certain time the atrophy remained localized in the right upper limb and the posterior-superior region of the trunk. Afterwards it invaded the trunk, the left arm, the legs, the diaphragm, the muscles of the glottis. Little by little the patient was changed to a living skeleton. Dyspnea, dysphagia, aphonia, difficulty of mastication, followed, while the intelligence was preserved. He finally died of asphyxia, in April, 1890.

The autopsy revealed: Thickened medulla, atrophy of the anterior roots, profound alteration of the anterior cornua, with signs of a diffuse and intense vascular myelitis.

[3] Bull. et mém. de la Soc. méd., des hôp., Paris, 3 Fev., 1893.

There is also a series of affections which may at some time be included in the category of parasyphilitic diseases, though our knowledge of the relationship is as yet too small to make any such classification with certainty,— among which one may include the following:

(1) Diabetes, which occurs so often in relation with syphilis that it seems as though there must be something more than an accidental connection.

(2) Hemoglobinuria.

(3) "Auricular tabes," that sudden form of deafness which resists all treatment.

(4) Certain dermatoses of the tertiary period, described by Fournier under the name of Tertiary Erythema.

(5) Perhaps certain forms of buccal leucoplasia.

In the fetus, in addition to its own proper manifestations, syphilis produces troubles of another order — to which may be applied the new term parasyphilitic affections:

(1) It diminishes vital resistance.

(2) It hinders the development of the embryo.

(3) It gives place to certain failures to reach perfection.

One of the first effects of syphilis upon the products of conception is a polymortality. Of the children who thus perish, not all show actual syphilitic lesions. Many seem to die simply from inability to live; something that may be called *fetal cachexia* or an *inaptitude for life*. Hereditary syphilitics often die without having any anatomical reason for dying.

Upon many of the children that live we find a curious retardation in development. They are backward in growth, in the evolution of their teeth, in learning to walk, in the signs of puberty, in the growth of the beard. Every one knows that at adult age hereditary syphilitics remain, not always but often, little men and little women, reduced in all proportions so that at eighteen or twenty they seem like children. In one word, that which is called infantilism is one of the most characteristic traits of hereditary syphilis. In the same way hereditary syphilis may cause certain partial dystrophies of certain organs, as of the testicle, the breasts, the ovaries, or the bones; or of the brain, as in certain children of backward development, imbeciles and idots.

A good example of arrest of development in a single system is found in the dental malformations of heredo-syphilis.

In the first place there is a notable retardation in their general evolution, the milk teeth beginning to appear only at the tenth, twelfth, fifteenth month, or even later;

(2) Dental malformations, usually symmetrical, are very common, especially in the permanent set, of which the teeth known as Hutchinson's present the most characteristic and best-known example;

(3) Microdentism, or dental dwarfing, and

(4) Unusual vulnerability of the dental system are often observed.

Can infantilism go further yet and produce dwarfs? In other words, is heredo-syphilis the

cause of dwarfs? Fournier hastens to answer that he does not know, but without special research upon the subject two cases have come to his knowledge which seem to call for an affirmative answer.

His first case is one of a dwarf issue of parents who show nothing abnormal in figure, constitution or health. They are in easy circumstances, and all causes of depression are wanting. But the father had syphilis but a short time before he was married, and Professor Guyon believes it to be in all probability the cause of the child's deficient stature.

The second case is that of Bébé, the celebrated dwarf of King Stanislas I of Poland. When born he weighed about 15 oz., and his first cradle was an old shoe half filled with cotton. At fifteen he had attained his growth, and weighed nine pounds and a half. He died of senility at twenty-five. His intelligence was poorly developed. He could never be taught to read.

His skull, preserved in the Medical Museum in Paris, shows bosses upon the two parietals, the results of gummy osteomata, which correspond in seat, perfect symmetry and exact limitation to the two parietals exactly to the lesions of hereditary syphilis described and figured by Parrot.

These two cases would seem to show that the dystrophic influence of heredo-syphilis may be carried so far as to produce dwarfs — but certainly two cases are not sufficient to establish that proposition, and it may very well be true that if syphilis is a cause, it is but one of the causes which may produce dwarfs.

Fournier believes that syphilis constitutes one of the remote and occasional causes of certain congenital malformations — spina bifida, hare-lip, cleft palate, microcephalism.

Rickets is said to show itself with frequency in the subjects of congenital syphilis. Certainly rickets cannot be regarded as a late stage of hereditary syphilis as was claimed by Parrot. It occurs in animals and in children in whom there is no suspicion of syphilis. But syphilis may very properly be regarded as one of the predisposing causes of rickets.

So far only the arrest of physical development has been mentioned, but a possible consequence of hereditary syphilis consists in a similar arrest of intellectual development; certainly hereditary syphilis sometimes gives rise to veritable idiots.

Hydrocephalus is another pathological condition which sometimes owes its origin to hereditary syphilis. This assertion rests —

(1) Upon the frequency with which hydrocephalus shows itself in the issue of syphilitic parents. Fournier has himself observed more than thirty such cases in his private practice.

(2) In the family conditions under which hydrocephalus presents itself.

The following two cases are from Boerensprung:[3]

First case:

First pregnancy, infant born dead at eight months.
Second pregnancy, infant born dead.
Third pregnancy, infant born dead.
Fourth pregnancy, hydrocephalus, dead at five months.
Fifth pregnancy, stillborn.
Sixth pregnancy, syphilitic infant.
Seventh pregnancy, syphilitic infant.

Second case (14 pregnancies):

First, child born dead at seven months.
Second, child syphilitic, died at one year and a half.
Third, hydrocephalus, died at one year and a half.
Other pregnancies produced children either dead, syphilitic or apparently healthy.

The following is from Jonathan Hutchinson:

First infant syphilitic and hydrocephalic.
Second infant died at ten months.
Third infant born dead and macerated.
Fourth infant syphilitic and hydrocephalic.

Fournier has seen three hydrocephalic children in one syphilitic family.

Dr. F. Astors of Marseilles believes that there are two classes of hydrocephalic cases resulting from hereditary syphilis:

(1) Hydrocephalus of syphilitic nature, resulting from syphilitic lesions.

(2) Hydrocephalus of syphilitic origin, resulting from a disturbance of nutrition and coinciding with certain arrests of development in the brain.

It is this second class only that can be classed with parasyphilitic affections.

Meningitis is a frequent cause of death in syphilitic infants. Some of them are certainly syphilitic. They are in a measure amenable to antisyphilitic treatment, and, as shown by autopsy, they are due to syphilitic lesions.

In others no syphilitic lesions are found, and Fournier believes that they belong in the same category with the parasyphilitic affections.

The history of certain families is instructive in this connection, of which only two, the most striking, are given:

First family: Father and mother both syphlitic; first child hydrocephalic — dead; second child meningitis — dead.

Second family: Father syphilitic; mother healthy; twelve pregnancies. Third infant hydrocephalic; fifth infant stillborn; sixth — living — syphilitic, Hutchinsonian teeth, infantilism, — epilepsy at the age of fifteen, dementia paralytica; seventh and eighth abortions; eleventh deaf mute, epileptic and hydrocephalic; twelfth died of meningitis.

Little's disease (spastic paralysis, cerebral infantile paralysis) is also included in the category of parasyphilitic affections.

It is needless to describe this disease, but it is necessary to inquire as to the evidence that refers it to a syphilitic origin. Fournier gives two cases. In one the child was affected with spastic paralysis of all four members. He also bore evidence of hereditary syphilis, and his father also gave a history of syphilitic accidents.

In the second case the antecedent history of syphilis in the father was known. The second child was seen with typical Little's disease. The

[3] Die hereditäre Syphilis, Berlin, 1864.

first child, already dead, was said by the parents to have been exactly like the second, and their statement was confirmed by the physician who had charge of it.

Furthermore, Little's disease is the result of a lack of development in certain portions of the nervous system, and lack of development in other portions of the economy are absolutely common in hereditary syphilis.

It is interesting to see what has been said on this subject by the writers previous to the time when views embodying parasyphilis were brought forward.

Bradford and Lovett have devoted considerable space to Little's disease. Concerning its etiology, they consider together three groups of cases — hemiplegia, spastic paralysis, incoordination, or idiocy — under the one head of cerebral paralysis of children.

As a cause they reject difficult labor and injury from forceps.

They report from Little that a large number of these cases are born prematurely, and say that premature labor has not received due attention as a causative factor. Infectious diseases have presented several cases, and syphilis is mentioned as undoubtedly a cause.

By way of parenthesis, it may be added that syphilis is a frequent cause of premature labor.

To quote a paragraph from their section on pathology: "The pathology of the condition is, in short, a lesion of the motor tract of the brain with consequent atrophy and retarded development of the affected portion and descending degeneration of the pyramidal tracts and lateral columns of the cord; from the extensive atrophy found in young children at autopsy, it seems that unquestionably sometimes the disease originates in defective development of the nervous centers, especially the pyramidal tracts, rather than in an acute cerebral hemorrhage or embolism."

These authors lay particular stress upon two etiological factors — premature labor and defective cerebral development, both of which factors are very commonly to be referred to a common source, namely, syphilis.

A question of great interest is raised as to the possibility of hereditary syphilis causing the group of nervous symptoms already mentioned in the category of parasyphilitic affections due to acquired syphilis, or, in other words, does there exist a neurasthenia, an hysteria, an epilepsy due to hereditary syphilis as an exciting cause?

Our knowledge allows only an imperfect answer. In the first place, the study of late congenital syphilis is of very recent date, and the study of the relation of syphilis to the so-called parasyphilitic phenomena is but just begun.

Professor Kowalewsky of Charchow believes in a neurasthenia of hereditary syphilitic origin.

There are many cases of hysteria in the children of syphilitic parents, but the relation of cause and effect is not so sure. And, also, of epilepsy it may be said of certain cases in heredo-syphilitics that while many of them are due to syphilitic lesions, there are many others in which the convulsive seizures are the only symptoms, and in which it is impossible to say whether there are syphilitic lesions, whether syphilis is a provoking cause, or whether syphilis bears no relationship.

One can feel more certain as regards tabes and general paralysis. There are some very interesting cases illustrating the possible hereditary origin of tabes.

One case concerns a woman of thirty already profoundly ataxic. The tabes began about the age of twenty. She was free from all personal contamination of syphilis, but she furnished a series of particulars which left little doubt as to the existence of an hereditary syphilitic infection. Her father was said to have died from the effects of syphilis contracted as a young man. Her mother had had numerous premature births that various physicians had attributed to the disease of the husband. The patient was herself affected with a grave and chronic disease of the eyes at the age of three or four, which lasted fifteen to eighteen months, and from which an opacity of the cornea still persists.

Another case is from Remak, and relates to a case of tabes occurring in a child, certainly an hereditary syphilitic, of which the following is a summary:

Marie D., aged twelve, born of a syphilitic father and a mother who is now suffering from a frontal periostitis.

There have been eleven pregnancies, of which four were abortions, three children who died during the first year, three children survived, of whom Marie is the eldest. At nine there was an invasion of tabetic symptoms — incontinence of urine and later of feces, occasional loss of consciousness, occipital cephalalgia, ptosis, diplopia; at present, atrophy of the optic nerves, girdle pains, lightning pains, diminution of sensation to touch and to pain in the lower extremities, paresthesia, sensation of cold, abolition of the patella reflex, gastric crises.

It is only within the last years that we have concerned ourselves as to hereditary syphilis, *apropos* of the etiology of tabes. It will be necessary hereafter to ask information as to a possible inherited syphilis, as one nowadays asks for personal antecedents.

In regard to general paralysis, M. Regis has collected fourteen cases of general paralysis in youth (from thirteen to nineteen years). Of this number, six were derived certainly, and one, perhaps two, probably from hereditary syphilis.

The following case is taken from Clouston :[4]

Girl of fifteen years. Father syphilitic. Paternal uncle dead of general paralysis. Mother's paternal cousin insane, afterwards demented. Twelve pregnancies, three stillborn, three children dead, one of hydrocephalus and one of meningitis. Six children living, of whom one is a deaf-mute, epileptic and hydrocephalic. Personal antecedents: Habitual good health; intelligence good; indolent; typical Hutchinsonian teeth; breasts rudimentary; never menstruated; aspect infantile. From

[4] Edinburgh Med. Journ., 1891.

six to nine years, three or four epileptoid attacks annually. At about fourteen to fifteen, sudden loss of consciousness, followed by prostration for two days. Two other similar attacks just before the beginning of the disease. All at once diminution of activity, indolence, indifference, mental enfeeblement, afterwards hesitating speech, difficulty in walking and muscular weakness. Admitted to the Edinburg Asylum at the age of nineteen, with the following symptoms: Dementia paralytica without delirium, physical signs very accentuated; nystagmus; disseminated opacities of peripheral coroiditis, which Argyle Robertson considered a manifestation of hereditary syphilis; coldness of the extremities with varying color, red to blue; spots of gangrene with erysipelas upon the feet.

This must not be considered as a final account of the subject of parasyphilitic affections. It is only a first attempt. It may be necessary in the future to add to or subtract from it. Perhaps the chapter can never be fully written until the bacteriology of the disease is known and enables us to distinguish between diseases which are syphilitic by nature and those which are parasyphilitic.

Certainly the consideration of the remote effects of syphilis increases considerably the gravity of its prognosis and gives an additional reason for the more careful study of the disease and for more careful attempt to control or suppress it.

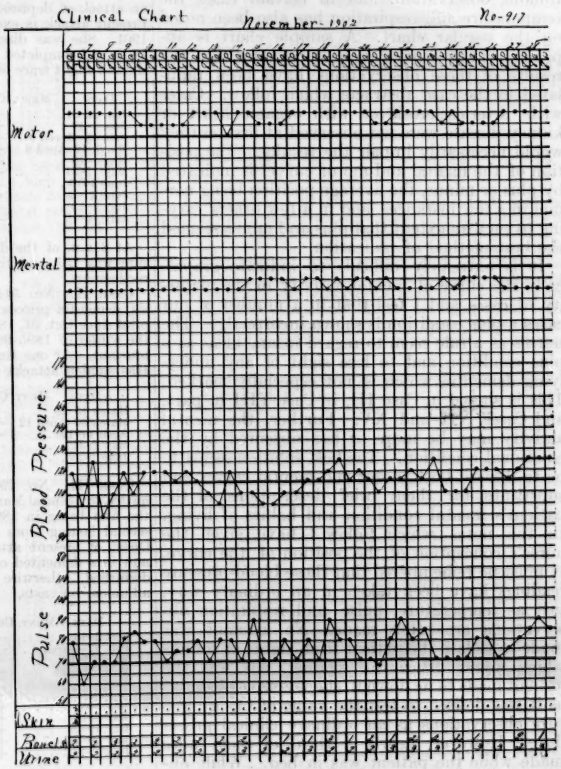
SOME OBSERVATIONS UPON BLOOD PRESSURE IN THE INSANE.

BY WILLIAM RUSH DUNTON, JR., M.D., TOWSON, MD.,

Assistant Physician The Sheppard and Enoch Pratt Hospital, Towson, Md.

THE literature on the subject of blood pressure is increasing rapidly, and much pleasure and profit might be derived from reviewing the major part of it, but I will resist the temptation and merely call your attention to certain articles which have a direct bearing on the results which follow. For a long time it has been conceded by some that the blood pressure was increased in depressive states and decreased in excited conditions. In 1900 Maurice Craig in an article entitled "Blood Pressure in the Insane,"[1] says: "We may now, I think, take it as accepted that in states of acute mania the blood pressure is low, whereas in the majority of cases of melancholia the blood pressure is raised; in other words, that with the affective disorders of the mind there is an alteration in the tonicity of the vasomotor system." Pilcz[2] reached the same conclusion, and in one of his cases of circular insanity the blood pressure varied from 60 mm. in the excited state to 160 in the depressed period. It has been found, however, that in agitated melancholia the blood pressure is low, and all the evidence seems to indicate that a low blood pressure in the insane accompanies motor restlessness. The article by Dr. Craig, from which I have quoted, and another by Dr. Henry L. K. Shaw[3] are two which I have found most interesting from the standpoint of the alienist. The latter contains a number of references to foreign literature, to several of which I shall direct your attention. Pilcz found the blood pressure normal in the early stages of paresis, but low in the terminal stage. Heim[4] found a high blood pressure in neurasthenics and hysterical children, and considered this a diagnostic point. The above references concern the points which will be of most interest to us in the consideration of the observations which form the subject of this paper. The other works to which Shaw refers deal with the effect of therapeutic measures upon the blood pressure, or with the history of the various methods of observing it.

Mention should be made of the investigations made at the Royal Asylum, Aberdeen, by Drs. Bruce and Alexander on cases of melancholia and of mania. Justice cannot be done to their work in a brief abstract, and I therefore append references to their published writings.[5]



Early in 1902 Dr. Harvey Cushing of the Johns Hopkins Hospital introduced to us his modification of the Riva-Rocci apparatus for determining blood pressure, and presented us with an instrument. Dr. Cushing's modifications are merely mechanical, and do not affect the principle of the apparatus. I wish to especially call your attention to the convenience of the Riva-Rocci instrument. Shortly before we began using it we were having constructed the elaborate apparatus of Mosso, which one might say requires a room to itself, and has as another disadvantage to its use that a number of patients are in no condition to be brought to this room. A number of those that might be would endanger the rather expensive apparatus. The form of the Riva-Rocci which we have used we have put together ourselves, and I am sure that three dollars will quite cover the cost of each instrument. It consists first, of a narrow rubber bag with linen covering with hook and loops, by means of which it is secured about the patient's arm. This bag communicates by rubber tubing with one arm of a glass T inserted in the cork of a wide-mouthed bottle, which latter is partly filled with mercury, and which has a straight glass tube with millimeter scale attached also passing through the cork, and from this the degree of pressure is read. The other arm of the above-mentioned T is connected by rubber tubing with a pressure bulb, such as is used on a Paquelin cautery. There is also a branch from the first tubing closed by a pinch cock, by means of which the air is allowed to escape from the instrument after the observation has been made. To operate the apparatus, the arm band is fastened about the patient's arm above the elbow, the radial pulse is palpated, and air is forced into the apparatus by means of the pressure bulb. The height

of the column of mercury at which the pulse disappears is noted, the pressure carried slightly beyond, the air slowly allowed to escape, and the height of the column of mercury at which the pulse returns is noted, and the mean of these two observations gives us the systolic pressure. Some observers only note the point where the pulse disappears, others only the point where it reappears. Either is correct, but taking both secures accuracy. Recently Dr. Cook [6] has described this instrument in a less homemade form, and discusses its manipulation very fully.

Stanton [7] has devised a very similar apparatus, which seems to have certain advantages over the Riva-Rocci, though practically differing from it only in the width of the arm piece and in using a foot pump to obtain the necessary air pressure. By means of his apparatus he is able to obtain both the systolic and diastolic pressures, and from them calculate the mean pressure. I have tried his method with the Riva-Rocci apparatus with an assistant at the air pump, but was not able to obtain satisfactory readings of the diastolic pressure, due, I think, to the narrow arm piece, which Stanton considers the great defect of the Riva-Rocci apparatus. Jackson [8] has compared the Riva-Rocci with the Gaertner, and finds that they give uniform results except in cases of arteriosclerosis, where the former instrument reads too high. In regard to the presence of arteriosclerosis as a complicating factor I wish to call your attention to a very interesting article by Dr. Clifford Allbutt, on "The Rise of Blood Pressure in Later Life," [9] in which he says: "In sufferers from arteriosclerosis — I use the name arteriosclerosis loosely for present convenience — exorbitant pressures are often but by no means constantly found. Between disease of the arterial tree and blood pressure there is no direct relation in arterial disease, even in the extreme degree of it normal or relatively low pressures are commonly observed; but I often notice that in cases of arterial degeneration the reading extends uniformly over a wider range of the scale, say, over 15 or 20 units, in which cases I record the mean figure and the extremes. In denying that elevation of blood pressure depends directly upon arteriosclerosis, I have stood alone for some years against the high authority of Von Basch and many others; but I think that some recent observers now admit the validity of my contradiction, and the matter is one of cardinal importance."

Since our introduction to the Riva-Rocci instrument we have taken a great many blood-pressure observations with a view of determining the value of such observations in mental diseases both as an aid to diagnosis and to treatment. It is the object of this paper to present the results which we have hitherto obtained. At first a number of single observations were made on a number of patients, but we soon realized that by such methods accurate results could not be obtained, and it was thought if we

Showing blood pressure, motor and mental chart reduced four times. Since the preparation of this paper, these charts have been amended so that the lines above and below the normal (motor and mental) lines signify a definite condition (quiet, restless, excitement, etc.), but so far an entirely satisfactory arrangement has not been obtained.

[6] Journ. Amer. Med. Assoc., vol. xl, p. 1199, May 2, 1903.

[7] Univ. of Penn. Med. Bull., February, 1903.

regularly measured the blood pressure of several cases during the whole course of their mental alienation with the changes which probably took place as recovery, or other change occurred, that we would have more instructive and more accurate data. It will be remembered that the Riva-Rocci apparatus shows the systolic pressure, and this, I think, serves our purpose sufficiently well.

As we did not wish to go to the expense of having charts for blood pressure made until we became satisfied with the form, we have used square ruled paper, which the nurses have divided as indicated. Also, for convenience, the observation has been recorded on a scale of fives, which gives approximate results. Should we consider the plan hitherto pursued sufficiently valuable to continue, we will have the blood pressure scale divided into millimeters. We have had charts made of the blood pressure, mental and motor condition, the condition of the skin, and the pulse in all the cases which have been under continuous observation, and in certain cases the temperature and respiration has also been noted on the regular chart. A sample chart is appended. For convenience of consideration the results of these observations have been tabulated in the case abstracts which follow. Cases with arteriosclerosis or with organic heart or kidney disease were not observed at first, as they would necessarily impair the results. The position of the mental and motor curves is indicated by plus or minus, the average position being normal in a few instances, and in a few others varying to such an extent that plus and minus seemed the best method of indication.

It is extremely difficult to indicate graphically the curve of mental activity in the majority of cases, and I feel that in a number of our cases a plus condition is shown incorrectly. The nurses as a rule seem to regard insane ideas as a plus condition and to lose sight of any underlying dementia which is not especially marked. This is shown in Case III, in Case VIII in part, and Cases XII and XV. Further, the mental activity may be more or less obscured by the emotional condition. The best solution seems to be to discard both motor and mental curves and substitute for them brief descriptions of the patient's mental condition and habits of living. In the notes which follow I have given the nurse's conception of the position of the curve. It must be remembered that these blood-pressure readings have been taken in an ordinary way, just as temperature, pulse and respiration observations are often made. No attempt was made to isolate the patient from sights or sounds which might affect the reading, nor was the patient made to lie down if she was up and about, as it was desired to test the value of blood pressure observations as an ordinary clinical procedure. However, nearly a third of them were made while the patient was in bed. While observers differ as to the effect of posture on the blood pressure, the consensus of opinion seems to be that we find a higher blood pressure when the patient is in a sitting position than in a recumbent one. The factor of posture may be ignored in a given case when all observations are made when the patient is in one position, that is, either sitting or lying, but in comparing cases this factor should be considered. One conclusion to which we came was that the continuous taking of the blood pressure has but little value in the majority of mental cases, and the plan has been adopted of taking it for a limited period, then discontinuing it and taking it again for another period whenever we felt there was a change in the motor or mental condition of the patient. I believe that the average of a week's observations give as accurate a measure as when they are continued for a longer period. Frequently the first two or three observations are higher than the others, due possibly to an element of fear in the patient, so that I am not satisfied that one or two accurately show the blood pressure.

CASE I. No 824. Woman aged twenty-five. Had an attack of depression September, 1897, to May, 1898. Present attack is excitement, and began about May 10, 1901. She was discharged from the hospital July 19, 1902, and completed her recovery at the seashore. Urine showed slight trace of albumen, no casts. Heart normal.

CASE III. No. 798. Woman aged twenty-six. Admitted to hospital March 29, 1901. Present is third attack, the first being in 1890 and lasting several months, the second lasting from October, 1892, to December, 1893. Onset of present attack was about Dec. 25, 1900. Is now in a demented condition. Heart rhythm somewhat disturbed, otherwise negative. Urine showed trace of albumen, no casts.

CASE IV. No. 924. Woman aged forty-one. Admitted to the hospital April 24, 1902. Shows depression and mental confusion with a good deal of motor excitement. Patient had a similar attack at twenty-one years, lasting three months. Had been mentally unstable ever

since. Her present illness began eleven days before admission.

Patient was discharged Feb. 3, 1903, much improved.

CASE VI. No. 977. Woman aged twenty-seven. Has appearance of being ten years younger. Patient had typhoid fever at fifteen and twenty-four. Was brought to the hospital Sept. 27, 1902, from Danville Sanitarium, where she had been since March, 1902. Is in condition of incomplete dementia, with attacks of sudden violence. Heart negative. No arteriosclerosis.

CASE VIII. No. 946. Woman aged fifty-one. Admitted to the hospital June 16, 1902, after attempting suicide. Mental symptoms had been noticed five weeks before admission. Had transitory delusions. Was depressed, restless and emotional, and at times much confused. Patient improved quite markedly up to a certain point where she had frequent emotional attacks, and begged to go home. Heart negative. No arteriosclerosis. Urine showed a trace of albumen, no casts.

The following abstracts are from cases in which the blood-pressure observations were not carried over so long a period, and have been taken usually in cases which were not so recent or were not undergoing any marked changes, or in other words, were more or less stationary.

CASE XV. No. 655. Woman aged thirty-four, has been under care since Dec. 30, 1899. Is a well-marked case of dementia precox, with considerable motor activity. Is usually elated mentally. Heart negative. No arteriosclerosis. Urine negative. Blood pressure observed March 24–30, 1903, averaged 122.7 mm., the mental, motor and pulse curves all being plus.

CASE XVI. No. 905. Woman aged twenty-two, admitted March 18, 1902. Case is one of well-marked dementia precox, with sudden impulses. Heart shows mitral stenosis, which improved while she was under care. No arteriosclerosis. The day of admission patient's blood pressure was 140 mm., and six days later was 146 mm., the patient lying quietly in bed on both occasions. Her mental condition was depression. Blood pressure

[10] Anton G. Ueber Gehirner krankungen mit Katatonie. Mittheilung des Vereins der Aerste in Steiermark, 1902.

observed March 1–15, 1903, averaged 124.4 mm., motor and mental curves both being plus.

CASE XVII. No. 78. Woman aged fifty-six, has been in the hospital for ten years. Original diagnosis chronic mania but now in a condition of incomplete dementia. Heart negative. Arteries somewhat sclerotic. Urine shows trace of albumen and a few epithelial casts. Blood pressure taken March 8–14, 1903, averaged 139 mm., motor and pulse curves plus, mental minus.

CASE XVIII. No. 380. Woman aged forty-seven. Case of imbecility with marked auditory hallucinations causing considerable excitement. Has been in hospital six years. Heart shows systolic murmur transmitted to the axilla. No arterio-sclerosis. Urine shows trace of albumen. Blood pressure taken March 8–14, 1903, averaged 142 mm., motor, mental and pulse curves all being plus.

CASE XIX. No. 1010. Woman aged forty-six, admitted Jan. 15, 1903. Her attack began suddenly May 16, 1902, following death of her child, the patient being much run down from nursing. The first symptoms were excitement, followed by depression, which was in turn followed by a confused, agitated condition, during which she was brought to us. She at present (April 11) has improved slightly both physically and mentally. Heart negative, no arteriosclerosis. Urine negative. Blood pressure observed March 8–14, 1903, averaged 121.5 mm., motor and pulse curves being plus, the mental minus.

CASE XX. No. 947. Woman aged fifty. Admitted June 20, 1902, depression having become marked about two months before admission. Somato-psychic delusions early became prominent, and at present are the most marked symptoms. Heart shows no murmurs. Arteries are diffusely sclerotic. Urine shows a trace of albumen. At one time pulse was high tension and a course of nitrates and nitrites caused a marked change without, however, any accompanying mental change. Blood pressure was taken for the first week of March, 1903, and averaged 140 mm., motor and mental curves both being plus.

CASE XXI. No. 959. Woman aged twenty-one admitted Aug. 3, 1902. The silliness of dementia precox is most marked. At admission was in a condition of excitement, which has since subsided. Heart shows slight systolic murmur transmitted to axilla. No arteriosclerosis. Urine negative. Blood pressure observed from March 26 to April 2, averages 124.3, motor curve being plus, mental minus.

CASE XXII. No. 908. Woman aged sixty-nine, admitted to the hospital Sept. 2, 1899. Is an involution case with slight dementia. Heart and kidneys negative. No arteriosclerosis. Blood pressure observed from March 1–17, averages 127.69, motor curve is plus, mental minus.

CASE XXIII. No. 908. Woman aged forty-four; a case of epileptic insanity. Dementia is very slight. Heart shows systolic murmur transmitted to the axilla. Urine negative. No arteriosclerosis. Blood pressure observed March 1–7, averages 132.2, motor curve plus, mental minus.

CASE XXIV. No. 936. Woman aged fifty-six. Case of melancholia "agitata." Heart negative. Urine shows trace of albumen. No arteriosclerosis. Blood pressure observed March 24–30, averaged 131.6, motor curve plus, mental minus, pulse plus.

CASE XXV. No. 1031. Woman aged forty. Recurrent melancholia. Had previous attacks six and four years ago. On admission was depressed with marked motor activity. Under treatment has improved. Heart negative. Urine shows trace of albumen. Slight arteriosclerosis. Blood pressure has gradually fallen from 140 to 120, averaging 127.6 for the three weeks observed. The motor curve has gradually fallen and the mental curve has gradually increased.

While on following down the blood pressure column I am unable to find the point where there was any change sufficiently marked to be noticed, which corresponds with any mental change and on going over the charts I am also unable to find any constant ratio, either direct or indirect, between the motor, mental and blood pressure curves, nevertheless I feel that these observations have their value, and in the data given above we find the general ratio is usually the same as that found by other writers; namely, that the average blood pressure is low in motor restlessness, or in mental excitement, and high in depressive conditions, or in cases where there is diminished mental activity. The blood pressure depends on so many factors that it is not surprising if we find occasional cases in which it does not accord with the usual observations. Some other factor which we may have overlooked may have caused the changed ratio, or our own observations may be at fault. For example, in certain cases with mutism I have had great difficulty in deciding whether there was increased mental activity or not.

A dry and moist skin seems to have no effect, and I think that the cases observed by Kornfeld[11] must have been actively perspiring to have had any marked influence upon the blood pressure.

Schaeffer and a number of others have observed that blood pressure was lower in the evening than in the morning, and have considered this a physiological variation. One writer gives this daily physiological fall as the reason that patients suffering from depression usually feel better at night, and the maniacal patients are usually worse. In our own observations the daily variation has been very inconstant. The morning and evening observations have frequently been the same, and the evening pressure has been higher than the morning quite as often as the reverse.

Briefly the conclusions based upon the present study may be stated as follows:

(1) The findings of other writers that (*a*) the blood pressure is increased in depressive states and decreased in excited states; and (*b*) that the motor condition has a greater influence on the blood pressure than does the mental condition, have been confirmed.

(2) A moist skin has no especial influence upon the blood pressure, although active perspiration may.

(3) There was no constant daily variation, as has been noted by Schaeffer and others.

I feel that further conclusions are not justified by the cases presented here and others which are in a too incomplete state to justify publication. This paper will have fulfilled its mission if others are stimulated to observe blood pressure.

Too much importance should not be ascribed to this symptom. Its accurate observation has its value, and will probably have a greater value later when we have a better knowledge of how it is influenced by various bodily conditions. The general clinicians are adding to this, and we should do our part by observing how it is influenced in mental affections.

THE FORMATION OF LOOSE CARTILAGES IN THE KNEE JOINT.[1]

BY E. A. CODMAN, M.D., BOSTON.

If I should ask each one of you for a definition of "loose cartilages in the knee joint," I should probably receive a number of replies, each one of which would have able arguments to sustain it. In the first place, many would consider that "loose cartilages" referred to injured or displaced semilunar cartilages, but it is not to these that I wish to call your attention. It is on the formation of the "joint mice," cartilage-like bodies, varying in size from that of a small bean to that of an oyster, and being either free in the joint or held by a pedicle or light adhesions to the capsule. Such bodies are common enough and in many cases cause little or no trouble, while in others much annoyance is produced by locking of the joint and the production of a chronic synovitis. When this condition is reached, the patient usually comes to operation, a small incision in the capsule is made, and the mouse popped out. The result is generally a perfect cure. Now what is the origin of these bodies? There seems to be a prevailing impression that the process of formation is one of concretion comparable with the formation of biliary or cystic calculi. The nucleus is guessed to be a clot of fibrin, a bit of torn fringe or a fragment of semilunar cartilege. Another common explanation is that such bodies are originally osteophytic growths on the lips of the articular surfaces, and when broken off become "mice." Finally, certain cases have been considered actual bits of articular cartilage set free by trauma. It is this latter theory which seems to me to clearly account for the vast majority of cases, although here and there a case from one of the other causes may occur. Until I took the pains to look up the question, I had supposed that this explanation was original, but I find that it has been frequently offered before.

The observations which suggested this theory to me were as follows: In 1895, when assisting at an operation on such a case, I noticed on the face of the articular surface of the internal condyle, a stellate star in the cartilage which was somewhat smaller than the mouse, but was of the same rough shape and suggested the site of origin. Since then I have, at every opportunity, in the cases of other surgeons, looked for this scar and have frequently seen it, even when the operator himself had not. In 1900 I had a case of my own in which I demonstrated that the mouse nearly fitted its bed in the internal condyle. The case which I have to show tonight, however, demonstrated this even more conclusively, for one of the four mice which I removed was still attached like a little trap-door; another fitted its former bed exactly; and a third resembled an old scar, but was too big for it. These four mice are numbers 2, 3, 4, 5 in the accompanying illustration, and show very clearly the stages of the growth. In 2 and 3 there is as yet no concretion, while in 4 and 5 the concretion has surrounded the cancellated bone. In all these, and in fact in the great majority of such bodies, you will see that one side is of cartilage and the other of modified spongy bone. The specimens on the card are dried and the cartilage is yellow and shrunken, but in the fresh or alcoholic specimen it is white and convex. I will pass about some alcoholic specimens from the museum.

It occurred to me to try experimentally on a cadaver to knock such a chip out by a sharp blow. If you will flex your knee you will see that the patella protects the external condyle almost completely, but that the internal cartilaginous surface is exposed to violence. I found, however, in the cadaver, that a blow merely dented in the articular surface in just such a manner as a fragment is depressed in a skull fracture. With a director this fragment can be easily pried out. In every case it brings with it a lamina of spongy bone. The skiagraphs of such pieces are shown in Figs. 1 and 6. How nearly these pieces resemble the essential structure of the loose cartilage is seen by comparing in order Figs. 1, 2, 3, 4, 5.

The life history of the loose cartilage, then, must comprise two injuries, one to depress it and one to free it. As a matter of fact this is often the case, though frequently the first injury is forgotten. By the first, a line of demarcation from the injured bone is made, and we must suppose that this demarcation is retained either by necrosis of the injured trabeculæ, or perhaps by a limited callous formation. Also after the osteo-cartilaginous chip has become free in the joint cavity, we must account for its continued growth. The fact that sections show that the cellular elements still stain in these bodies would at least indicate that they are alive, though not that they are capable of laying down new bone. Barth explains this growth by the very rational hypothesis that adhesions are formed with the capsule. As a matter of fact, this is often true. This condition was found in the fourth mouse in the patient before you.

Torn or displaced semilunars do not show in the x-ray. Such bodies as I have been referring to do, however, for they consist in part of bone. I will pass about a skiagraph taken before the operation of the left knee of the patient before you.

The practical surgical point to be learned from all this is, that in these operations the articular surface of the internal condyle should, if possible, be inspected. This patient would not have been permanently cured had I not done so.

EXPLANATION OF SKIAGRAPH 1.

Fig. 1. Osteo-cartilaginous chip removed from a knee joint of a cadaver by striking a blow with a mallet on the articular surface of the internal condyle, and prying out the depressed portion with a director. The cartilaginous portion does not show, but the bony trabeculæ which closely adhere to it give a characteristic appearance.

[1] Read at the Annual Meeting, Suffolk District Medical Society, April 25, 1903.

Figs. 2, 3, 4, 5 were removed from the patient shown at the meeting and are seen in the joint in Skiagraph 2. No. 2 was still attached like a trap-door. The base of its bed was of bare cancellated bone, and its own structure was apparently normal. It was the homologue of Fig. 1, which was removed experimentally. No. 3 was an exactly similar bit which was free in the joint, but filled its former bed. Its trabecular structure is somewhat less distinct than that of No. 2. Fig. 4 was too large for its bed, which had been partly healed in by cartilage. It was a typical joint mouse with one face of cartilage and the other of bone. The bony face had increased at the edges and had grown over on the cartilaginous face as if to bury it. This new growth is shown in Fig. 4 as an irregular concentric deposit about the original trabeculated bone.

Fig. 5. The fourth piece was found adherent to the capsule in the external cul de sac. By comparison with Fig. 4 the central trabeculated portion can be made out, but the structure has been much changed. The new concentric formation is denser than the original portion, and forms a dark ring about it.

Fig. 6 is a cross section of a bit similar to Fig. 1. The concave portion is cartilaginous and shows faintly.

Fig. 7. The x-ray of a median transverse section of a large specimen of a joint mouse from the Warren Museum. It had evidently been cracked in the middle, as had No. 4. On the under side the outline of the cartilaginous portion does not show, and on the edges one sees the bony portion tending to cover in the cartilage. Between, at the base of the cartilage, is a faint dotted line which probably represents the old trabeculæ originally torn off with the cartilage.

NOTE. — In addition to these specimens a number of others were shown, illustrating a series, from a chip in which the cartilaginous and bony faces were of equal size to one in which the bony portion had entirely infolded the cartilage. The latter had a clinical history of twenty-five years' duration.

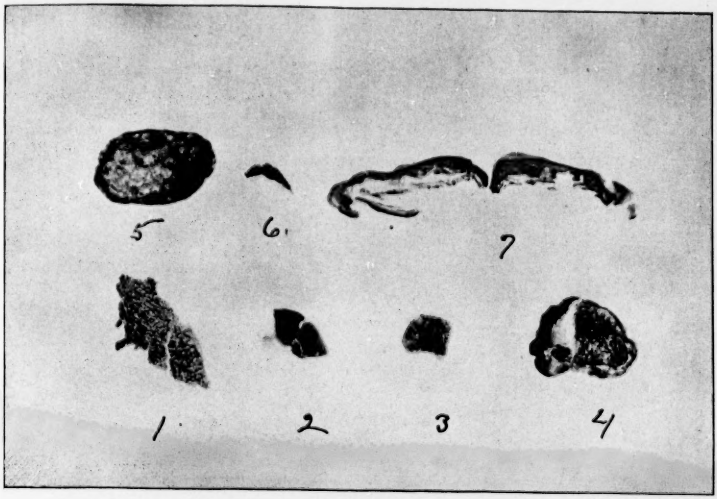
EXPLANATION OF SKIAGRAPH 2.

A skiagraph of the knee from which the bodies shown in Figs. 2, 3, 4, 5 were taken. No. 2 is probably the one seen directly between the joint surfaces. No. 5 probably lay behind the bone and does not show at all in this plan. The portion of the joint where No. 2 lies is the exposed portion in flexion.

Clinical Department.

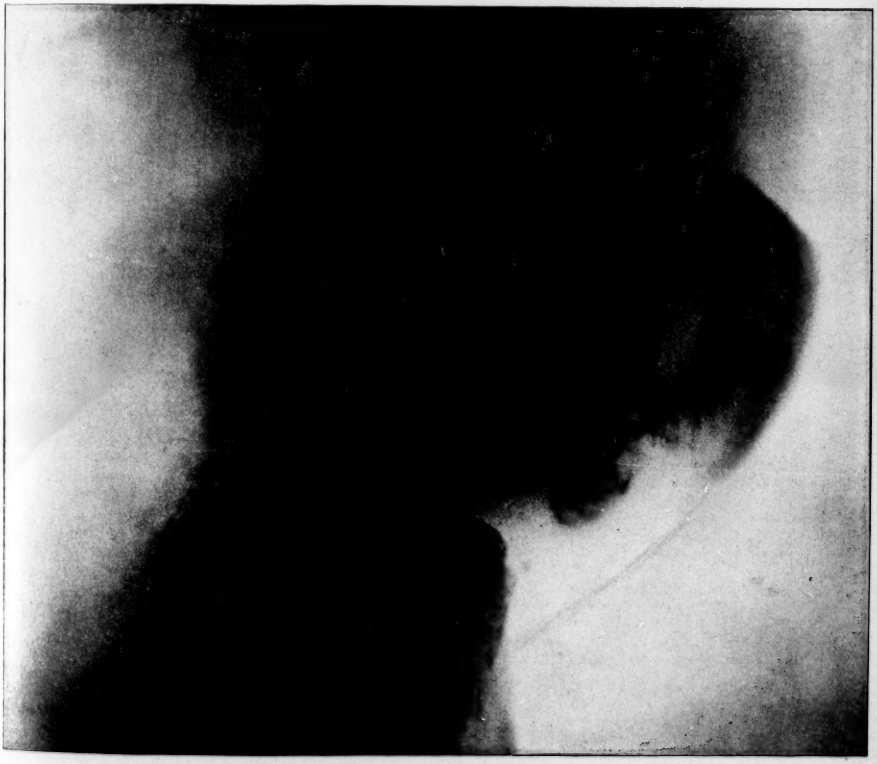
CLINICAL MEETING OF THE STAFF OF THE MASSACHUSETTS GENERAL HOSPITAL, APRIL 10, 1903.

The President, DR. J. COLLINS WARREN, in the chair.



GANGRENE OF TESTICLE.

DR. ARTHUR TRACY CABOT reported and showed a specimen of a case of gangrene of the testicle due to torsion of the cord. Patient was a young man of thirty-six, who had never had any injury or difficulty of a genito-urinary nature. He was taken suddenly without apparent cause with pain in the center of the abdomen, just above the pubes. This occurred in the early forenoon, and was so severe as to oblige him to go to bed. Later in the day, however, the pain diminished, and he got up in the afternoon, and the following morning went down to business. He was soon forced to return home, at that time having very severe pain at the right inguinal ring and in the right testicle. A swelling began to appear in the right side of the scrotum, which simulated and was believed to be due to an epididymitis. After two days the inflammation in the skin covering that side of the scrotum and an indisinct sense of fluctuation led to the belief that there was fluid, probably purulent, there, and I saw the patient. The pain at that time was not very marked. Hot antiseptic fomentations were applied, and the following morning, the condition not being materially changed, operation was advised. On cutting into the scrotum the tissues outside the tunica were edematous and thickened. On opening the tunica a little bloody fluid escaped and the testicle was then seen to be black in color. This condition was found to be due to strangulation of the cord due to one complete rotation of the testicle, rotation being from within outward. The mesorchium was not long in this case, and there was no adhesion or holding the testicle in its twisted position. It was difficult, therefore, to see why the twist had occurred. The cord was tied off through the healthy part and the testicle removed.



Dr. Cabot also reported a case of almost complete anuria which existed for three weeks, due to calculous pyelitis, and which was entirely relieved by operation. The case will be reported in full later.

DECORTICATION OF THE KIDNEY.

DR. E. G. CUTLER had shown a year ago, through the courtesy of Dr. Cabot and Dr. Elliot, three cases of decortication of the kidney. One that Dr. Cabot operated on was a woman of middle age, who looked as though she was fifty years old. She had all the symptoms of nephritis, and it was diagnosed, from examination of the urine, as glomerulo-nephritis. The operation was done by Dr. Cabot. She improved, and left the hospital July 12, tolerably well. She came back in October with the following history: The patient was somewhat pale. Examined hemoglobin, and it was found to be insufficient. She had been doing ordinary housework every day, and felt well, but about a month before she came to the hospital she had some swelling of the abdomen. We do not know whether this was due to fluid or gas. There was found to be $\frac{1}{8}\%$ of albumin in the urine. The urea does not

SKIAGRAPH No. 1.

SKIAGRAPH No. 2.

seem to have been estimated. There were a few waxy casts, many highly granular cells, with fat drops adherent, a few red blood corpuscles and compound granular cells. The woman said that she had been feeling perfectly well, as well as she had ever been in her life, but I doubt that. She had been an absolute invalid two years before the operation. She says that she did all her work up to the 1st of October, and since then she has been all right. When we last saw her she said she was better than she had been in a long time.

The next case of decortication which he spoke of was one which had improved until last June, operation by Dr. Elliott. Then the patient commenced to have the old symptoms, which gradually increased, and he died with the symptoms of a chronic nephritis. At the postmortem examination it was found that the capsule of the kidney had been entirely replaced. There was just as much of a capsule as there had been previous to the operation, and I understand that Dr. Wright said if the capsule had not been taken away at the operation he would say that he saw the original capsule of the kidney before him. The same condition of the kidney was seen at autopsy as was observed at the operation, so that the operation did not permanently help the patient. The disease went on, grew gradually worse and the patient died. It is obvious from this that if a patient does not continue to improve at the first operation of decortication, it is no more than fair to give him the benefit of a second operation.

The third case was that of a boy who had post-scarlatinal nephritis, of eight years' duration. Operation was done by Dr. Elliott. The boy improved, and the last time we saw him in the hospital was the 31st of October. At that time he is said to have had headache, and occasionally he had to rise three or four times in the night to make water. Examination of the urine showed a specific gravity of 10.30, with the slightest possible trace of albumin; 17.5 drachms of urea. The sediment showed one brown granular cast, a few red blood corpuscles, a few squamous cells and some leucocytes. The boy is here and seems to be perfectly well. When he first came he was thin, pale and bloated, but he does not look very ill now. Both kidneys were operated on in this case. He is going to night school and working around in the day time. We have given him instructions about diet.

CHRONIC GOUT.

DR. CUTLER then showed a case of chronic gout. He was a butcher or butcher's helper, and he had the characteristic symptoms of gout in the hands and feet, and had some in his knees. His fingers and feet were distorted. Ulcerations about the finger joints are spoken about in some of the English works, and he did have a number of such ulcerations, from which there came out urate of sodium crystals. Please note this finger, which is so distorted; some of the tophi on others are very well marked. He has a number of tophi in his ears. There are some x-ray pictures in the adjoining room which show the worm-eaten appearance of the bones. In the bones of the last phalanges you will see that same appearance. When he first came in there were a large number of these crystals which were coming out from the ulcerated places in all directions. He has improved very much since being here. We placed him on the proper regimen and the fingers have come out very nicely. I show him because it is the only case of the kind I have had since being in practice. I saw one case in England. All the books speak of it as if it were a not rare thing to see such fingers, but it is not so here. His feet show changes analogous to those in his hands, and show a deposit of sodium urate crystals in the cartilage and capsules of the joints, in the sheaths of the tendons, and in some of the tendons themselves. The patient's condition has continually improved since coming in here. He is under the ordinary treatment.

OBSTRUCTION OF INTESTINE.

The other case Dr. Cutler showed was the result of an operation for obstruction of the intestine. The history was as follows: Constipation, gradually increasing and finally attended by colicky pains. Then gaseous swelling of the abdomen, an enormous amount of peristalsis and finally vomiting. When he first came into the hospital it seemed obvious that he had chronic obstruction, and from indications present it seemed to be largely in the small intestine. Operation was deemed advisable. It was thought to be of sarcomatous nature. The operation was done by Dr. Elliott, and it was found that the tumor was low down in the small intestine. There was hypertrophy of the muscular tissue and infiltrated growth of the mucous membrane. Dr. Whitney found on examination that it was of a sarcomatous nature, and very kindly has given us a slide which shows the characteristic appearance. This tumor grew from the side of the intestine and looked very much like a stopper of a bottle, and it occluded almost entirely the gut.

DR. PORTER stated that the patient was doing very well now.

In answer to Dr. Cabot's question about the diet, Dr. Cutler said that the patient was given a liquid farinaceous diet.

DR. CUTLER. The man who writes the article on the kidneys in Allbutt's "System of Medicine," speaks of the great increase of urine which results from cutting out pieces of the kidney in animals, and after operations on the kidney in human adults. I do not see why it should not be a reasonable thing to do an operation such as decortication. Patients certainly seem better for a time, whether it be from the bleeding or ether or from other cause. I should think it might be a fairly good procedure to try when ordinary medical treatment does not seem to do any good. Surgical treatment does not do any harm. The patient will die anyway if left alone, and the surgical operation apparently

does no harm and sometimes does some good. I should think it might be useful in those cases which do not seem to improve under ordinary treatment after several months. It seems to me a reasonable thing to do.

DR. A. T. CABOT said that it was interesting to notice that the case just alluded to by Dr. Cutler had the clinical appearance of parenchymatous nephritis rather than of an interstitial nephritis. It was, therefore, not one of the cases in which it was claimed decapsulation was likely to be of service, and yet it had derived very evident benefit from the operation. Dr. Cabot said that since he last reported on this subject he had had one other case, also one of parenchymatous nephritis, in which the operation was done rather at the urgency of the family than because the case seemed proper for surgical interference. It was carefully explained to the people that the condition was not one in which improvement from the operation was to be expected as far as could be judged from clinical symptoms. They, however, wished to have the attempt made, hoping that the unexpected might be fortunately accomplished. In this case, there was no apparent result from the operation; patient bore it well; suffered no detriment from it, but afterwards went on slowly failing, and died some months later.

DR. C. A. PORTER showed the following cases:

PANCREATITIS. OPERATION. RECOVERY: 1. ACUTE PANCREATITIS.

Simon Pinaski, aged thirty-six, Russian, entered the hospital on October 30, 1902, in Dr. Warren's service, complaining of dull pain in the right hypochondrium for the past seven years, with chronic constipation. One week before entrance he was seized with a very sharp pain in the epigastrium, later localizing itself in the right iliac region. Pain was very severe. No vomiting, no jaundice, no chills. Bowels moved the last two days. Examination of the abdomen: quite tender in epigastrium and especially in region of gall bladder, where the resistance is marked. No tenderness in iliac fossa. Under rest in bed and poultices the symptoms abated, and he was seen by Dr. Shattuck on Nov. 5, who found nothing pathological. Between that time and Feb. 17, when he entered the accident room again, he had had five attacks of agonizing pain in the epigastrium. He has been seen by Dr. Pfaff when he was slightly jaundiced, who believed that he had gallstones. He was also seen by Dr. Vickery and Dr. Gannett once or twice, without a definite diagnosis being made.

On Feb. 17 he was brought into the accident room, having been seized two and a half days before with a particularly severe and sudden pain in the epigastrium, which required a larger amount of morphia to give relief. The pain radiated to the right into the hypochondrium, and to the iliac fossa. On the night before entrance the patient began to vomit, and the vomiting has been persistent. The bowels moved on the morning of this last attack. He had no chill. Examination showed a rather poorly nourished man, temperature 100, pulse, 80, poor quality. Slight cyanosis. Heart and lungs negative. Abdomen much distended, with a large amount of free fluid, which moved on shifting position. Tenderness was most marked in the right iliac fossa, but was also present in the epigastrium, with some rigidity. Patient vomiting continuously. In view of the previous attacks, the free fluid, distention, vomiting and most marked tenderness in the right iliac fossa, with normal temperature, a diagnosis of probable intestinal obstruction from a band was made, and an immediate operation done.

A long incision was made through the right rectus muscle, showing the intestines moderately distended, and everywhere injected. A large amount of blood-stained fluid escaped from the abdomen and pelvis. No collapsed intestine could be found, no band or adhesion. Scattered everywhere through the abdomen, especially marked in the omentum, were areas of fat necrosis, varying in size from a pinhead to a large pea. The mesentery of the appendix was especially involved, the appendix was large, injected, and was therefore removed. On examining the gall bladder it seemed to be somewhat distended, and possibly to contain a small stone. Examining further, it was found that the pancreas was very large, remarkably tense, standing up from the spinal column like a plaster of Paris cast. The vessels in the small intestine were tremendously engorged, and the intestines somewhat cyanotic, as if there might be pressure on the mesenteric veins from the swollen pancreas. After thorough irrigation with salt solution, the opening was closed and another incision made along the left costal margin. The intestines were packed inward and upward with large gauze sponges, and the pancreas could then be clearly seen, of a deep purplish color, appearing through the peritoneum. About it the areas of fat necrosis were especially well marked. In order to relieve tension a longitudinal incision was made from the median line, avoiding the mesenteric vein, out to the tail of the pancreas. This incision was about four inches long and about three-quarters of an inch deep. No pus was discovered, but the peri-pancreatic tissue was infiltrated with blood, with here and there large areas of fat necrosis. The wound was packed with gauze strips, in order to wall off the pancreas from the rest of the abdominal cavity. A rubber drainage tube was placed in the center of the gauze.

Convalescence has been uninterrupted since then, except for occasional vomiting for a few days. On the 26th, nine days after the operation, a dressing was done under ether, and all of the gauze removed. The pancreas was plainly seen to have diminished about one-third in size. One or two areas of fat necrosis were still visible. Repacked with smaller wicks.

On March 12, twenty-three days after operation, on doing the dressing, two portions of necrotic tissue were removed, one about three

inches long by one-half inch in width. Examination showed nothing but necrotic fat. Since then the wound has been granulating well, and now is marked by a small sinus.

During convalescence the interesting features have been an entire absence of fever, a white count which has never been over 12,000 and has averaged about 8,000; the hemoglobin six days after operation was 80%; blood coagulation, time, six seconds. Examination of the urine, which has been followed closely, showed at first numerous hyaline and fine granular casts, with a slight amount of albumen. On the 23d a large amount of indoxyl, 1½% of sugar. This was the only time in which sugar was found in the urine. On the 26, 27th, and 28th small amounts of albumose were present. Skatol and kreatinin increased. At no time have the stools been clay colored, nor have they shown any signs of abnormal intestinal digestion.

The case is reported not simply because the man has recovered, but because the diagnosis of the cause of the pancreatitis is still unmade. The pancreas at present is slightly enlarged, at times somewhat tender. Nothing was removed at the operation, and yet the man has been much better since it than before. The question arises as to whether he had swelling of the duct from infection, or whether a stone were impacted in the ampulla of Vater. This case will be later reported in greater detail.

(To be continued.)

Medical Progress.

REPORT ON PROGRESS OF SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D., BOSTON.

ATTEMPTS AT LEUCO-THERAPY.

Labbé [1] reviews the various experimental work that has been done in the line of inducing hyperleucocytosis in animals as a protection against infection. He shows that the induced hyperleucocytosis, while theoretically a powerful means of aiding the natural defenses, is in practice able to confer a preventive protection only and seems to be powerless against already established infection. At the same time, he adds, the hyperleucocytosis induced by nuclein — which is the substance that has been most generally employed — is possibly not intense enough for the desired purpose. It is not to be compared with the hyperleucocytosis induced by disease germs. When we have learned some more efficient means of inducing hyperleucocytosis in animals, it is possible that the results of this leuco-therapy may be applied to man with success.

IGNITION OF ETHER VAPOR BY AN ELECTRIC LIGHT.

Every surgeon thoroughly appreciates the danger of an open lamp anywhere near ether vapor, but it is generally supposed that an electric incandescent light is perfectly harmless. To be sure, accidents from this cause are extremely rare, but D. H. Murray [2] reports an instance in which the ether vapor about a cone, by which a patient was being anesthetized, was ignited when an electric light was turned on near by. The patient's hair was badly singed, but no serious injury resulted. As there was no exposed fire or blaze in the operating room at the time, it was concluded that the ignition resulted from the spark in the electric light, made when the contact took place in turning on the light. It is a possible danger worth remembering.

ON THE FATAL EFFECTS OF CHLOROFORM ON CHILDREN SUFFERING FROM A PECULIAR CONDITION OF FATTY LIVER.

Leonard G. Guthrie [3] gives a résumé of a paper written some years ago entitled "On Some Fatal After-effects of Chloroform on Children," as an introduction to the present article. In the ten cases reported in the previous article it was not proven that death was not due to carbolic acid poisoning. In this article four cases are added which he thinks throw light on the original ten recorded in the earlier paper. He says the additional cases seem to prove the following: (1) That neither carbolic acid poisoning nor fat embolism will account for these mysterious fatalities. (2) That the severity of the operations has little if anything to do with the cause of death. (3) That the only pathological condition commonly found after death is a peculiarly intense fatty degeneration or fatty infiltration of the liver. This condition was found in five of the first series and in three of the second series of cases. It was not noted in three of the first series, and in three of the second series of cases. It was not noted in three of the first series, but in these a microscopical examination was not made. Of the remaining three one recovered and in two permission for a post-mortem examination was refused. (4) The only other circumstance common to all the cases was that chloroform had been administered some hours or days before death. We are therefore driven to seek an explanation in the morbid state of the liver, which was demonstrated in 8 out of 14 cases, and can therefore not be regarded as a pure coincidence, and also to inquire again what part (if any) was taken by chloroform in producing it.

RESEARCH WITH RADIUM RAYS.

London [4] used for all his tests 30 mg. of radium bromid in a rubber and metal box with a mica cover. He found that radium rays are able to kill mice without direct contact. Twenty-one grown mice and six controls were placed in glass vessels, three or four in each, and the box of radium was laid on the cover of the vessels for one to three days. The controls were lively at the end of the fifth day, but the other animals were all dead by this time. The symptoms noticeable

about the third day indicated depression of the cerebral nervous system at first, followed by arrest of the functions of the cerebro-spinal system in four to nine hours. The most profound anatomic alterations were in the skin and cerebral cortex. He further refers to the fact that if a stick of sealing wax is rubbed with flannel, scraps of tissue paper will cling to it, but he found that if the wax were passed over the radium box after being rubbed the tissue paper was not attracted to it. On the human skin the rays induced a so-called "cold gangrene" in tests on himself and his assistant. The lesions were so peculiar and characteristic that they must be designated as dermatitis radiogenes. He also states that arterial blood became dark-colored under the influence of the rays. In his tests on blind subjects he found that they perceived a visual sensation when the radium was applied to their eyes, but this occurred only in those subjects who still retained a certain perception of light. The blind who had never experienced the sensation of light afforded negative or contradictory results. Blind subjects still able to distinguish between light and darkness were able to see in outline dark objects held against the fluorescent screen lighted by the radium rays. Two lads, blind from atrophy of the optic nerve, were thus able to learn by the silhouettes all the letters of the Russian alphabet and make out entire words. He also states that he found certain persons who were able to tell — by the visual sensation experience — when the radium was brought close to the back of their heads, but only when approached to a certain point. He suggests that this may possibly be the result of excitation of the visual center at this point by the rays. The visual impression is perceived from the radium rays even when the eyes are closed, bandaged and covered with three or four superposed hands. His concluding statement is to the effect that it is possible to examine articles through the microscope in a dark room with merely the light from a good screen under the influence of the radium rays. His research was conducted at the Institute for Experimental Medicine at Berlin.

SUTURE OF HEART.

Wolff [5] states that 39 cases have now been recorded of suture of the heart, and the results indicate that suspicion of a stab wound of the organ imposes operative intervention, even in the absence of vital indications, as a prophylactic measure. On the other hand, wounds from firearms may be treated expectantly. In the former cases the pleura has almost invariably been opened and, therefore, it is not necessary to operate extrapleurally. The pericardium should be sutured, the tampon used only when the wound is infected. The button suture has proved most effective; the threads tied during the diastole. The left ventricle is most favorable for an operation of this kind, as the patients are not so liable to bleed to death on the spot. The case reported by Pagenstecher confirms Bode's experimental research, demonstrating that the nourishment of the heart does not suffer materially after ligature of a coronary artery. Wolff reports three cases of suture of the heart with two recoveries, and states that this brings the total on record to 42, with 17, that is 40.4%, recoveries. Only one was a firearm wound. Fischer's statistics showed that only 10% recovered in the unoperated cases. Wolff adds that intervention may be necessary and successful even in the absence of an external wound, as witness a case described in the *Lancet* in 1897. A young man was kicked in the breast at football. Unconsciousness persisted and the heart dullness kept on increasing. The pericardium was incised and found filled with blood, but bleeding from the heart had ceased. After the blood had been drained away the young man was fully restored and was able to join in the game again.

STATISTICS OF OPERATIVE-TREATED ANEURISMS.

This communication of Jakobsthal [6] issues from Braun's clinic at Göttingen. In the first part the history of operative treatment of idiopathic aneurism of the subclavian is reviewed, with a bibliography of 94 references and 21 new cases collected since Souchon's statistics of 81 in 1890. In the 21 new cases there were 17 men and 1 woman; the right subclavian was affected in 12 and the left in 5. In 19 cases followed for sufficient length of time 13 were permanently improved and 3 definitely cured. Treatment by distal ligature has 3 improvements out of 5 to its credit; proximal ligature, 5 out of 7; both distal and proximal, 1 out of 2 and extirpation, 3 cures out of 4 cases. The general conclusions of the work are that extirpation is the ideal method of treatment. It not only guarantees a radical cure, but also prevents the pains liable to occur after the aneurism has been obliterated by thrombi. Extirpation is not practicable if the walls are thin and pulsating unless the aneurism is very small and free from adhesions, or if large, is partially obliterated with thrombi. In case the aneurism is adherent to the clavicle and subclavian vein, the parts involved must be resected too. When extirpation is impossible, proximal ligature is next advisable. If the contents of the sac do not become solid after central ligature, a distal one should be applied. The latter alone offers little prospect of a cure. In case operative treatment is impossible, Macewen's method of introducing needles and scratching the walls certainly deserves attention, as it proved successful in one case in his experience. As a last resort, electrolysis and "filipuncture" might be tried. Each has one case of improvement to its credit. Judgment is still in suspense in regard to the efficacy of gelatin injections.

The second part of the work is devoted to aneurism of the aorta, reviewing 13 new cases in addition to the 34 previous statistics. In 10 the thoracic aorta was involved and in 3 the abdomi-

nal. The results of operative treatment demonstrate that simultaneous ligature of the right carotid and subclavian in case of aneurism of the ascending aorta cannot be considered a particularly dangerous operation. In a number of cases it was followed by improvement in both the subjective and objective symptoms. The same remarks apply also to ligature of the left carotid or simultaneous ligation of the left and subclavian in case of aneurism of the arch. Reports of the ultimate outcome of the cases on record are needed before final judgment can be passed on this operative treatment.

ENTEROSTOMY FOR DRAINAGE AND NOURISHMENT.

An interesting paper on this subject, by Finney and Pancoast, appeared in *American Medicine*, Philadelphia, Aug. 22, 1903.[7] After the loop of bowel is brought out and opened, a rectal tube is inserted first in one direction and then in the other, for several feet each way. This allows escape of gas and feces with less risk of soiling the peritoneum than by other methods. The special indications for enterostomy considered in the article are as follows: (1) Temporary drainage of a distended intestine, allowing it to regain its normal tone in cases of functional paralysis of the bowel of septic or other origin, especially in those cases following appendicitis with peritonitis. (2) To enable one to nourish a patient whose stomach and rectum are for any reason irritable and unable to retain or absorb a sufficient amount of nourishment. The operation of enterostomy, when quickly done under local anesthesia, is a comparatively slight one, and causes little disturbance to the patient. The relief afforded thereby often enables him to withstand, later, more radical measures. The amount of fluid that can be given in twenty-four hours by this means and retained is surprisingly large. Finney calls attention not only to the advantages of relieving the distended intestine, but insists that the intestinal fistula once established should be looked on more as a mouth than as an anus. It should be used for irrigation of the intestinal canal, for the nourishment of the patient and for the introduction of cathartics. He has often noticed that food introduced into the intestinal canal through the fistula had of itself a stimulating effect on peristalsis. He reports seven casess in detail, some followed by postmortem examination, as the enterostomy was undertaken as a last resort. It always caused great relief and postponed the inevitable fatal termination, and saved several otherwise doomed patients. The fistula usually closes spontaneously.

(*To be continued.*)

THE VALUE OF THE FINGER-JOINT. — Five hundred dollars is the value placed on a man's finger-joint by a jury at Newark, N. J. Henry Klein, a hatter, in Newark, was the plaintiff. While at work on Sept. 21, 1902, Klein's left hand was caught in a forming machine, and one finger was so badly crushed that it was necessary to amputate it at the first joint.

Reports of Societies.

AMERICAN GYNECOLOGICAL SOCIETY.

PROCEEDINGS OF THE TWENTY-EIGHTH ANNUAL MEETING, HELD IN WASHINGTON, D. C., MAY 12, 13 AND 14, 1903.

(Concluded from No. 15, page 409.)

PRESIDENT'S ADDRESS.

This was delivered by the President, DR. JOSEPH E. JANVRIN of New York City.

After paying fitting tributes to Dr. John Byrne, Dr. T. Gaillard Thomas and Dr. Edward W. Jenks, he discussed the subject-proper of his address, namely,

SURGICAL TREATMENT OF EARLY DIAGNOSED CANCER OF THE UTERUS, MORE ESPECIALLY BY HYSTERECTOMY.

He pointed out the conditions in which vaginal and abdominal hysterectomy held out good hopes for a radical cure; also the conditions in which the operation held out some prospects of a radical cure, and certainly a prolongation of life with a more comfortable existence than could possibly be hoped for if hysterectomy was not resorted to.

He took up the development of cancer in and from the cervix. His own observations as to the extension of epithelioma beginning in the cervix are as follows: (1) Up and into the cervical canal; (2) up and into the uterine body; (3) to the tissues surrounding the cervix, the parametrium especially; (4) downward upon the vaginal mucosa, and after a certain time through the mucosa into the wall itself.

The author, after quoting freely the statistics of other writers, both European and American, regarding cancer of the uterus, stated that his own statistics up to Jan. 1, 1899, were as follows: Abdominal and vagino-abdominal hysterectomy: 12 cases, 2 cured, more than eight years having elapsed since operation; 6 recurrences; 4 deaths from operation, 2 from shock, one from septicemia, and 1 from uremia; percentage of cures, 16.6. Vaginal hysterectomies: 38 cases, 10 permanently cured; 15 recurrences; 4 deaths from operation; 10 lost sight of after a few months; percentage of cures, 26.3. Total number of cases, 50; 12 cured; general percentage of cures, 24.

He believes that vaginal hysterectomy, with removal of as much parametrium as is possible by this method, and also the removal of the upper half inch or more of the vagina, will accomplish just as much as any other method, and at the same time carries with it the least danger as an operation *per se*, for it is extremely rare that a patient succumbs to this operation. It was by following out this rule that the statistics of his own cases up to January, 1899, have been so favorable. During the past four years he has extended the field of operation for the purpose of removing a highly offensive local condition, and in that way making a longer lease of life

more comfortable to the patient and less offensive to herself and to her friends.

DR. THADDEUS A. REAMY of Cincinnati, Ohio, read a paper on

CARCINOMA OF THE CERVIX UTERI.

Among other things, he stated that spontaneous recovery from carcinoma does not occur. Unequivocal recovery lasting from ten to twenty-five years of two cases following removal of the diseased and adjacent tissues proves the curability of carcinoma of the cervix and also its local origin. The author reports six cases of carcinoma of the cervix uteri. No. 1 was operated upon eighteen years ago, and is in good health to-day; No. 2 has gone nine years without recurrence of the disease, and No. 3, fifteen years without recurrence; twelve years have elapsed without recurrence in Case No. 4; in No. 5 eighteen years have elapsed since removal without recurrence; and No. 6 has gone twelve years without recurrence.

DR. REUBEN PETERSON of Ann Arbor, Mich., followed with a paper on

PRIMARY CARCINOMA OF THE VULVA.

He reported four cases of primary carcinoma of the vulva. He presented a résumé of the literature of the subject, and the conclusions drawn therefrom. The cases were narrated in detail. He spoke of the frequency as compared with other carcinomatous conditions of the genital tract, and discussed at length the diagnosis and symptomatology. In considering the operative treatment, he spoke of the advisability of removing the inguinal glands. If carcinoma of the vulva is seen and treated early enough, good results can be obtained. Veit quoted Schwartz as having ten permanent recoveries out of twenty-three cases. While this may be overstating the fact, it is unquestionably true that there is much more hope of cure in cases of carcinoma of the vulva after the radical operation than after the most radical operations for carcinoma of the uterus.

DR. GEORGE M. EDEBOHLS of New York City read a paper on

RENAL DECAPSULATION FOR PUERPERAL ECLAMPSIA.

This operation for puerperal eclampsia of renal origin is the logical outcome of the encouraging results following the author's operation in cases of chronic Bright's disease. The author said he has successfully performed bilateral renal decapsulation for puerperal eclampsia upon a primipara two days after a forced delivery. The convulsions began before labor, and continued until the time of operation, the patient having a convulsion while under chloroform on the operating table. This operation, performed on Feb. 17, 1903, is believed to represent the first instance of renal decapsulation, or, for that matter, of any operation upon the kidney or kidneys ever undertaken for the cure of puerperal convulsions. The favorable results, both immediate and remote, in this case, full details of which are given in the paper, at once assign a place to renal decapsulation as one of the resources at the command of the profession in the treatment of puerperal eclampsia. He said a woman who is suffering from uremic convulsions is entitled to the positive benefits of decapsulation whether pregnant, in labor or in puerperium.

The following topic was discussed in a series of papers:

SHOULD THE UTERUS BE REMOVED WHEN THE OVARIES AND TUBES ARE REMOVED IN CASES OF DOUBLE PYOSALPINX, WHEN OPERATING EITHER THROUGH THE ABDOMEN OR THE VAGINA?

DR. ANDREW F. CURRIER of New York City, in his paper, stated that if this is proposed as a matter of routine, he would reply emphatically, no. If it is proposed as an expedient, when the uterus itself is diseased extensively, he would say Yes. It may also be removed if it has been greatly injured in the extrication of the appendages, or if it should seem to be required as a means of controlling troublesome hemorrhage. To remove the uterus in a young woman may possibly produce an unfavorable mental effect as a consequence, near or remote. To remove the uterus of a woman near, at or past the menopause, might add an element of risk to the operation. To remove the uterus might weaken the pelvic floor and introduce an element of danger from enterocele. To remove the organ unnecessarily is bad morally, for it tends to establish the impression of the unimportance of the organ, and that it may be unhesitatingly extirpated by any one who has the requisite skill. To remove the uterus on the ground that it may possibly be the seat of malignant disease in the future is assuming more than the clinical history teaches in the great majority of cases, and is, moreover, a reproach to surgery, making it destructive instead of conservative.

DR. PHILANDER A. HARRIS of Paterson, N. J., stated that when suppuration has become well established in both tubes their exsection is the only operation which can be relied on to effect a cure. By exsection is meant the removal of the lumen of the tube to the uterine mucosa. Less radical operations, as hemisection and disinfection of the ampulla and larger portions of the tube, probing and washing of the tube and amputation of distal portions of pus tubes, are incomplete operations, and are proportionately unsuccessful in that they leave behind a diseased sinus, which not only continues to exist, but is productive of discomfort and other ill consequences to a greater or less extent. In bilateral exsection of double pyosalpinx, sufficient ovarian stroma may be left to influence and continue menstruation in at least 95% of any large class of cases operated upon. The ovaries frequently participate in suppuration, which they derive from pus tubes. But in them suppuration is more easily terminated,

and exsection is not advised excepting for extensive abscess of the ovary at the time the tubes are exsected, or a belief or knowledge that the suppuration in the ovary is tubercular in character. Simple excision of double pyosalpinx affords the maximum degree of relief, with a minimum of mutilation and interference with the functions of the pelvic organs. The complaints arising from the existence of endometritis often cease after simple exsection of double pyosalpinx. If the symptoms of endometritis continue and greatly harass the patient, the uterus may be removed by vaginal section. The price of removal of the uterus in every case of double pyosalpinx may be partly estimated by the following results: (1) Loss of menstruation in every instance. (2) Partial or complete extinction of the sexual quality in a large proportion of the cases, together with incomplete physical capacity for sexual participation. (3) Injury to the nervous system of the patient, arising from her knowledge and appreciation that she has been prematurely and possibly unnecessarily deprived of these and other qualities which render her physically and, to a certain extent, morally inferior to other women.

Dr. I. S. Stone of Washington, D. C., stated that no organ should be removed unless it is absolutely necessary. In a large majority of cases the pus found in diseased adnexa is sterile. It follows that the chief element of danger from sepsis is eliminated, and the uterus is not the seat of dangerous microbic infection. The exception to the above rule may be found in puerperal infections. When purulent adnexa are removed, the uterine cornua should be excised, and the uterus permanently sealed, and thus made a barrier against further infection and also to permit effective treatment addressed to the uterine cavity, if necessary. Hysterectomy requires additional time, causes further traumatism and necessitates changes in the anatomical relations of the vagina, bladder, etc. If necessary to drain the pelvis by way of the vagina, the usual route through the cul de sac posterior to the uterus answered every purpose; finally a number of women object to pan-hysterectomy, and besides the question of its effect upon the mental status of the patient is *sub judice*.

Dr. Matthew D. Mann of Buffalo, N. Y., said that the almost sole cause of pus tubes is gonorrhea, though there may be a mixed infection. The uterus is usually infected and may make trouble afterwards and be the cause of spreading the infection. The uterus is no longer of any use. Menstruation does not always stop after the removal of the tubes and ovaries, and if it remains, it might become excessive and cause trouble. The uterus might become the seat of cancerous disease. In acute infection the removal of the uterus affords the best means of securing drainage. The results by the vaginal route, where the uterus is always removed, warrant its removal by the abdominal route. The woman's sexual life is unaffected by the removal of the uterus. The additional time taken for its removal is more than counterbalanced by the securing of good drainage.

Dr. Charles P. Noble of Philadelphia, Pa., said that of hysterectomy for circumscribed pus limited to the uterine appendages, that is, pyosalpinx or abscess of the ovary, he has had fifty-eight cases, one death, a mortality of 1.7%. Of hysterectomy for intraperitoneal abscess, in addition to pus in the uterine appendages, he has had six cases, four deaths, a mortality of 66⅔%. Of appendages removed for circumscribed pus contained in the tube or ovary, that is, pyosalpinx or abscess of the ovary, seventy-six cases, seven deaths, a mortality of 9.2%. Of appendages removed for circumscribed pus contained in a tube or ovary since Jan. 1, 1895, thirty-six cases, two deaths, a mortality of 5.5%. Of appendages removed for intraperitoneal abscess in addition to pus in ovary and tube, twenty-two cases, five deaths, a mortality of 22.7%. Incision and drainage for pelvic suppuration, fifty-eight cases, one death, a mortality of 1.7%.

Dr. J. Wesley Bovee of Washington, D. C., read a paper on

URETERO-CYSTOTOMY.

He narrated the history of this operation, pointed out the indications, discussed the diagnosis, routes and methods of operation, complications, technique, after-treatment, detailed histories of cases and gave the results.

Dr. Walter P. Manton of Detroit read a paper on

OCCURRENCE OF GALLSTONES IN INSANE WOMEN.

He stated that cholelithiasis is of frequent occurrence among the insane women, but that symptoms are usually wanting, so that statistics must be obtained solely from autopsy findings. From his experience at the Eastern Michigan Asylum he finds that gallstones are present in rather more than 26% of the patients dying at that institution, in whom the abdominal contents was examined. The paper was intended only as a small contribution to the knowledge of the subject, and as preliminary to more extensive study of gallstones in insane women at some future time.

EXCISION OF THE PROXIMAL ENDS OF THE FALLOPIAN TUBES AT THEIR ORIGIN IN THE UTERUS THE OPERATION OF CHOICE FOR THE EXTREMELY RARE CASES WHEREIN STERILITY IS DESIRABLE.

Dr. Philander A. Harris of Paterson, N. J., read a paper with this title. The object of this operation is to take the place of the Porro operation, the bilateral removal of the ovaries, or to take the place of bilateral excision of healthy tubes. Menstruation would not be sacrificed. Every advantage arising from retention of the ovaries would be preserved to the individual, excepting the single item of impregnation. Tubes thus disconnected from the uterus would probably remain immune from future gonorrheal infection of the endo-

metrium. A patient thus sterilized can doubtless be cured of her sterility by implantation of the tubes through the uterine cornua to the uterine cavity. While there are doubtless cases which are characterized by certain conditions of the body, mind or nervous system, calling for the voluntary production of sterility, there must necessarily be a very limited field for the employment of this operation. If a case is to be surgically sterilized, it should be effected in such manner that the patient and her friends may feel that she can be restored to fertility, should the pathological factors of her case so abate or disappear as to render impregnation and pregnancy permissible. No attempt was made by the author to present the indications for an operation which would produce sterility for temporary purposes, although such instances are believed to be within the range of possibility, and if so, emphasized the advantage of doing the primary operation in the manner proposed.

PERSONAL EXPERIENCE IN OPERATIONS UPON DIABETIC PATIENTS.

In a paper on this subject, DR. CHARLES P. NOBLE of Philadelphia stated that of the seven patients operated upon by him six made good recoveries and one died of diabetic coma. In the six remaining cases the healing of the wounds and the general progress of the patients toward recovery were not different from that in patients not the subject of glycosuria.

In looking up the literature of the subject, he has been able to add to his own list sixty-two cases of operations upon diabetics, upon those organs of the body which are the special field of the gynecologist and abdominal surgeon, making a total of sixty-nine cases.

The contraindication to operation was strongest in those patients suffering markedly from the constitutional symptoms of diabetes — poor nutrition, wasting, intense thirst and morbid appetite.

OFFICERS FOR THE ENSUING YEAR.

The following officers were elected: President, DR. EDWARD REYNOLDS of Boston, Mass.; First Vice-President, DR. J. WHITRIDGE WILLIAMS of Baltimore, Md.; Second Vice-President, DR. EDWARD P. DAVIS of Philadelphia, Pa.; Secretary, DR. J. RIDDLE GOFFE of New York City, re-elected; Treasurer, DR. J. MONTGOMERY BALDY of Philadelphia, Pa., re-elected. Place of meeting, Boston, Mass., fourth Tuesday in May, 1904.

THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

SEVENTEENTH ANNUAL MEETING, HELD MAY 12, 1903, WASHINGTON, D. C.,

PAUL THORNDIKE, M. D., of Boston in the chair.

THE PERMEABILITY OF THE URETHRA FOR CERTAIN SILVER SALTS.

DR. EDWIN C. BURNETT of Boston read this paper. He said that during the past four months he had undertaken a series of experiments to determine, if possible, the permeability of the urethral mucous membrane for certain silver salts, and although he had not concluded them, the results thus far had been so uniformly alike that he felt justified in presenting them to the society as a preliminary report. Argyrol was the salt he had experimented with. As this salt was very soluble and readily washed from animal tissues, it was necessary to find some means of precipitating it in an insoluble form in the tissues and, at the same time, to have the precipitate distinguished from tissue elements by its color; a solution of hydrogen sulphide slightly acidulated with hydrochloric acid was found well adapted for this purpose. This produced an insoluble black stain of dead tissues that had first been immersed in solutions of argyrol. In the first series of these experiments the urethræ of dogs were injected with solutions of the salt, the strength of which varied from 1% to 5%. This was repeated for six days, and on the last day, after washing the urethræ thoroughly from the argyrol so that no postmortem staining could take place, the urethræ were removed. The tissues were then immersed in a solution of hydrogen sulphide to fix the silver taken up by the cell, and was then prepared for the microscope. In the next series of cases silver nitrate was used. In the third series rabbits were used instead of dogs. In all the experiments the results were the same. It was found that the silver solutions did not penetrate, only the upper surface of the top layer of cells showing a trace of silver in the form of a thin black line of silver sulphide, the result of the reduction of the residue of the two silver salts by the hydrogen sulphide left after washing.

INFECTION OF THE PROSTATE.

DR. JOHN VAN DER POEL of New York said that the element of infection of the prostate should be more often considered because, in a large number of cases, the posterior urethra becomes infected and more quickly than is generally supposed. The statistics regarding this varied from 10 to 90%. Frank of Berlin gave 33%. In 190 cases which Dr. Van der Poel reported a year ago last June, he reported evidences of posterior urethritis in 39%. This condition should not be lightly overlooked and, although in all cases symptoms were not given, such a condition might exist and then extend to the prostate. Cloudy second urine and frequent micturition came on, however, in a large number of cases at the end of the first week, but he thought it a mistake to always trust to this test, as it sometimes may not be present. The prostate itself, he said, became infected in those instances when the posterior urethra was infected in almost 100%. This could not be always proven by the

obtaining of the gonococci from the prostate itself, although it could be in many instances. He said the method of simply irrigating the anterior and posterior urethra before massage and then obtaining the prostatic fluid from the meatus for examination for gonococci was open to question. The more correct way would be to obtain the fluid direct from the prostatic duct through the endoscope after thorough irrigation, though this was impracticable for obvious reasons in many cases. When once the gonococci reach the prostatic gland he said it was almost impossible to say how soon we were going to get rid of them. Massage would accomplish a great deal, but we were unable to get at the entire gland in this way, although we could empty the lateral lobes to a greater or less extent in those cases where the prostatitis was simply catarrhal or follicular in form. He believed we should differentiate between the different forms of prostatitis. That the gonococci might enter the parenchyma of the gland in a short time had been proven by many observers, and after having once obtained a foothold it was a very difficult question to say how soon we were going to get rid of them. If they were confined to the ducts of the gland (a simple catarrhal prostatitis) or to the follicles, we might be able to get rid of them by massage. He said, therefore, that we should not forget that in about one-third of the cases there will be shown a posterior involvement, and that it might be taken for granted that the gonococci would extend directly into the prostate in many cases; that, when once in the prostate, they often get into the parenchyma of the organ, and this fact explained why a great many cases did not permanently respond to any of the silver salts, and why reinfection, or more properly auto-infection, of the urethra was so frequent.

A CASE OF STRANGULATION OF THE TESTIS DUE TO TORSION OF THE CORD.

Dr. Arthur Tracy Cabot of Boston read this paper. He said that such cases were extremely rare, Dr. Scudder being able to find only thirty-two cases in literature. The patient was twenty-six years old. One morning, without previous injury or disturbing case, he was suddenly seized with a severe paroxysmal pain in the center of the lower abdomen, close above the pubes. He was pallid, nauseated and covered with sweat. In the afternoon he was so much better that he got up from bed. For two days following, the pain was more or less severe and there was an increase in the size of the testicle. Antiseptic fomentations not giving relief, operation was decided upon. The tissues were thick and edematous. A little blood-stained fluid escaped from the tunica vaginalis when opened. The testicle was black, mottled with plum color. The cord was slightly twisted, the rotation being from within outwards. One complete twist of the cord untwisted it. The mesorchium was not long, and the cord was tightly wrapped about it. The testicle was in a gangrenous condition, and had to be removed. Convalescence was uninterrupted.

Dr. Ramon Guiteras of New York reported an interesting experience he had while operating upon a case of varicocele; he found a complete twist of the cord and yet the patient had never felt any pain.

Dr. Van der Poel of New York said that he thought there were a great many instances in which the cord might become untwisted or be untwisted by the patients themselves, without their being aware of it. In the *New York Medical Record*, June 15, 1895, he reported a case occurring in a medical student who had had an undescended testicle at birth, though at two years it came down to the upper part of the scrotum. Suddenly, when he was twenty-one years old, he experienced a sharp pain along the cord, with more or less abdominal tenderness, which ran down into the testicle. He did not know the nature of his trouble, and continued to work until obliged by the pain to remain quiet. After some manipulation of the parts for two or three hours the pain was relieved. He had similar attacks at intervals of from once in six months to twice in twenty-four hours, which seemed to come on without any known reason both during the day and night, but they were more frequent when he was up and about. Soon the true nature of the attack became evident. He found that he had a true twist or torsion of the cord, and that he could untwist it himself. When he now has these attacks he simply untwisted the testicle from within outwards, and so is relieved. The torsion was upon the right side. Upon examination he found the testicle hugging the upper part of the scrotum, and that it was not well developed, and that it could be twisted about one and a half complete turns without pain, and that when turned for another quarter it would remain in that condition, then become painful, and swelling of the cord at once began.

Recent Literature.

The Prevention of Disease. Translated from the German with Introduction by H. Timbrell Bulstrode, M.A., M.D., D.P.H., Med. Dept., H. M. Local Government Board. 2 v. New York: Funk & Wagnalls Co. 1903.

Vol. I has thirteen chapters, to which nine German writers contribute. Vol. II has eight chapters, to which nine writers contribute. The first chapter is devoted to a history of the prevention of disease. Then follow articles on general prophylaxis, and prophylaxis as applied especially to separate organs, systems or tissues. The term "preventive medicine" is associated in the minds of most people with the work of legislatures and boards of health. This book seeks to extend the term more precisely to personal prophylaxis and to other pathological conditions than those due to contagion or infection. It is intended for the use of the medical profession.

THE BOSTON

Medical and Surgical Journal

THURSDAY, OCTOBER 15, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

OVERCROWDING OF THE PROFESSION.

IN a recent number of the *New York Medical Journal* a signed editorial from the pen of Andrew F. Currier has appeared, on the subject of "Medical Practice as a Means of Livelihood." That this is a matter of vital importance to many practicing and prospective physicians is self-evident, and it is also apparent that more or less artificial means of regulating the situation are not likely to meet with the least success. Dr. Currier makes the following statement: . . . "I believe that every man who has intelligence enough to get a medical degree at the present time ought to be able to reckon with confidence that he will gain a comfortable living from it. Since there are so many who do not, ought we to encourage any but the exceptionally gifted or the exceptionally situated as to opportunity and means, to enter it? I think not."

He suggests two remedies. First, that other avenues of work than strictly medical practice should be cultivated, such, for example, as positions on health boards, and also that hospital positions, which indirectly lead to practice, should be so regulated that they could not be held indefinitely. A second remedy is suggested of limiting by legislation the yearly number of medical graduates, to the end of allowing the chosen few a broader and hence more lucrative field for their professional work.

We are not inclined to agree with this point of view. In the first place the world owes nobody a living, and there is certainly no good reason why every man who receives a medical degree should reckon with confidence upon a comfortable income simply because he has passed with success through the four years of a medical course. Nothing to our way of thinking could be more detrimental to the cause of medical progress than the assurance on the part of young graduates that four years of study, however arduous and successfully performed, are a guarantee of future success. The standard of admission to our medical schools, and the requirements after admission, may with justice be raised to any reasonable degree, but here the responsibility of the school stops.

There can, however, be no objection to the cultivation of lines of work not strictly medical by men primarily trained for practice. In fact, it is one of the hopeful signs of the times that physicians of good preliminary training are more and more taking up collateral branches, to the good, no doubt, of all concerned, thereby spreading the gospel of sound medical doctrine into various fields of work. Insurance companies, corporations burdened with numerous damage suits for personal injuries, manufacturing chemists, quarantine stations, hospital superintendencies, as well as health boards, are all affording physicians of good standing an opportunity beyond the scope of ordinary practice for the gaining of a livelihood. The more widely such work is undertaken by properly equipped medical men, the more surely will the dignity of the profession be elevated and its influence widened. That the medical school of the future will become a place of training for men who have no idea of practicing their profession in the ordinary sense of the term is becoming every day more evident. When we bewail the overcrowding of the profession, this fact should always be taken into account that there is an increasing number of positions to be filled, and that there is continually a demand for competent men for such positions. It is evident that we cannot all do as our forefathers have done, but, on the other hand, we, as physicians, may do many things which were not even thought of by them, and until we have done all these things well, it is hardly worth while to bewail the number of our competitors.

The suggested remedy of limiting the number of doctors by legislation is of a piece with limiting a man by law in the exercise of his freedom of action. We question whether so autocractic a proceeding is countenanced in any civilized country, and it certainly can never be with us. As already suggested, medical schools may and should continually raise their standards, but this is quite different from an attempt to legislate a man out of a profession for which he believes

himself fitted. Remedies for legitimate competition are not easy to find, nor are they to be in the least encouraged. The saving grace of medical practice, as of every other intellectual pursuit, is the freedom of its competition, and the fact that one can neither buy nor legislate himself into a position of authority. It is quite inevitable that many should go to the wall in medicine, as in other callings, which may be unfortunate for the individual, but is none the less essential to the future development of medicine as a profession calling for keen intellect and constant endeavor. Well worn as the adage, "room at the top" may be, it continues to have a very large element of truth. What happens to the great majority at the bottom in medicine, as in everything else, is certainly not a subject for legislation.

THE INOCULATION OF A CHIMPANZEE WITH SYPHILIS.

At the meeting July 28 last, of the French Academy of Medicine, Messrs. Roux and Metchnikoff presented a communication concerning some experimental researches upon anthropoid apes.[1] The most important of these investigations relates to the inoculation of a young female chimpanzee with syphilitic virus. Twenty-five days later this was followed by the development at the point of inoculation of an indurated sore. The development of this sore was followed in a few days by a bubo. Monsieur Fournier, who was asked to examine these manifestations, stated his opinion that they responded in all respects to the characteristics of the chancre and the bubo as observed in man, and in this opinion he was supported by other well-known syphilographers. His lucid exposition was summed up with the phrase, *Rien ne manque au tableau* — nothing is wanting to the picture. Before affirming that the important question of the possible inoculation of animals with syphilis had been definitely and affirmatively settled, he preferred at that moment, with scientific caution, to await the subsequent appearance of secondary or constitutional manifestations. This caution some of his colleagues seemed to regard as excessive, and were disposed to regard the question as already answered.

However this may be, we are now informed by a most competent witness that when he was in Paris about a month later, Metchnikoff sent one of his assistants to show him the chimpanzee. At that time the primary sore was healing, but skin lesions were pointed out to our informant as beginning to appear. In conclusion, the daily press published about ten days ago a cable from Paris announcing the death of this chimpanzee, and stating that she "succumbed to the malady" induced by the inoculation. Of this last statement we await confirmation. It is also stated that five other chimpanzees are being subjected to investigations having the same object in view.

The chimpanzee is one of the most anthropoidal, if not the most anthropoidal, of the monkeys. It is a somewhat rare and costly animal, and Messrs. Roux and Metchnikoff have been enabled to pursue these experiments by means of funds supplied through the agency of the Institute of France and the Fourteenth International Medical Congress. Similar inoculations have been attempted many times by others upon the lower orders of monkeys and upon other animals, but hitherto without definite results. The nearer relation of this particular monkey to man seems to be the qualifying difference, for the inoculations were not surrounded by any especial or exceptional precautions. One is led to conclude that the blood of the chimpanzee, from the point of view of the precipitation and agglutination of its serum, has close affinities to the blood of man.

M. Fournier sees in the success of these experiments, and in the possible inoculation of animals with syphilis, new and splendid horizons opening themselves before the syphilographer — the study and probable solution of many different problems, and among such those of therapeutics, of immunization, of vaccination. It is possible, he thinks, that we view the dawn of one of those discoveries, of which several have in the past come from the laboratory of Pasteur, which constitute at once a distinguished honor to science and a vast benefit to the human race. For the realization of such a prospect must we deplore the sacrifice of these apes!

[1] Bull. de l'Acad. de Méd., No. 30, 1903.

NEW OUT-PATIENT DEPARTMENT, MASSACHUSETTS GENERAL HOSPITAL.

It is fitting that the formal opening of the new Out-Patient Department at the Massachusetts General Hospital, together with the inspection of various other recent additions to the hospital, should be held on "Ether Day," October 16, a day so closely associated with the history of the institution. Invitations have been

sent by the trustees of the hospital to the friends of the institution to inspect on that day the new building for out-patients, which has recently been completed and put in service.

To those who have not recently paid a visit to the hospital this will afford an opportunity to see the very great changes and improvements which have taken place within the last few years. It is difficult for a hospital to keep pace with the demands made upon it for medical and surgical treatment, but there can be little doubt that this really elaborate out-patient building will for many years completely fulfill its function. For a number of years the old building in which ambulant patients were seen had proved wholly inadequate. The importance of work connected with patients not sufficiently ill to be treated in the hospital wards is growing yearly more apparent, and the Massachusetts Hospital has shown a most decidedly progressive spirit in establishing a department which certainly will prove a model for similar departments which are sure to follow in various other large institutions.

We extend our heartiest congratulations to the hospital for the completion of this much-needed building, and we have no doubt that the work done in it will redound still more to the credit of an institution already rich in achievement.

MEDICAL NOTES.

HONORARY DEGREES CONFERRED BY UNIVERSITY OF TORONTO. — At a special convocation, held Oct. 2, 1903, for the purpose of conferring honorary degrees in connection with the opening ceremonies of the new physiological and medical laboratories, the University of Toronto gave the degree of LL.D. to the following men: Dr. Henry Pickering Bowditch, who was unable to be present at the ceremony, Dr. William Williams Keen, Dr. William Henry Welch, Dr. William Osler, Dr. Russell Henry Chittenden and Dr. Charles S. Sherrington.

A PROFESSORSHIP OF ORTHOPEDIC SURGERY. — It is again reported that Mr. J. Ogden Amour intends to found a professorship in orthopedic surgery, to be endowed in the sum of one hundred thousand dollars.

AN OLD STORY IN A NEW DRESS. — The following appears in a recent French journal. It might be added, when the anti-vaccinator changes his opinions, then will "the Ethiopian change his skin and the leopard his spots":

Le Dr. Emmanuel Pfeiffer de Boston, un des plus fervents ennemis de la vaccination, ayant le courage de ses convictions, s'est rendu aux iles Galloupes pour s'exposer à la contagion de la variole; le résultat a été celui auquel on devait s'attendre; le docteur a contracté une variole très grave qui, pendant quelque temps, a mis sa vie en danger. L'expérience faite par cet anti-vaccinateur a eu pour résultat d'activer les lancettes vaccinatrices à Boston. Quant à l'expérimentateur, cela, dit-il, n'a changé en rien ses idées sur la contagion de la variole.

En effet, la difficulté de convaincre un anti-vaccinateur est de trouver un esprit qui puisse s'ouvrir à la conviction. — *Rev. d'Hygiène, August*, 1903.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Oct. 14, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 46, scarlatina 30, typhoid fever 16, measles 19, smallpox 0.

A WARNING AGAINST SWINDLERS. — An organized attempt at swindling has recently been unearthed in Boston. On the plea of soliciting funds for the Boston Floating Hospital, certain men have approached individuals and succeeded in certain instances in securing money. Such solicitations are not authorized by the authorities of the Floating Hospital, and the public should be warned against giving money except to persons with proper credentials.

NEW YORK.

HOSPITAL BEQUESTS. — By the will of Mrs. Mary Lewis, widow of Col. Edwin P. C. Lewis, and daughter of the late Edwin A. Stevens of Hoboken, N. J., are left, among other charitable bequests, $3,000 to Christ Hospital and $2,000 to St. Katharine's Home, both in Jersey City.

ROCKEFELLER APPLES FOR HOSPITALS. — The apples from the many orchards on the estate of John D. Rockefeller, near Tarrytown on the Hudson, which this year produced an enormous yield, are being sent to hospitals and institutions in New York.

REPORTS OF HEALTH DEPARTMENT. — The statistical reports of the Health Department for the month of September show the lowest death-rate of any month during 1902 or 1903, and possibly of any on record. In two of the weeks of the month the rate fell below 16, and the corrected rate below 15. The mortality recorded

represents an annual death-rate of 15.75, as against 17.28 for the month of August and 16.81 for September, 1902. The corrected death-rate, excluding non-residents and infants under one week old, was 15.18. Among the diseases which showed a decline in mortality were the following: The weekly average of deaths from scarlet fever decreased from 6.25 in August to 4.5 in September; the weekly average from measles, from 5.25 to 3.25; from whooping-cough, from 9 to 6.5; from pulmonary tuberculosis, from 145.75 to 133.75; from diarrheal diseases, from 257.75 to 151.5; from diarrheals under two years of age, from 225 to 133.25; from cancer, from 52.75 to 43.25; and from organic heart diseases, from 72.5 to 71. Among the diseases which showed an increased mortality were the following: The weekly average of deaths from diphtheria and croup increased from 24.75 to 28.75; from typhoid fever, from 14.75 to 16.25; from pneumonia, from 51.5 to 61.5; from broncho-pneumonia, from 32 to 36.5; from acute bronchitis, from 16.5 to 27; and from Bright's disease and nephritis, from 84.25 to 91.5.

A Centenarian. — W. H. Seymour of New York City, whose father and uncle were soldiers in the Revolutionary War, died at his country home at Brockport, N. Y., on Oct. 6, at the age of 101 years 2 months and 21 days, having been born on July 15, 1802. The records of the family appear to have been accurately kept, and it is stated that his age with that of his four predecessors in the line amounted to 428 years.

Attendance at Public Vacation Schools. — It is officially announced that the attendance in the public vacation schools during the past summer was 567,891, as against 405,169 in 1902, while the attendance at the playgrounds provided by the city was 3,346,291, as against 2,194,666 in the summer of 1902.

Tenement Houses. — In presenting his estimate, on Oct. 8, for the expenses of his department for the ensuing year, Tenement House Commissioner DeForest made the statement that his staff of inspectors have examined 43,580 buildings. During 1902 they supervised the erection of 643 new houses, the estimated cost of which was over $20,000,000, and the alteration of 1,468 old ones; and during the first six months of the present year, the erection of 699 new houses, at an estimated cost of $20,837,270, and the alteration of 1,266 old ones. While much has been accomplished in the way of reform, much yet remains to be done. There are still in Greater New York over 350,000 of the dark rooms, against which the law is expressly aimed, and an unknown number of cellar rooms occupied in tenement houses, which are forbidden as living rooms, as well as of bakeries, which the law proscribes in tenements.

NOTE FROM THE PHILIPPINES.

Work of Board of Health. — Summarizing the general sanitary work of the Board of Health during the month of May, the total number of inspections and reinspections of houses amounted to 204,277; and of cascoes and other water craft to 2,480. There were 19,854 houses cleaned as a result of sanitary orders, and 431 painted or whitewashed; 649 houses and 22 water craft were disinfected. A total of 15,410 yards were cleaned, repaved or repaired, and the contents of 1,470 cesspools and vaults were removed. During the month 672 sanitary orders were issued, of which 350 were complied with, and proceedings in 17 instances were pending in the courts. A total of 7,598 animals were inspected on arrival at the port; 8,212 were inspected at the abattoir, of which number 21 were condemned. The crematories disposed of 15 543 dead animals and birds, which number included 9,413 rats, and, in addition, 2,121 loads of refuse. The excessive number of animals requiring disposal was due to the loss of animal life in the Santa Cruz fire. There were 17,432 persons vaccinated in the city of Manila, and 125,725 units of vaccine virus issued for use throughout the islands.

Obituary.

WILLIAM JOHNSON DALE, M.D.

Dr. William J. Dale died at Andover, October 7, in his eighty-ninth year. He had been in poor health for some years and had recently suffered from a cerebral hemorrhage.

He was born in Gloucester in 1815. His father was a surgeon in the War of 1812, his paternal grandfather, Ebenezer Dale, fought at the battle of Bunker Hill, and his maternal grandfather, William Johnson, at the battle of Lexington. He graduated at Harvard College in 1837, and at the Harvard Medical College in 1840. He practiced his profession with success in Boston. In June, 1861, soon after the outbreak of the War of the Rebellion, he was appointed by Governor Andrew surgeon-general of Massachusetts and commissioned with the rank of colonel. Late in that year he was appointed an acting assistant surgeon of the United States Army. In October, 1863, he was promoted by

Governor Andrew to the rank of brigadier-general. All through the Civil War the responsibility for providing proper medical officers for the Massachusetts regiments, the general supervision of all matters relating to the medical staff, the care of the invalided sick and wounded fell upon General Dale. For many years after the war he had charge of the distribution of state aid and of invalided soldiers

He was an admirable organizer and a first-rate executive, and his duties were discharged with great credit to himself and great advantage to the state, and at the same time with a sympathetic regard for those dependent upon his decisions. An increasing deafness prevented private practice, and gradually interfered with the discharge of his public duties. He resigned his office in 1876, and presently withdrew to the family estate, a farm of about one hundred acres, in North Andover, which had descended in the Johnson family from the original Indian grant in 1636.

Dr. Dale was a handsome man, of large stature and fine presence,— such an one as would anywhere attract attention. He outlived all his family. His only surviving son, W. J. Dale, Jr., who was at one time assistant postmaster of Boston and subsequently a member of the State Board of Railroad Commissioners, died in 1896.

Correspondence.

A LAWYER'S VIEW OF "PRIVILEGED MEDICAL COMMUNICATIONS."

BOSTON, Oct. 2, 1903.

MR. EDITOR: I have read with considerable interest the papers on "Privileged Medical Communications," published in the JOURNAL Sept. 3, 1903. Mr. Stimson makes out a pretty strong case for the law as it stands at present. I do not think, however, the policy of having such communications privileged ought to be condemned because the New York law has worked poorly. I believe that communications between physician and patient ought to be privileged just as much as those between attorney and client. At present the physician and his patient are at the mercy of attorneys who may be unscrupulous and may put in evidence which is immaterial to the issues in a case, solely for the effect to be produced upon a jury. In the excitement of a trial the temptation to do this sort of thing may be pretty great. On the other hand, if such communications are privileged the physician will be the judge whether certain communications made to him by his patient, which may not be material to the case, shall or shall not be disclosed. And the physician being a witness, impartial, and not under the same excitement as an attorney, I think can be counted on to decide the propriety of giving such testimony more fairly than an attorney.

Where confidential communications are by law made inadmissible in evidence, or "privileged," the purpose is to shield the person whose interests are at stake — not to excuse the other party to the communication from divulging it. So in the case of conversations between attorney and client — the privilege of excluding them is that of the client and not of the attorney. The attorney is excused from testifying, not for his own sake, but because his testimony may injure his client. And this is the way in which the New York law operates in the case of physicians. It is the patient who has the power to decide what shall be told and what withheld, and not the physician. The faults of the New York law are obvious, and outweigh its advantages. It increases the difficulty of defending actions for personal injuries, and this tends to encourage the bringing of such suits for blackmailing purposes. I think few lawyers of standing would favor it.

But a law making medical communications privileged in the interest of the medical profession would stand on a different footing, and would be approved by many members of the legal profession. Such a law roughly should allow the physician to refuse to testify as to matters that in his opinion have no bearing upon the issues raised in the case at bar. Of course, this leaves the physician to pass upon the materiality of the evidence, but the question is one which he is probably better fitted, by reason of his professional knowledge, to decide than the court He has, supposedly, no interest in the outcome of the case. If he believes justice requires the disclosure he can make it; but if he thinks a question is intended to prejudice a party by dragging in irrelevant matter, he can plead the privilege of his profession, and refuse to answer.

Moreover, there should be exceptions in certain cases, as Dr. Cheever suggests. And yet, his exception, including cases where the patient is unwilling to have the testimony go in, I think, is too far-reaching, because it practically would put the law on the same basis as that in New York. His third exception "to expose crime" is rather too narrow. It would be better to make no change in the existing law so far as it affects criminal cases.

Two reasons suggest themselves for confining the proposed change to civil matters. The first is that in criminal cases the most searching and thorough examination of all evidence should be encouraged; and second, that such legislation being experimental, it is just as well to confine it at the outset within rather narrow limits.

Truly yours,

JOHN NOBLE, JR.

AN OVERWORKED THEORY.

PHILADELPHIA, Oct. 10, 1903.

MR. EDITOR: In reference to your courteous editorial criticism of my article in your columns upon the "Ill Health of Parkman" will you permit me in view of the anomalous condition (criticism by one's own host before the other guests) a few words of reply? The first word of my protest must refer to your commendation of my method as "scientific" and at the same time taking away the essential qualities that make an opinion scientific. If my theory is "carried to an extreme"; if few "follow me"; if my theory is "somewhat overworked"; if my "attitude is extremely radical"; if you carefully abstain from assenting that there is any truth whatever in the "theory" — then of course the theory and its author are not scientific. The essence of science is accuracy in gathering and stating facts and in logical induction from them. To be scientific is certainly to avoid theorizing, extremism, hobby-riding, etc. I have sought to be scientific; I believe I have been; I value at the very highest my own consciousness that I have been, and next to that the opinion of my professional colleagues that I have succeeded. You charge me with what all scientists recognize as the greatest scientific sin. I think this was both unnecessary and unwarranted.

In the same mail that brought me your editorial comment was the following letter. I could furnish you with the details of almost any number of such cases:

"916 PINE STREET, PHILADELPHIA.

"MY DEAR DR. GOULD: After all the cases you have reviewed one case more or less can count for little, but I would like to give you mine at least as an illustration. I was an omnivorous reader from early childhood, and early had irritable headaches. They were laid to various causes, and when I was twelve to fourteen my eyes began to 'trouble me.' I was in an Asiatic town, where my father (Rev. W. F. Williams, D.D.) was a missionary, and

I remember he could not understand why eyes which saw so well and were without inflammation or a touch of the all-prevalent ophthalmia should give trouble. With cessation of reading the 'trouble' disappeared. At sixteen I came to this country and was a year on a farm at work and had no trouble and no headache. My study began again at seventeen (Andover and Amherst), entering journalism after graduation. From seventeen until thirty-one, when I was fortunate enough to fall into the hands of a physician who put me into glasses, I had at intervals what I called 'bilious attacks'—frightful headaches and really indescribable sufferings. These attacks came and went apparently without reason and the headaches were disabling. I see now that they were worst when I had office newspaper work and lightened when reporting. The first requires steady eye work and the latter very little, in active open-air work. With glasses my headaches and other peculiar sufferings disappeared, never to return. I may add that as my accommodation disappeared with age my nerves have seemed to be steadier. The last three or four years I am conscious of the lessening of a certain amount of irritability.

"For myself it is as clear as any fact in my personal experience that my health as a writer has turned on being 'glassed.'

I am cordially,

"Talcott Williams."

This gentleman is not a patient of mine; his letter was spontaneously written; he is a man upon whom one of our great universities conferred the degree of LL.D. because of his high intellectual, literary and scientific character.

"One swallow does not make a summer"? Would you care any more for hundreds? For fifteen years I and many others have published clinical reports of such cases, and the ignorers of "an overworked theory" have not heard. In the city of Boston there are to-day thousands of sufferers from "sick," "bilious" or "nervous" headache — such as most of the twelve patients (Mrs. Carlyle, Wagner, Carlyle, Huxley, Nietsche, Margaret Fuller, etc.) were afflicted with. I have — you compel me to say it — cured thousands of just such cases with spectacles alone. If I fail to do so I tell my patients frankly my work has not been well done. If I go over it with greater care I am sure to find my error. You may say that others do not report the matter so. I answer that there is a perfect reason for that, and it is suggested in the enclosed pamphlet, entitled *Sixty-Eight Reasons*, etc. A second answer would be that many other physicians do not fail.

If you will pardon me the frank word, I would like to add that my evidence and accuracy in reporting, together with my experience with some ten thousand cases, should not be called in doubt so lightly. Has the writer of your editorial a greater special experience? He should at least have specified in detail wherein I have "carried to an extreme" and "overworked my theory" and been "extremely radical." I distinctly deny the charges and re-emphasize the entire contention of my writings upon the subject—namely, that the attitude of twenty-eight years on the part of many members of the profession which cries *Exaggeration, Theorizing, etc.*, the attitude of calmly and scornfully ignoring the theory of eye-strain reflexes, is not scientific and has become the most striking illustration I know of "overworking a theory" and of "carrying to an extreme." It is a crime against millions of sufferers who in this time have failed to get relief at the hands of their physicians. At the risk of ruining my little reputation as a scientific man I for one will no longer adhere to this old "overworked theory." The truth for which I contend is understated and is far more important and frequently exemplified than I have represented. If it were not, how could I dare to say so and practice medicine? If oculists advocating this theory did not generally and daily cure these diseases, how could they for a month succeed in practice? The implication need not be more definitely stated that there is some fault in the method of those who do not succeed in giving relief. "Overworked theories" come home to haunt the overworker.

Respectfully yours,

Geo. M. Gould, M.D.

RECORD OF MORTALITY

For the Week ending Saturday, Oct. 3, 1903.

Cities.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 2,908; under five years of age, 916; principal infectious diseases (smallpox, measles, scarlet fever, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 830, acute lung diseases 251, consumption 345, scarlet fever 13, whooping cough 15, cerebro-spinal meningitis 7, smallpox 16, erysipelas 1, puerperal fever 8, measles 8, typhoid fever 64, diarrheal diseases 278, diphtheria and croup 75.

From whooping cough, New York 5, Chicago 1, Philadelphia 3, Baltimore 1, Pittsburg 3, Boston 1, Malden 1. From erysipelas, Chicago 1. From smallpox, Philadelphia 5, Pittsburg 11. From scarlet fever, New York 2, Baltimore 3, Pittsburg 4, and Worcester, Lowell, Lawrence and North Adams 1 each.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Sept. 19 the death-rate was 16.5. Deaths reported, 4,775; acute diseases of the respiratory organs (London) 128, whooping cough 79, diphtheria 40, measles 35, smallpox 5, scarlet fever 39.

The death-rate ranged from 4.5 in Handsworth to 30.2 in Middlesbrough; London 15.8, West Ham 17.9, Brighton 15.0, Portsmouth 12.6, Southampton 15.6, Plymouth 12.1, Bristol 12.8, Birmingham 18.5, Leicester 14.9, Nottingham 16.5, Bolton 17.7, Manchester 18.7, Salford 15.0, Bradford 13.4, Leeds 17.2, Hull 20.3, Newcastle-on-Tyne 23.5, Cardiff 10.9, Rhondda 11.8, Liverpool 21.0, Bournemouth 8.3, Wigan 18.5.

METEOROLOGICAL RECORD.

For the week ending Oct. 3, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING OCT. 10, 1903.

T. W. RICHARDS, surgeon. Commissioned surgeon, with rank of lieutenant-commander from March 3, 1903.

B. L. WRIGHT, assistant surgeon. Ordered to the Naval Hospital, Pensacola, Fla.

F. A. RICHARDSON, acting assistant surgeon. Appointed acting assistant surgeon, with rank of lieutenant (junior grade) from Sept. 29, 1903.

W. N. MCDONNELL, acting assistant surgeon. Ordered to the Naval Academy.

D. N. CARPENTER, surgeon. Commissioned surgeon with rank of lieutenant-commander, from March 3, 1903.

E. J. GROW, surgeon. Detached from the Naval Hospital, Mare Island, Cal., and ordered to the "Mohican."

C. N. FISKE, assistant surgeon. Detached from the "Mohican" and ordered home and to await orders.

L. H. SCHWERIN, acting assistant surgeon. Detached from the "Southery" and ordered to the "Yankton."

J. T. MILLER, acting assistant surgeon. Detached from the Navy Yard, Mare Island, Cal., and ordered to the Naval Hospital, Mare Island, Cal.

J. COWAN, pharmacist. Detached from the Naval magazine, Iona Island, N. Y., and ordered to Washington, D. C., for examination for retirement, and then home and to wait orders.

E. H. MARSTELLER, surgeon. Detached from the "Panther," and ordered home and to wait orders.

J. C. THOMPSON, passed assistant surgeon. Ordered to additional duty at the Navy Yard, Puget Sound, Washington.

W. H. BELL, passed assistant surgeon. Detached from the "Yankton" and ordered to the Navy Yard, Portsmouth, N. H., for additional duty on "Southery."

RECENT DEATHS.

WILLIAM JOHNSON DALE, M.D., M.M.S.S., died in North Andover, Oct. 7, 1903, aged eighty-eight years.

CORNELIUS SHEPERD, M.D., of Trenton, N. J., died on Oct. 7. He was born in Bucks County, Pa., and was a graduate of the Medical Department of the University of Pennsylvania. Dr. Sheperd took much interest in public affairs, and was active in establishing the present school system of New Jersey.

DAVID FRANKLIN, M.D., one of the most prominent physicians in the Harlem District of New York, died from appendicitis, after an operation, on Oct. 7. He was forty-eight years of age, and was graduated from the Medical Department of the University of the City of New York. Dr. Franklin served on the House Staff of Bellevue Hospital, and later practiced for a number of years in California. He was president of the Harlem Medical Association.

OSSIAN W. GOSS, M.D., of Lakeport, N. H., died Oct. 8. He received his medical education at the Harvard Medical School, and was graduated in 1882. He was a leading physician of the town in which he lived and in which he had spent the greater part of his life.

ALBERT NOTT, M.D., M.M.S.S., died in West Newton, Oct. 10, 1903, aged fifty-six years.

BOOKS AND PAMPHLETS RECEIVED.

Manual of Practical Anatomy. By D. J. Cunningham, M.D. (Edin. et Dubl.,) D.Sc., LL.D., D.C.L. (Oxon.), F.R.S. 2 volumes. Third edition. Illustrated. J. B. Lippincott Company: Philadelphia. 1903.

The Treatment of Chronic Catarrhal Deafness (Otitis Media Catarrhalis Chronica). By George W. Hopkins, M.D., of Cleveland, Ohio. Reprint. 1903.

The Diagnostic Value of Abdominal Rigidity. By Joseph A. Blake, M.D., of New York. Reprint. 1903.

A Case of Progressively Developing Hemiplegia, Later Becoming Triplegia, Resulting from Primary Degeneration of the Pyramidal Tracts. By Charles K. Mills, M.D., and William G. Spiller, M.D., of Philadelphia. Reprint. 1903.

Exhibition of a Specimen of Abdominal Pregnancy Removed at the end of Twenty-one Months by Coeliotomy. By Charles P. Noble, M.D., of Philadelphia. Reprint. 1903.

A Study of the Degenerations and Complications of Fibroid Tumors of the Uterus from the Standpoint of the Treatment of these Growths. By Charles P. Noble, M.D., of Philadelphia. Reprint. 1903.

The Treatment of the Peritoneum in Diffuse Peritonitis. By Joseph A. Blake, M.D., of New York. Reprint. 1903.

Colchicum in the Treatment of Gout. By Charles C. Ransom, M.D., of New York. Reprint. 1903.

The Rôle of the Cystoscope in the Diagnosis and Treatment of Some Diseases of the Urinary Tract. By Charles P. Noble, M.D., of Philadelphia. Reprint. 1903.

The Significance of the Temperature in the Diagnosis of Extra-Uterine Pregnancy during the Period of Collapse from Hemorrhage. By Charles P. Noble, M.D., of Philadelphia. Reprint. 1903.

Preliminary Report of an Operation for Abdominal Pregnancy of Twenty-one Months' Duration. By Charles P. Noble, M.D., of Philadelphia. Reprint. 1903.

Adeno-Myome des Uterus. Von Thomas S. Cullen. Illustrated. Verlag von August Hirschwald, Berlin. 1903.

Transactions of the American Pediatric Society. Fourteenth Session. Held at Boston, May 26, 27 and 28, 1902. With Addenda from the Thirteenth Session and an Index, Vols. i–xiv, inculsive. Edited by Walter Lester Carr, M.D. Reprinted from The Archives of Pediatrics. 1902.

Nose and Throat Work for the General Practitioner. By George L. Richards, M.D. Illustrated. International Journal of Surgery Co npany, New York. 1903.

Surgery, Its Theory and Practice. By William Johnson Walsham, F.R.C.S. (Eng.), M.B. and C.M. (Aberd.). Eighth Edition. Illustrated. By Walter George Spencer, M.S., M.B. (Lond.), F.R.C.S. (Eng.). P. Blakiston's Son & Co., Philadelphia. 1903.

Functional Diagnosis of Kidney Disease with Especial Reference to Renal Surgery. Clinical Experimental Investigations. By Dr. Leopold Casper and Dr. Paul Friedreich Richter. Translated by Dr. Robert C. Bryan and Dr. Henry L. Sanford. P. Blakiston's Son & Co., Philadelphia. 1903.

Physical Diagnosis of Diseases of the Chest. By Richard C. Cabot, M.D. Second Revised Edition. Illustrated. New York: William Wood & Co. 1903.

Right-Sided Cardiac Hydrothorax. By Alfred Stengel, M.D., of Philadelphia. Reprint. 1901.

History of the Evolution of the Brain. By Charles H. Hughes, M.D., of St. Louis, Mo. 1903.

On a Method by Which the Eggs of a Sea-Urchin (Strongylocentrotus Purpuratus) can be Fertilized with the Sperm of a Starfish (Asterias Ochracea). By Jacques Loeb. University of California Publications, Vol. I, No. 1. 1903.

The Medical Epitome Series. Physics and Inorganic Chemistry. A Manual for Students and Practitioners. By Alexius McGlannan, M.D. Series edited by V. C. Pedersen, A.M., M.D. Illustrated. Lea Brothers & Co., Philadelphia and New York. 1903.

The Ill Health of Richard Wagner. By George M. Gould, M.D., Philadelphia. Reprint.

The University of Chicago. The Decennial Publications. The Structure of the Glands of Brunner. By Robert Russell Bensley. Illustrated.

Transactions of the American Otological Society. Thirty-sixth Annual Meeting, Washington, D. C., May 12 and 13, 1903. Vol. viii. Part ii. Mercury Publishing Company, New Bedford, Mass.

Case of Splenomedullary Leukæmia Successfully Treated by the use of the Röntgen Ray. By Nicholas Senn, M.D., of Chicago, Ill. Reprint. 1903.

Some Problems in the Major Surgery of the Kidneys; with a Report of Cases. By Joseph A. Blake, M.D., of New York. Reprint. 1903.

Original Articles.

FURTHER OBSERVATIONS ON CERVICAL DISLOCATION AND ITS REDUCTION.

BY G. L. WALTON, M.D., BOSTON.

CERVICAL dislocation is not a mere medical curiosity, but a pathological condition likely to appear in the practice of any physician or surgeon. Its pitiable results are generally, perhaps always, capable of speedy, safe and complete amelioration. It occurs with sufficient frequency to justify every practitioner in familiarizing himself with the diagnostic features and the method of reduction. The limit of time after which operation is contraindicated has yet to be determined; it certainly exceeds six months.

The frequency of this accident is shown by the fact that, in addition to the eight cases whose details I have previously published,[1] at least as many other cases have come under my observation not presenting peculiarities worthy of separate description. All but three of these cases appeared at the Massachusetts General Hospital.

My attention was first directed to the importance of finding an efficient method of reduction by the case in Dr. Warren's service, in which the most vigorous traction with manipulation failed, but spontaneous reduction was effected later by involuntary movement on the part of the patient following the application of cold water to the spine. This case illustrates the futility of traction and at the same time shows the ease with which reduction can be effected if the proper movements are made. Such movements are not likely to be made voluntarily by the patient on account of the instinctive fear of injury, though in the case of Blasius, a child on the way home from an unsuccessful operation is said to have reduced its own dislocation by pressure upon the neck, the head and shoulders being fixed.

Among the methods practiced prior to 1893 none seemed quite to meet the requirements. Traction with or without abduction and rotation was the keynote. The method proposed by Hueter[2] and favored by Stimson[3] seemed most reasonable; this method consisted of abduction and rotation without traction. Abduction, however, may fail to free the displaced articular process, which is held by the ligaments firmly locked against the anterior surface of the articular process of the vertebra below.

The observation of Dr. Warren's remarkable case induced me to make a careful study of the vertebræ. This study resulted in the conclusion that dorso-lateral flexion, combined if necessary with slight rotation (to enable the upper articular process to pass the brim of the lower articular process), would fulfil the requirements, the vertebra being afterward rotated into place as by the old methods. This plan was first suggested to Dr. Richardson, who demonstrated its efficiency upon the cadaver, then to Dr. Beach, in whose service the next case appeared at the Massachusetts General Hospital. The details of Dr. Beach's case, with photographs before and after operation, successfully performed by this method, were reported in this JOURNAL.

This method has since received further authoritative surgical endorsement.[4]

Dr. Mixter has recently reduced by this method a case of six months' standing resulting from a railway accident. The final outcome of this case it is too soon to report, as the head is still in plaster, but in the normal position.

I have seen two other cases which have slipped back during the etherization preparatory to operation. One of these was a unilateral case in Dr. Warren's service. The other case was that of a young man whose head was bent into the typical position of left unilateral dislocation during a football scrimmage. I saw him in consultation with Dr. Sherman of West Newton, who was immediately summoned. It was decided to etherize the following morning, and Dr. Perkins, the regular attendant, into whose hands the case passed, and who coincided in this opinion, reports that during etherization a sudden movement on the part of the patient restored the head to its normal position.

The following case is of interest on account of its etiology, as well as illustrating the ease with which spontaneous reduction may take place while the patient is relaxed in sleep:

CASE. C. V., twenty-eight, an architect, a tall man of slender build and long neck, active in movement, but not especially athletic, consulted Dr. Paul (at whose request I also saw him) Dec. 3, 1901, for a displacement of the neck which he had produced three hours before by a violent movement made during the act of brushing the hair with military brushes. The patient presented the characteristic attitude of right unilateral dislocation; the head was tilted as well as rotated to the left, showing that the articular process had not fallen into the intervertebral notch. Operation was advised and accepted, and the patient entered the Massachusetts General Hospital in Dr. Warren's service. On awaking the following morning the patient found his head restored to its proper position, the spontaneous reduction having occurred during sleep. No further treatment was needed.

Dr. Beach has kindly furnished me the following reports of two other cases coming under his observation:

CASE. Patient, a child between six and seven years old, living in Edgartown; was brought to me one week after a fall from a hammock. It was not known how she struck the earth, but her neck was stiffened by the tenderness and rigidity of the muscles on each side, and permitted very little motion of the head. When examined there was a distinct and considerable projection

of the bodies of two vertebræ into the pharynx as seen from the mouth. There was also a distinct concavity on the dorsum of the neck at a point corresponding with the second and third cervical spinous processes. No attempt was made at reduction on account of the change in the rigidity of the muscles following the accident. I sent word to her attending physician, Dr. Thomas J. Walker of Edgartown, that I hoped he would preserve the anatomical appearances by a plaster cast. Before that could be obtained spontaneous reduction took place, as will be seen by the following quotation from Dr. Walker's letter of July 1:

DEAR DOCTOR: I am very sorry to report to you that the time when I could have made a valuable cast of the injury of our little patient had gone by before I got time to attend to it. She did not get any sleep from 4 A.M. Saturday until that night, when she slept very soundly, during which sleep no doubt the system became thoroughly relaxed. On my visit in the morning (Sunday) I found the cervical vertebræ in perfect position and free motion of the head in every direction.

(Signed) T. J. WALKER, M.D.

CASE. C. McL. entered the Massachusetts General Hospital May 8, 1890. Seventeen days ago, while running around a corner, turned her head sharply, upon which it was caught, and it has remained in that position since. Has had considerable pain in neck and head. Patient, an apparently healthy child, walks about with ease. Head in position of decided wry-neck, turned sharply to the right, sterno-mastoids flaccid, slight amount of antero-posterior motion to head, lateral motion very slight, head cannot be brought to median line, spine of third vertebræ felt out of position one-half inch from median line to the left. Right side higher than left. Right side of back of neck concave, left side convex.

May 18. Poultice to neck after consultation with the staff. She was given ether, breathed quietly for a few seconds, then struggled suddenly and the dislocation was reduced. Motion of the head possible in all directions.

May 19. Head fairly moveable, but with some pain.

May 20. Head in good position, supported by tin internal angular splint.

May 21. Splint not satisfactory. Head resumes the former position.

May 22. Patient in bed, poultice applied.

May 23. Moves head quite freely and without pain.

June 1. Poultice omitted.

June 2. Neck much stiffer, poultice applied.

June 6. Mobility returning. The motion varies much on different days. It has been noticed that when patient is asleep the head is freely movable.

June 10. Patient measured for wry-neck apparatus.

June 12. To return in two weeks for apparatus.

Nov. 10. Returns wearing apparatus. Can move head freely, no deformity. Dispense with apparatus.

Nov. 20. Perfect result. Moves head freely in all directions. No pain or tenderness, no deformity or displacement.

In the seven cases, then, coming to my knowledge since proposing this method of reduction, two have been replaced in sleep, three during etherization and two by the operation itself.

The success of the method in the cases which came to operation, together with the general lack of familiarity with the subject, will perhaps justify a recapitulation of the salient features of this dislocation and its relief.

Mechanism of the dislocation. — In the lumbar and dorsal regions the articular processes are so upright that dislocation can hardly occur without fracture. But the articular processes in the cervical region are so nearly horizontal that a process of one vertebra can readily slip forward over that of the vertebra below and fall into the intervertebral notch. More rarely both of the articular processes of a vertebra may be displaced, probably successively rather than simultaneously.

With regard to the position assumed by the head in these cases, let us suppose an articular process on the left has slipped over; the head will be rotated with the face to the right. If the articular process has slipped down into the notch the head will be tilted to the left, the face being still rotated to the right. If the articular process has become caught on the crest of the process below, the head will be tilted to the right as well as rotated to the right. *The side on which dislocation has occurred can always be determined, therefore, by the direction of rotation; the question whether the articular process has slipped into the notch* (a matter of secondary importance, inasmuch as the movement of reduction is the same in both cases) *may be determined by the tilting of the head.* In case bilateral dislocation has occurred, the head will be carried forward and tilted directly backward.

Diagnosis. — The only conditions with which dislocation is likely to be confused are torticollis and vertebral disease (tubercular caries). In case of torticollis, assuming the head to be rotated to the right and the head tilted to the left, this movement will have been produced by the sterno-mastoid muscle on the left, which will therefore be contracted. If this position is assumed in unilateral dislocation, on the other hand, the left sterno-mastoid will be lax, but the right will be put more or less upon the stretch. In cervical caries the history is the important diagnostic factor.

In the majority of cases of unilateral dislocation no paralysis occurs, sufficient of the lumen being left for the safe passage of the spinal cord, the nerve roots also escaping pressure. In the unilateral cases coming under the writer's observation, paralysis (obviously from root pressure) occurred in two only. In the case of bilateral dislocation spastic paralysis of the lower extremities indicated pressure upon the spinal cord itself.

Operation. — The method of reduction will be made clear by the following diagram (Fig. 1):

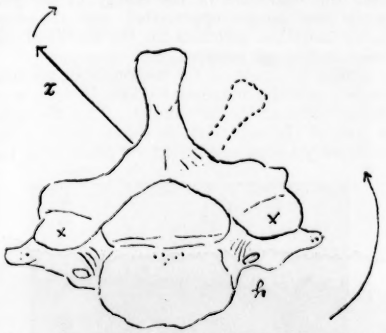

Fig. 1. Diagram of upper surface of lower vertebra, arrows indicating movements for reduction.

This diagram shows the upper surface of the lower of the two vertebræ concerned, that is, the one in normal position. The articular processes of this vertebra are marked XX. The left articular process of the vertebra above having slipped into the intervertebral notch (Y), the situation of the spinous process of the dislocated vertebra will be indicated by the dotted lines. The direction in which the head must be tilted for reduction is indicated by the line Z (in other words, if the patient is facing north the head must be tilted southeast). Slight rotation in the direction of the short curved arrow on the right of the diagram may be necessary to free the process. After the articular process is freed, rotation into place in the direction of the long curved arrow on the left of the diagram will complete reduction. In case the right articular process is displaced by the dislocation, these movements must be reversed.

The patient should be in the sitting position for the operation, and the head should be rocked without traction, for traction only lessens the effectiveness of the fulcrum necessary to reduction.

LESIONS THAT AUGMENT THE DEVELOPMENT OF TETANUS AND OTHER INFECTIONS IN GUNSHOT WOUNDS.

BY LOUIS A. LAGARDE, M.D., WASHINGTON, D.C.

The object of this paper is not so much to discuss the lesions that predispose to infection in gunshot wounds as it is to point out the histological anatomy of such wounds as revealed by microscopic sections.

Gunshot wounds are often referred to as punctured, penetrating or perforating wounds, such as are apt to be inflicted by any blunt instrument wielded with sufficient force. This idea is correct only within limits. A punctured wound from a blunt instrument exhibits lacerations and contusions in and immediately around the area of injury, while a punctured wound by a bullet propelled by a certain degree of velocity will exhibit loss of tissue and lacerations, not only in the immediate vicinity of the channel made by the projectile, but lesions will appear in the parts beyond to an extent dependent upon:

(1) The sectional area of the bullet.
(2) Its velocity.
(3) The resistance encountered on impact.

The greater the velocity or sectional area of the bullet, the greater will be the lesion in the surrounding tissues; and in those instances when the velocity is great, and the resistance on impact is unyielding, as in the case of a ball colliding with the shaft of a long bone like the tibia or femur, the destructive effects are enormous. These effects are so extensive that the wounds produced in this way are referred to as explosive wounds, or wounds showing explosive effects. It is not necessary to resort to the latter class of wounds to study the lesions that are thus created; in fact, microscopic sections of gunshot wounds in soft parts reveal all the characters of gunshot wounds sufficiently for the purpose of study.

Aside from the microscopic studies of the contused area, we know that the tissues are injured beyond the track of the bullet by certain appearances, which reveal themselves in the history of such cases. Thus slough often occurs in the skin beyond the margins of entrance and exit. Later, when healing is well along, a cord marking the track of the bullet running in the soft parts between the two external wounds is easily discernible to the sense of touch.

In recent studies upon the character of the various tissue lesions Strick has shown that hematomata especially predispose to the development of infections. He was able to show that hematomata in wounds increase the susceptibility to infection from tetanus a thousand times more than exists in a clean incised wound. More recently we have demonstrated that burn, as in toy-pistol wounds, adds to the susceptibility, and that animals infected in a cut made by a red-hot knife, with a certain spore mass of tetanus, died in every case, while animals similarly infected in incised wounds made with a cold knife lived in every instance.

Dr. Lardy, in the Greco-Turkish war, in commenting upon the conditions found in 95 infected gunshot wounds out of a total of 469 cases, gives the following:

Pieces of cloth in wound carried by the ball	13
Hematomata	3
Fragments of bone acting as secondary missiles	29
Lodged balls	22
Cause of suppuration undetermined	28
Total	95

In this estimate we must conclude that the percentage of cases showing hematomata is small in view of the twenty-nine cases which presented fragments of bone lodged as secondary missiles. Each one of these fragments was displaced by the force of impact, which of necessity possessed energy enough to rupture the tissue about it, and there was doubtless a corresponding degree of hematomata.

That suppuration should have been so seldom attributed to the lodgment of either the ball or the pieces of clothing seems to accord with the observations of Strick, who experimented with a known spore mass of tetanus with which he contaminated his bullets before firing into rabbits. The animals died of tetanus in every instance. In order to estimate the influence of implantation of foreign bodies in wounds devoid of the lesions which come with the mechanical effects of a missile while traversing tissues, he experimented with four different kinds of foreign bodies; namely, bullets, splinters, cloth and paper. Out of seven rabbits in which the ball was infected with a tetanus culture and implanted in a simple incision in the muscles of the thigh five recovered and two died. Six rabbits inoculated with splinters similarly treated and planted in clean cuts all got well. When placed on cloth and buried in clean incised wounds, the tetanus killed two rabbits out of six; and but one rabbit out of six died when the culture was placed on filter paper which was buried in a clean wound. These results, compared to those of Strick, in which every animal died when shot with infected balls, show that the lodgment of foreign bodies *per se* adds but little to the susceptibility to infection, and that the special lesions from a ball animated by a certain degree of velocity as it passes through tissues are necessary to augment the susceptibility to infection. As already stated, these lesions partake of the nature of hematomata.

The influence of velocity in creating hematomata in soft tissues was the subject of certain experiments that prove of value. We fastened a rusty nail of thirty-two calibers to the end of a board, and, using the board as we would the handle of a hammer, a perforated wound was inflicted in the thigh of a cat by delivering a sharp blow. In the other thigh we fired a thirty-two caliber bullet at a distance of one foot. After death a block from each wounded area showed no gross appearances of hematomata about the perforation caused by the nail, while hematomata extended in the interstices of the muscle fibers for a distance of 5 mm. about the bullet wound in the opposite thigh. The influence of velocity was again shown by firing into cats with the Krag-Jorgensen service rifle. We give below the measured distance of the hematomata as observed away from the channel made by the bullet:

Krag-Jorgensen bullet, cal. 30, v. 835 f. s., hematoma, 8 mm.
Krag-Jorgensen bullet, cal. 30, v. 1138 f. s., hematoma, 12 mm.
Krag-Jorgensen bullet, cal. 30, v. 2200 f. s., hematoma, 23 mm.

The areas, as influenced by this bullet in the order given, would, therefore, be as follows:

Velocity 835 f. s. . . . . 201 sq. mm.
Velocity 1138 f. s. . . . . 453 „
Velocity 2200 f. s. . . . . 1664 „

See Fig. 1 and 2. The extent of hematoma is marked by the darker areas.

It is thus seen that the extent of the hematoma increases with the velocity of the projectile to a marked degree. The fact that destructive effects in the hard bones increased with velocity from the dispersion of the energy of the projectile was always appreciated, and the same factor doubtless accounts for the extent of the lesion in the soft parts.

Again, we know, as far as bone tissue is concerned, that the destructive effects increase with the sectional area of the bullet. That the same is true of the soft parts is shown below. The experiments were conducted by firing into the

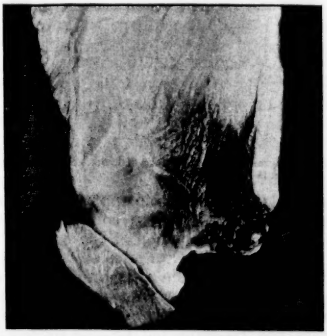

FIG. 1. — Krag-Jorgensen bullet, cal. 30, vel. 835 f. s.

FIG. 2. — Krag-Jorgensen bullet, cal. 30, vel. 2,200 f. s.

gluteal region of cats with the Springfield and Krag-Jorgensen rifles, the velocity of the bullets remaining approximately the same. The measured distance of the hematomata from the channel of the bullet is:

Springfield rifle ball, cal. 45, v. 1301 f. s., hematomata, 30 mm.
Krag-Jorgensen rifle ball, cal. 30, v. 1138 f. s., hematomata, 12 mm

The thoroughness with which tissues are often infected by the energy of an unclean bullet has a great bearing upon the susceptibility to infection. This is well shown by firing bullets of varying velocities and calibers into animals in which the skin has been well rubbed with finely-powdered charcoal. The numbers in millimeters

represent the distance the charcoal particles were found in the tissues away from the channel caused by the bullet:

Pistol ball . . . . . cal. 32, v. 300 f. s., 3 mm.
Krag-Jorgensen bullet. . . . . cal. 30, v. 2200 f. s., 10 mm.

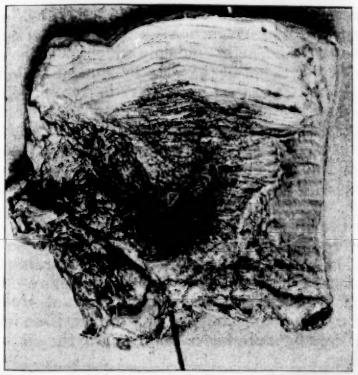

Fig. 3. — Springfield rifle bullet, cal. 45, vel. 1,301 f. s.

Fig. 4. — Krag-Jorgensen bullet, cal. 30, vel. 1,138 f. s.

If we compare the distribution of carbon particles as influenced by the sectional area of bullets, the velocity being about the same, we find the following:

Krag-Jorgensen bullet. . . . . cal. 30, v. 1138, 6 mm.
Springfield bullet . . . . . cal. 45, v. 1301, 17 mm.

This result corresponds closely with that obtained by Koller and Karlinski, who found that foreign bodies (such as carbon or particles of cloth) were driven at a distance of ½ to 2 cm. from the channel track while experimenting with the Swiss model reduced caliber rifle.

Among the lesions of gunshot wounds which predispose to infection another important factor (aside from the hematoma) is the fissuring, extending laterally from the channel track, and the disturbance of the muscle or tissue fibers, which is apt ultimately to lead to necrosis of the same. Microscopic sections show the muscle fibers torn, twisted, and otherwise distorted at a distance of 3 mm. to 10 mm. from the channel, varying with the velocity and sectional area of the projectile (see Fig. 5).

The foregoing has a very important bearing upon the rational treatment of gunshot wounds. In view of the extent to which extraneous matter

Fig. 5.

containing bacteria may be driven into tissues, it is hopeless to attempt to disinfect the channel made by a bullet. Extended experiments were conducted by Muller and Koller, in which they essayed various methods of treatment of the channel track in gunshot wounds caused by projectiles that were primarily infected, namely:

(1) Controls, for which nothing was done.
(2) Those treated with a glass drain.
(3) Those treated with an iodoform gauze drain.
(4) Those irrigated with a 5% solution of carbolic acid.
(5) Those treated by rubbing with a cotton mop soaked in tincture of iodine.
(6) Those treated by cauterizing the wound.

However treated, all the wounds were dressed with a clean sterile dressing.

The results showed that the animals treated by a simple dressing did best of all, and that all those treated by radical measures, such as swabbing with iodine and the application of the thermocautery, gave evidence of suppuration in every instance.

THE PLAGUE OF ATHENS.

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

If one consults mythology the origin of the first great epidemics, so called, will there be found, but leaving aside the myths, it may be said that it is more than probable that the pathology of the

human species is quite as old as its physiology; in other words, that as soon as man existed on this earth disease made its appearance likewise. From this I would not be understood as inferring that the number of diseases originally attacking man was as large as at the present time, but there is no doubt that many of them appeared at about the same time that the human race developed.

Leaving aside the ordinary infectious diseases, such as pneumonia or rheumatism, which certainly must have afflicted the earlier human races, I would say that among the contagious epidemic affections, such as syphilis, the eruptive fevers, typhoid fever, typhus fever, cholera, yellow fever, etc., all these maladies entered upon the pathological scene at different epochs.

Under the very general term of "plague" (λοιμὸς) the ancients included a number of diseases, whether contagious or not, which had as a common character to extend in the form of epidemics. It is not always an easy matter to determine exactly the nature of the various maladies included in this denomination, because the facts which have been handed down to us by the ancient writers regarding many of them are so insufficient that one could hardly guess the true nature of these diseases; but for all that there are a certain number of others of which we have more precise details, and thus it is quite possible to make a distinction between them and to a certain extent suspect their nosological signification.

The most remote mention that has been handed down to us regarding the plague is that of Moses, who says: "Fiat pulvis super omnem terram Egypti; et erunt super homines et quadrupade, ulcera, vesicæ effervescentes. . . . Et facta sunt ulcera, vesicæ effervescentes. . . . Et in hominibus et in quadrupedis facta sunt ulcera in veneficis (magiciens) et in omni terra Egypti." The ulcers and tumors which develop on both men and animals form the entire disease, and it is quite difficult with these two signs alone to pass an opinion on the exact nature of the form of plague described by this wise man, even although one may take into consideration everything that he has written.

The extraordinary phenomena which were said to precede the appearance of the disease throw no light on the question, but many have been the conjectures made regarding it. Certain writers have considered the affection as an epidemic of smallpox, while others are of the opinion that it was nothing more or less than the true bubonic plague, whose antiquity is thus made to extend back to the year 2443 of the Christian era. Daremberg thinks that the pathologic character as given by Moses, consisting in the presence of small pustules preceded by blisters, is in some respects similar to the disease described by Thucydides. The loimographs also refer to a plague which shortly after the one referred to by Moses arose in Egypt and ravaged Greece. The same origin is also attributed to another epidemic plague which also ravaged Greece, but all the data regarding these are so vague that no positive conclusion can be drawn.

We are not any better acquainted with the nature of the plague which attacked Troy during the reign of Priam in the year 1285 B.C., and which caused so much ravage in the Greek army. The description given by Homer is far too incomplete to enable one to say whether the disease was the true bubonic plague or typhus fever. Ovid also speaks in the seventh book of his "Metamorphoses" of a fearful epidemic which took place in the city of Egina in the year 2500 under the reign of Eacus. The poet even gives numerous details relating to the causes which prepared for the appearance of the scourge, and he gives some of the principal symptoms of the affection; but it should not be lost sight of that Ovid was a contemporary of Augustus and still more he was a poet, which should greatly decrease the value of his descriptions.

Herodotus, who lived in the fifth century before our era, has given more exact details regarding the epidemics, and while Sophocles and many other authors have considered all epidemics as due to the wrath of the Gods, as did Homer, Herodotus occasionally searches a solution in the natural causes.

After the battle of Salamimus, when Xerxes left Mardonius in Thessaly and directed his troops toward the Hellespont, the army who followed him gathered the wheat on its route, and when this was wanting ate the herbs, leaves and bark of trees, so great was the necessity for food. The plague (λοιμὸς) and dysentery (δυσεντερίη) was the result of this extreme misery, and killed large numbers of men. The Greek historian also says in another passage of his works that the inhabitants of Chios, having sent a choir of one hundred young boys to Delphes, where the plague was probably reigning, ninety-eight of them were killed off by the disease.

Dionysii Halicarnassensis in the first volume of his "Opera omnia" speaks of an epidemic which occurred during the third year of the LXIX Olympiade, and which, after having devastated the country surrounding Rome, invaded the city itself with great violence. It is said by this author that the mortality reached such proportions that in order to get rid of the corpses of the slaves they were thrown in masses into the Tiber. It is unfortunate, however, that this historian has given us no account of the symptoms of the disease, so that its nature is quite lost to us. Such, briefly, are the great epidemics which were observed before the plague of Athens appeared, and although they are of not much interest, on account of the few facts we have regarding them, they have nevertheless been mentioned here as a sort of introduction to what is about to follow, and it may be said that the plague of Athens is the commencement of the medical history of the great epidemics.

The plague which appeared in Athens in the LXXXVIII Olympiade, or, in other words, 429 years B.C., is the first great epidemic mentioned by Fodéré, but there is no doubt that other epidemics had been observed before this time, because a well-known writer, by name Papon, mentions in the first volume of his work entitled "De

la Peste," which was published about a century ago, twenty-two epidemics of the plague, which had preceded that which attacked Athens. But nevertheless it may be said that the first epidemic of which we really have any precise documents is that which appeared in the capital of Greece.

In his memorable history of the Peloponnesian war, Thucydides has transmitted to us a very complete description of the scourge which attacked Athens, and although one might say that the subject is only spoken of incidentally, it is nevertheless true that this historian relates the epidemic as a great occurrence coinciding with the epoch of the war whose history he relates. Although Thucydides was not a physician, he has not omitted a single detail in the account of the symptoms presented by this great epidemic, and he is all the more authorized to describe the disease because he was himself afflicted by it.

A circumstance which is hard to explain is the absolute silence regarding this disease on the part of the physicians living at the time, and Hippocrates, who was living at the time of the epidemic, has written nothing regarding it, or rather what is more probable, is that that part of his works where he treats of this plague has not been handed down to us. It would seem inadmissible that the father of medicine who wrote on every subject relating to the healing art should have remained dumb regarding this great pathologic tragedy. The silence of Hippocrates regarding this epidemic might also be explained from the fact that he was not an eyewitness of it, and it seems fairly well established at the present time that the great physician of Cos was not at Athens at the time the scourge made its appearance.

Thucydides tells us that the disease broke out during the second year of the Peloponnesian war, at the time when the inhabitants invaded Attica for the second time, and it confined its ravages principally to Athens, although other cities were not completely free from its attack. The disease continued for three years with alternatives of remission and recrudescence, killing off the army and the civil population. When this plague fell upon Athens it was said that it had already broken out in several other districts in the direction of Lemnos and in other places. The death-rate, which in the beginning was terrific, caused the greatest consternation among the inhabitants, and nothing so terrible could be recalled in the memory of man. The disconcerted physicians, on account of the novelty of the disease with which they had to deal, were utterly incapable of combating it, and many of them died victims of their duty.

The origin of this disease is quite obscure and nothing very precise is known regarding it, and I here give the literal translation of a passage from Thucydides which shows that he was badly informed regarding this point: "*It is said* that the scourge commenced in Ethiopia above Egypt and that it then descended into Egypt as well as into Libya and into a large portion of the possessions of the king of Persia." It nevertheless remains a fact that in the city of Athens the disease appeared suddenly. The inhabitants of Piræus were the first attacked, and they affirmed that the Peloponnesians had thrown poison into their wells. Here is textually the description of the symptoms as handed down to us by Thucydides according to the French translation by Charles Zévort of Bordeaux: "Generally speaking one was suddenly seized amidst the most flourishing health, without any apparent cause. In the beginning a violent heat in the head was experienced; the eyes were red and inflamed. The inside of the mouth and tongue were not long in becoming injected by blood; the respiration was irregular, the breath fetid. Then sneezing and hoarseness occurred; in a short time the disease extended to the chest, giving rise to violent spells of coughing; when it became situated in the stomach it caused, in the midst of painful efforts, the evacuation of bile, to which physicians have given different names. The greater number of patients were attacked by hiccough without vomiting, accompanied by violent spasms, which sometimes stopped with the hiccough, at others being prolonged much after.

"Externally the body did not appear very warm to the touch, nor livid; it was reddish, covered with spots and small pustules and ulcers. The interior was so burning that the patients could not endure either the slightest bit of clothing or the very finest linen covers; their only desire was to be naked, and above all wished to throw themselves into cold water. One could see many of those who were abandoned to themselves jump into the wells, tormented as they were by an inextinguishable thirst. It made little difference whether they drank little or much, the result was the same. The patient was the prey of a continual agitation and insomnia.

"As long as the disease was at its height the body did not become thin, and this was a most astonishing fact that it could resist the suffering to such a point; but the greater number of patients who still preserved some strength did not die until the seventh or the ninth day, devoured as they were by the internal fire. If they escaped at this term, the disease descended into the abdomen and there produced a violent ulceration, accompanied by a continuous diarrhea, from the result of which many died from exhaustion later on; because the disease, after having commenced in the upper part of the body and establishing its seat in the head, from here extended to the entire body. If any one was to escape from the more serious accidents it was indicated by the fact that the disease attacked the limbs. It then made eruption on the natural parts, on the ends of the hands and feet, and several patients only escaped from death by the loss of these members. Some also lost their eyes; others during the early part of their convalescence were found to have forgotten everything, and neither recognized themselves nor their friends.

"There is no expression which can give an idea of this disease; its violence, in every instance, was far above all that human nature could stand; but what distinguishes it especially from other dis-

eases which occur to mankind is that the birds and quadrupeds who live upon the flesh of corpses did not come near the dead, although there were a great many without graves, and if they did partake they died as soon as they had eaten. What proves it is that the birds of this kind completely disappeared, and none were seen around the corpses or elsewhere. The dogs, who on account of their familiarity with man, rendered this phenomenon still more marked.

"Such was, in general, and without speaking of a large number of accidents and symptoms peculiar to different patients, the character of the disease. None of the usual diseases were present at this time; if one did occur it terminated in the reigning disease. Some died neglected, while others died after tender care. There was, so to speak, no efficacious remedy, because what did well in one case did badly in another. There was no human being whose vigor or weakness placed him out of reach of the scourge; it carried everything before it, no matter what care or diet the patients followed. The most frightful thing of all was the discouragement of those who were afflicted by it, and believing at once that there was no hope they gave themselves up, and did not resist the disease; what was no less sad was to see, as among the herds, the contagion and death extend by the help that the afflicted gave each other, and this was the cause of the great mortality.

"No one felt more deeply for the dying and the sick than those who had recovered from the scourge; they knew the sufferings and personally were forever without fear, because the disease never proved fatal if contracted the second time.

"What contributed above all to increase the ills of the time was the arrival of people from the country into the city. The latter had much to suffer because they were without homes and without shelter; exposed to an extreme heat, and massed together in badly ventilated huts they died by the score. As there was no order reigning in the city the cadavers remained piled in heaps. These unfortunate patients could be seen rolling in the streets, huddled around the fountains, half dead and devoured by thirst. Even the temples were full of cadavers of those who had sought shelter and died. The excess of the disease was such that not knowing what to do the unfortunates lost all respect for divine and human things. The laws followed up to that time regarding funerals were forgotten, and each one buried his dead as well as he could.

"In other respects this disease inaugurated other troubles in Athens. The vices that were formerly only sought for secretly were indulged in now without concealment. . . . They desired to enjoy as much as possible without delay, and only thought of momentary pleasures . . . ; neither the fear of the Gods nor any human law could stop them; because as every one was dying they considered righteousness and unrighteousness indifferently; for that matter the afflicted did not expect to live long enough to reach the day of judgment and punition. . . ."

Such is the striking description that the illustrious Athenian general has left, and which quite properly follows in his work the beautiful words that he attributes to Pericles, pronounced on the tomb of the soldiers who died during the first year of the Peloponnesian war. This picture given us of the epidemic leaves nothing to be desired, and all symptoms of the affliction are carefully given as well as all the data regarding the duration, prognosis and hygienic condition of the population, so that it can be said without any exaggeration that this writing is one of the most beautiful pages of antique medicine.

The plague did not limit itself to Athens, and, in truth, the disease starting in the Orient undertook a long voyage, during which the capital of Attica was only a stopping-place.

Thucydides also tells us that the plague occurred at the same time among the Athenians who were besieging Potidæa, and he says: "The same summer Agnon, son of Nicias, and Cleopompos, son of Clinias, colleagues of Pericles, took the army that he had commanded and immediately marched against the Chalcidians of Thrace and against Potidæa, the siege of which continued. . . . But the plague having declared itself made such terrible ravages among the Athenians that it ruined their army; even the troops which had arrived before them, and who had not been attacked, took the contagious disease by contact with Agnon's soldiers. . . . Agnon re-embarked and brought his troops back to Athens; out of four thousand men he lost one thousand and fifty within the space of forty days."

As has already been said, this epidemic remained at Athens for three years, and various writers have endeavored to ascertain approximately the number of victims that it made. Thucydides only gives the number of deaths occurring in the army, which amounted to four thousand seven hundred souls. Now, according to Littré, the military population of Athens would hardly amount to twenty thousand men, while the total population of the city, including the slaves, is placed at about four hundred thousand, so that if the plague attacked the civil population with the same severity that it did the soldiers, more than eighty thousand deaths must have occurred. It is quite probable that the poorer classes, as always happens under such circumstances, were more cruelly attacked than the aristocracy, although the rich paid their tribute as well. The great Pericles was a victim of this epidemic, and Plutarch tells us how this great man died after seeing his relations and friends swept away around him. The disease with him took on a chronic form, and he finally died exhausted. In Plutarch's "Vitæ parallelæ," Vol. I, will be found the following passage, which would lead one to suppose that the disease had acted on the mental condition of this great man: "Per id tempus videtur corripuisse pestis Periclem non perindeut cæteros, acris et acuta, sed quae lento morbo diuturnoque, et sæpius alternante corpus ejus sensim conficeret et vim obtunderet mentis."

In "Æliani," Varia hist., lib. XIII, cap. XXVII,

it is stated that the celebrated contemporary of the plague, Socrates, remained in Athens during all this sad time, but on account of his severe manner of living remained free from the affliction.

From all that has been said, it is evident that the plague of Athens was a contagious epidemic disease, and the question now arises as to its real nature and its causes. Thucydides gives no opinion regarding the latter point, and only gives us the facts as he saw them pass under his eyes. This silence as to the cause of the plague of Athens on his part certainly goes to show the great mind that he possessed. The opinion of Democrites, who was a contemporary of the great Grecian historian and of Hippocrates as well, and who was considered the greatest of Greek minds before the advent of Aristotle, found expressed in a work which he composed, according to the authority of Cœlius Aurelianus, on plagues and pestilential diseases, — which unfortunately has never come down to us, — attributes the great epidemics to the destruction of the celestial bodies and the fall of the atoms composing them, the latter being the enemies of human nature. If this singular theory of the philosopher of Abdera is mentioned here, it is simply to show how extensive were the researches of the philosophers of antiquity, although it has no other merit than its great originality. These men not only studied the organization of bodies, but also the origin of diseases, and it may be said that it is from their schools as well as from the colleges of the physician priests who attended to the temples of Esculapius, and were designated by the name of the Asclepiades, that all the medical doctrines originated which Hippocrates collected and handed down to us. According to Diodotus of Sicily extremely abundant rains occurred in Greece in the winter which preceded the advent of the plague and so impregnated the soil that large pools of stagnant water resulted. The excessive heat which followed in the summer caused a putrid fermentation to arise in these marshes, which infected the atmosphere and produced the plague. On the other hand, Plutarch thought that the scourge was brought about by the great number of people collected together in close quarters, for it must not be forgotten that the population of the country surrounding Athens came into the city for protection.

Such are the various opinions of the ancients regarding the cause of this great disaster. The people naturally attributed the disease to the anger of the Gods, and this was still more confirmed in their minds from the fact that no remedy could be found which had any action on the disease. For this reason they resorted to supplications and prayers in honor of Apollo. The opinion of Lucretius regarding the Athenian pest is worth while mentioning, and runs somewhat as follows: "Are not the germs of our diseases transmitted to us from far-off places? Suckled in the bowels of the earth, in the aërian fields, the multitude of contagious ills rise, travel both the heavens and the earth and formed in an instant, these tempests grumble, strike and suddenly disperse." In this passage the poet only develops the ideas of Epicurus on the causes of epidemics, for this philosopher attributed all of them to the presence of miasma in the atmosphere, and thus he explained the propagation of the disease to a large number of human beings.

In modern times many have been the opinions regarding the nature of the pest of Athens. Dalmas, in the Dictionnaire de Médecine in thirty volumes, says in his article on typhus that the plague of Athens was nothing else than this disease, while Mertens, who wrote the history of the plague of Moscow in 1770, believed that there was a difference between the two epidemics. Rosenbaum attributed the mortification of the genital organs to syphilis, while Krause, basing himself entirely on the generalized eruption of pustules which occurred to those afflicted with the plague at Athens, believed that it was nothing more or less than smallpox. Why Webster and Smith should have emitted the idea that the pest of Athens was yellow fever is hard to understand. Schoenke and Osann make no distinction between the true bubonic plague and that which occurred at Athens, while Hoeser considers that the latter was nothing but the plague which had not arrived at its complete development, although later on the professor of Breslau changed his opinion on this point. Hecker found, after careful research, that the plague at Athens could not be compared with any affection known at the present day, and believes that it was a disease which is now extinct. This was also the opinion of Brandeis.

In a very interesting article which appeared in the *Revue des Deux-Mondes* in 1836 from the pen of Littré, entitled "Des Grandes Epidemies," the learned author expresses himself as follows: "Quand on examine attentivement les détails et l'ensemble de cette peste il est impossible de retrouver aucune des maladies qui nous affligent maintenant. La peste d'Athenes est une des affections aujourd'hui éteintes."

Daremberg, who was so great an authority in researches pertaining to the history of medicine, considered the plague of Athens as a particular disease which has no analogy to any one reigning at the present day.

As will be seen, there exists a considerable divergence of opinion regarding the nature of the plague of Athens. This cannot be due to any want of description, because the illustrious Grecian historian is far from being obscure and has certainly well described the symptomatology of the affection. In order to come to any definite conclusion, each one of the opinions emitted should be separately considered, and it may be said at once that among the diseases observed at the present time those to which the plague of Athens has been compared are typhus, bubonic plague and smallpox. The question of scarlet fever, syphilis, yellow fever or measles should not be discussed, because the scourge of the capital of Greece had nothing in its nature which could in the least be compared with any of these. But the bubonic plague, typhus and perhaps more especially smallpox do present similar characters, and it is only

these three epidemic diseases that we shall take into consideration.

It is a fact that the plague of Athens presented certain characters which simulate typhus. In both diseases we find great prostration, violent congestion of both the respiratory and digestive systems, vomiting of bilious matter and partial gangrene of certain members. The special type of eruption which appeared on the integuments in the form of ulcerated pustules, gangrene of the eyes and genital organs, as well as a certain number of other symptoms, distinctly separates the plague of Athens from typhus.

Thucydides states very explicitly that the body was covered with small blisters and ulcerations. Now, the word "blister" implies a small vesicular ampoula, which is simply composed of a quantity of serum underneath the epidermis, and which forces it up into an elevation, and the consecutive ulceration of these vesicles is easily explained. Now, in typhus, no such cutaneous lesion is to be found. In this disease the integuments are covered by pale or bright red spots which do not proeminate above the cutaneous surface and in size never measure more than 3 to 4 mm. These spots are usually present in such numbers that when one looks at a patient afflicted with this disease at some little distance off, the skin simply looks a little redder than usual, but is uniformly tinted. In typhus an inflammatory process is frequently present in the region of the parotid gland, but this appears to have been completely absent in the disastrous epidemic of the Grecian capital.

These signs seem to be quite sufficient to warrant us in making a distinction between the two diseases, and an error could have only been committed by those who examined the question superficially. Typhus is a disease which develops in places where a large number of men are collected, such as in camps, hospitals, ships and prisons, where it seems only to develop spontaneously when a subject already ill with it has been brought among the others, and then it is contracted by mediate or immediate contagion. Now, all these conditions were present at Athens during the first years of the Peloponnesian war, so that it is not to be wondered at that some medical historians considered this epidemic as typhus, but if one recalls that this plague came from the upper Orient, and that before it reached Athens it had ravaged Egypt and the greater part of the Persian Empire, typhus must be excluded necessarily when it is recalled that the plague of Athens was not localized to this city alone but had raged over large countries.

It does not seem possible that the plague of Athens can be considered as bubonic plague. Evagoras, in his "Historiæ ecclesias ticæ," lib. IV, cap. XXVIII, De pestilente morbo, relates how he was eye-witness of several invasions of the bubonic plague at Antioch, and he has not failed in the description that he has left us of establishing a parallel between the plague occurring in his time and that described by Thucydides. His conclusion was extremely explicit, and is as follows: "This disease has certain characters similar to those described by Thucydides, but it differs from it in many respects." Ranchin of Montpellier observed an epidemic of plague which ravaged his city in 1629 and 1630, and after having reproduced literally the description given by Thucydides, he goes on to say: "Voilà une déscription de la peste bien extravagante, et qui ne s'accorde pas avec les signes de la nostre." Fodéré is less affirmative when he says: "La peste d'Athenes décrite par Thucydide, ainsi que celle qui devasta l'Europe et l'Asie sous Marc-Aurele *ou l'on n'observe ni bubons ni charbons*, mais bien la gangrene des extremités . . . pourraient bien n'avoir pas été la veritable peste."

Pariset distinctly says in his "*Mémoire sur les causes de la peste et les moyens de la déstruire*," which was published in Paris in 1837, that the plague of Athens was not the true bubonic plague, and to try to assimilate one with the other would be to fall into a great error, and Littré in his translation of the works of Hippocrates categorically declares that the disease which afflicted Athens was entirely different from the true bubonic plague. Anglada is no less explicit when he states in his "*Etude sur les maladies éteintes et les maladies nouvelles*," published in 1867, that the epidemic which afflicted Athens was not the bubonic plague, for the peremptory reason that bubos were wanting in the symptomatology. Daremberg also distinctly separates the two diseases.

Now, in point of fact, the true bubonic plague is ushered in by fearful hallucinations or by the sudden appearance of a slight fever. Procope, who was an eye-witness of the first invasion at Constantinople of the Oriental plague occurring during the reign of Justinian, says in his well-known description, which will be found in his "Historiarum sui temporis," lib. VIII, vol. I, cap. XXIII, that the bodies of those afflicted did not change in color and that their temperature was not that of fever. No indication of inflammation was noted.

The beginning is entirely different in the case of the plague of Athens, as has already been pointed out: hallucinations were wanting, and the eyes, tongue and pharynx were highly hyperemic. The patients sneezed, and were attacked by violent fits of coughing; their voice was hoarse, while the skin was either red or livid. Thucydides also mentions free vomiting of bile and a general eruption of small pustules followed by ulceration. In the bubonic plague, as described by Procope, there was no vomiting, but the body was covered with black spots, accompanied by bubos in the inguinal and axillary regions. In the plague of Athens gangrene of the genital organs, the limbs and eyes occurred; there was an incessant agitation and a persistent insomnia, while in the plague which afflicted Constantinople we find large plaques of gangrene of the skin, marked depression or a furious delirium. In the former disease death occurred either on the seventh or the ninth day, while in the latter it occurred very suddenly in the beginning of the disease, or during the second or third day.

From all that has been said, it would appear conclusive that the plague of Athens was not the true bubonic plague, and it simply remains for us now to examine whether or not it was the smallpox which afflicted the capital of Greece.

In both smallpox and the epidemic which afflicted Athens we find a generalized eruption followed by ulceration, hyperemia of the eyes, tongue and pharynx, while the general symptoms are more marked in the respiratory and digestive systems. It is well known that in smallpox the eruption may interest the conjunctiva and the cornea, and may thus give rise to more or less severe ophthalmia, which from the destruction resulting may cause complete cecity. This fortunately rarely occurs in smallpox.

On the other hand, death is not the same in the two diseases which we are considering. This occurred on the seventh or the ninth day in the plague of Athens, while in confluent smallpox the patient rarely dies before the eleventh day, and, generally speaking, it may be said that from the twelfth to the fourteenth day is the usual time of the fatal ending, should it occur in this disease. Occasionally the patient is carried away during the first five or six days of smallpox, but this apparently only occurs when the disease presents an exceptional malignancy or when it assumes an abnormal type.

To still further show the differentiation between the two diseases, we would here append the following conclusions taken from the dissertation of Krauss, which was published in 1831, and had for title "*Disquisitio historico-medica de natura morbi Atheniensium a Thucydide descripti*," an analysis of which has been given by Littré in the second book of the epidemics of the French translation of Hippocrates:

"(1) True smallpox does not transform into ulcers, the pustules remain full of puriform lymph until desiccation occurs. (2) Thucydides does not intimate that the eruption had a critical character; now, in all epidemics, in the greater part of patients afflicted by smallpox, the eruption has this character. (3) Several symptoms which, according to Thucydides, occurred to some patients, for example, gangrene of the feet, the hands or the genital organs, have not been mentioned by any author who has described epidemics of smallpox. (4) In the long interval of time occurring from Thucydides to the sixteenth century of the Christian era, when smallpox is expressly named, one finds, it is true, various eruptions mentioned that some writers have called traces of smallpox; but one does not find a description of smallpox, and from this fact it may be argued that the latter disease did not exist in antiquity. Now in point of fact, since its first appearance in the sixteenth century of the Christian era, it has always preserved the character by which we know it at the present time, and it constitutes a disease of a perfectly constant type. Now, who would dare to reproach the ancient writers to have not taken into account this type which is so distinctly characteristic. (5) The cicatrices which smallpox leaves on the skin have never been mentioned by any of the ancient writers, and this seems to be an argument of the greatest force."

From all these considerations I believe that we may conclude that the plague of Athens cannot be compared with any of the diseases known at the present time, and, consequently, it should be considered as a special epidemic disease which is now extinct. Without emitting any hypothesis as to the real nature of this scourge, which would be time lost, it is quite admissible to believe with Littré, Hecker, Daremberg and others that it should occupy a special place in the great class of exanthematic fevers.

THE CONDITION OF THE VASOMOTOR NEURONS IN "SHOCK."[1]

BY W. T. PORTER, M.D., AND W. C. QUINBY, M.D.[2]

(*From the Laboratory of Physiology in the Harvard Medical School.*)

INJURIES to peripheral tissues may at times be followed by a condition termed "shock," characterized by a great fall in blood pressure, sinking of the body temperature, weak and often irregular heart beats and lessening of the normal irritability of the nervous system. Such symptoms may also be called forth by the direct mechanical injury of the nerve cells which maintain these several functions, but this should be distinguished from shock. In shock the primary injury lies outside these nerve cells.

The symptoms which characterize shock have often been ascribed to a depression of the vasoconstrictor nervous system. Each of the nerve chains which constitute the vasoconstrictor nervous system has three neurons. The cell body of the first lies in the bulb; its axis cylinder process ends in the spinal cord or in the bulb itself, in physiological contact with the second neuron. The cell body of the second neuron lies in the cord or bulb, but its axis cylinder process leaves the cord and ends in physiological contact with a sympathetic cell. The sympathetic cell is the third neuron. Its axis cylinder process ends in the wall of a blood vessel.

The bulbar cells, or first neurons, affect the blood vessels only through the second and third neurons. Consequently, if stimuli which pass through afferent nerves to the bulbar cells call forth a normal change in the caliber of the blood vessels, the condition of all three neurons must be normal.

The most conspicuous afferent path to the vasoconstrictor center is furnished by the depressor nerve. It has been shown by Porter and Beyer[3] that the depressor nerve connects with all the bulbar vasoconstrictor cells alike. The fall in blood pressure occasioned by the stimulation of the central end of the depressor nerve is therefore a quantitative test of the condition of all the vasoconstrictor neurons,

[1] Presented before the Boston Society of Medical Sciences, Oct. 20, 1903.

[2] Dr. Quinby took part in this research at the instance of the Surgical Department of the Harvard Medical School.

[3] W. T. Porter and H. G. Beyer: Amer. Journ. of Physiol., 1900, iv, pp. 283-299.

those of the first order, in the bulb, and those of the second and third order through which alone the bulbar neurons can alter the constriction of the blood vessels. If, therefore, the stimulation of the central end of the depressor nerve produces as great a fall in blood pressure during shock as before shock began, the condition of the three vasoconstrictor neurons must be normal even in shock.

Upon this conclusive reasoning rests the method pursued in this investigation. The normal fall of blood pressure produced by stimuli of uniform intensity applied to the central end of the depressor nerve was measured in the rabbit and the cat. In the same animals shock was then brought on and the measurements repeated. Following is an abbreviated but typical protocol:

EXPERIMENT XI, SEPTEMBER 24, 1903.

9 A.M. Rabbit anesthetized with ether.

9.15. Carotid blood pressure 67 mm. Hg. Rectal temperature, 38° C. On stimulation of the depressor nerve the blood pressure fell to 36 mm., a fall of 46%.

9.20 to 9.30. Applied nitric acid to exposed intestines. The blood pressure at first rose slightly and then sank slowly; the rectal temperature also sank steadily. Shock soon progressed so far that the anesthetic was no longer necessary. The gradual sinking of the blood pressure to a point almost 50% below the normal and the effect of stimulation of the depressor are shown in tabular form. At 3.25 P.M. the rectal temperature was 26° C.

Hour.	Blood Pressure, Mm. Hg.	Fall on Stimulation of Depressor, Mm. Hg.	Percent of Fall.
3.25 P.M.	53	30	43
3.30	53	30	43
4.50	40	22	45
5.16	35	23	34

At 5.16 P.M., eight hours sixteen minutes after the beginning of the experiment, the rectal temperature was 25° C.

In other experiments the blood pressure, which had fallen in shock, was temporarily raised to normal by the injection of saline solution in the jugular vein, and the depressor *immediately* stimulated. In such cases the blood pressure fell as many millimeters as it had on stimulation before shock set in.

Exhaustion in the vasoconstrictor neurons cannot therefore be the essential cause of the symptoms termed "shock."

A HITHERTO UNDESCRIBED MEMBRANE OF THE EYE AND ITS SIGNIFICANCE.[1]

BY FREDERICK HERMAN VERHOEFF, A.M., M.D., BOSTON,

Pathologist, Massachusetts Charitable Eye and Ear Infirmary; Assistant Ophthalmic Surgeon, Carney Hospital.

WHILE studying the external limiting membrane of the retina in a section of a normal eye, the writer was surprised to find it continue on at the margin of the disc and pass into the layer of pigment epithelium, where it could be followed until the gradually increasing pigmentation hid it from view. Other sections of the same eye, bleached by the method of Alfieri and stained in a variety of ways, showed the still more surprising fact that this membrane was present in the pigment layer throughout the fundus. Mallory's phosphotungstic acid hematoxylin seems to be the best stain for the membrane, because in specimens fixed in formaldehyde and in bleached specimens fixed in Zenker's fluid it does not stain the cells to any extent, and the membrane is brought out in sharp contrast.

The appearance presented by this membrane in cross section is that of a delicate line running along near the inner margins of the cells, the latter projecting beyond it in the form of processes of variable length. Occurring at almost regular intervals on the line there are black dots, each of which on close examination is found to be situated at the line of junction of two cells. On careful focusing it can be seen that the line is not always on the same level, evidently passing sometimes behind and sometimes in front of the cells. Rarely it is missed entirely for a cell or two. In oblique sections the true structure of the membrane is at once apparent, the latter appearing then not in the form of a straight line, but as a series of hexagonal loops which are fused together at their sides of contact so as to form a screen into the openings of which the pigment cells project. The little dots resolve themselves into the sides of the loops, which in cross section had pointed more or less directly at the observer.

That this is a true fenestrated membrane, and is not an appearance produced by the contours of the cells, there can be no doubt whatever. In the first place, as just stated, it does not correspond in position to the margins of the cells. Secondly, in phosphotungstic acid hematoxylin followed by acid fuchsin it stains blue, whereas the cells stain pink or not at all, and show no vertical lines between them. Thirdly, in certain places where two neighboring cells have shrunken apart, it remains intact. Fourthly, it can frequently be seen projecting beyond a fragmented portion of the pigment layer.

The membrane in the pigment layer is similar to the membrana limitans externa of the retina in structure and also in staining reactions, both membranes giving the staining reactions of neuroglia. The writer has a few specimens which seem to show a similar membrane in the ependymal epithelium of the brain and spinal cord. Possibly this has already been described by others.

For years the membrana limitans externa has been described as being formed either by the apposition of the outer ends of Müller's fibers, or by lateral interlacing offshoots from them. Greeff, in his elaborate article on the retina, still holds to this view. The basis for this belief seems to rest on the fact that Müller's fibers have been seen to end in contact with the membrana limi-

[1] This paper will appear in full with illustrations in the Reports of the Royal London Ophthalmic Hospital.

tans externa. Since, however, an entirely similar membrane, and one with which it is directly continuous, exists in the pigment layer, where there are no such fibers, the writer feels that this theory must be abandoned. The little processes that have been described as arising from the membrane and passing in between the rods and cones so as to isolate them are evidently nothing but the cut ends of loops seen obliquely. The appearance of other little processes extending inwards is due to the sharp contours of the cones.

No one can doubt that the membrane in the pigment layer is a product of the cells which project through it. It seems clear, therefore, that the membrana limitans externa must have a similar origin. The latter membrane, however, makes its appearance long before the rods and cones are formed, so that it must be manufactured by cells which later become converted into these elements. The natural deduction from these conclusions is that the rods and cones and the cells of the pigment layer are essentially of the same nature, and that the former are really only modified spongioblasts (of His). Two facts already mentioned support this deduction: one is that at the margin of the optic disc the rods and cones can sometimes be seen gradually to assume the character of the pigment cells, and the other is that the membrana limitans externa gives the characteristic staining reactions of neuroglia. The writer has found, too, that the rods and cones, and frequently also their nuclei and fibrils, can be differentiated from the bipolar cells of the retina by the neuroglia stain. The theory that the rods and cones represent modified ependymal cells is not new, but it seems to the writer that the foregoing considerations make this theory practically a certainty. It is interesting that this supports Barker's contention, based on analogy, that the rods and cones are not nervous elements but sensory epithelium and that the bipolar cells of the retina correspond to the cells of spinal ganglia.

As is well known, in the rosettes of glioma retinæ there is a membrane which on cross section appears to be identical with the membrana limitans externa of the retina. So far as the writer can ascertain, however, its appearance in plane section has never been described. To determine the structure of this membrane, a glioma retinæ was selected in which the rosettes were both unusually large and numerous. Sections from a portion of this tumor, fixed in Zenker's fluid, show conclusively that the membrane in the rosettes is a fenestrated structure similar in every way to the membrana limitans externa and to the membrane of the pigment layer. The same stains were applied as in the case of the other two membranes and with identical results. Rosettes are frequently to be seen in parts of which the membrane is cut transversely, while in other parts it is cut in plane section and can be seen to become continuous with a series of hexagonal loops. The fenestrated structure of the membrane seems to explain the formation of the rosettes, for it is evident that if a few cells became bound together by such a membrane, and they were otherwise unhampered in their growth, they would be compelled to form a more or less spherical body.

The similarity of the rosettes of glioma retinæ to the layer of rods and cones, the neuro-epithelium of the retina, was first pointed out by Flexner and a few years later by Wintersteiner. Each observer suggested the term "neuro-epithelioma" as the proper designation for these tumors. A strong argument against the theory of Flexner and Wintersteiner in regard to the nature of rosettes is the fact that according to accepted views the membrane of rosettes could not be formed in the same way as the membrana limitans externa, since there is nothing corresponding to Müller's fibers in these bodies. Strangely enough, this fact seems to have been entirely overlooked. The observations of the writer, however, render this objection no longer valid, for it has just been shown that the membrana limitans externa is in all probability produced by the cells which go to form the rods and cones. It was pointed out, too, that the two membranes are identical in structure.

While, then, the nature of the rosettes in glioma retinæ seems plain, the character of the other elements in these tumors is still undetermined. Thus far there is no trustworthy evidence that the cells are differentiated into true ganglion cells or neuroglia cells. Greeff claims that by means of the Golgi-Cajal method he has not only demonstrated several types of ganglion cells but neuroglia cells as well. If ganglion cells can be found in cheese by the Golgi method, it is not surprising that they should have been found in a tissue so prone to undergo degeneration as is glioma retinæ. Then, too, the ganglion cells and neuroglia cells belonging to a portion of retina incorporated in the tumor might easily be mistaken for elements of the tumor itself. By Mallory's method the writer has been unable to find neuroglia fibers in these tumors which were not connected with the retina. Brown Pusey has recently described a case that he evidently regarded as glioma retinæ, and has arrived at the conclusion that glioma retinæ consists essentially of neuroglia elements. He also concluded that the limiting membrane of rosettes corresponded to the internal, not to the external limiting membrane of the retina. Judging from the description of the case, however, the writer is very sure that it was really one of phthisis bulbi posterior following metastatic ophthalmitis, one of the conditions known clinically as pseudo-glioma. The "rosettes" were evidently nothing more than retinal folds.

In view of the fact that there is no reason to believe that these tumors contain neuroglia, it is obvious that the term "glioma retinæ" is an inappropriate one. It is all the more so because there are tumors of the brain termed "gliomata," which are believed to be made up of neuroglia, and it seems possible that such tumors may yet be encountered in the retina. The term "neuro-epithelioma," however, is no less inappropriate

than the other. If it indicated no more than that the tumor took its origin from the epiblast of the neural canal of the embryo, it would unquestionably be a most suitable term. Unfortunately, the term "neuro-epithelium" has been applied to the layer of rods and cones in the fully differentiated retina, and hence "neuro-epithelioma" indicates a tumor whose essential elements correspond to the rods and cones. But as a matter of fact it is rare for rosettes to form more than an insignificant part of the tumor, and in most of these tumors they are entirely absent. It is possible, if not probable, that they do not represent the only form of differentiation and that the essential elements of the tumor may undergo differentiation in other directions as well. The possibility remains that many of the elements represent neuroblasts. It is evident, therefore, that "neuro-epithelioma retinæ" is a no more suitable designation than "glioma retinæ" for the tumors to which they have been applied, and that at present there is no reason why the latter should be supplanted by a term over which it has long priority.

CONCLUSIONS.

In the pigment layer of the retina there is a fenestrated membrane, identical in structure and staining reactions with the membrana limitans externa.

The rods and cones are not nervous elements, but modified ependymal cells, and are analogous to sensory epithelium.

The limiting membrane of the rosettes of glioma retinæ is a fenestrated membrane similar in every way to the membrana limitans externa, and the rosettes correspond to the neuro-epithelium of the normal retina.

The structure of the limiting membrane of rosettes explains why they assume their characteristic spherical and spiral-like forms.

"Neuro-epithelioma retinæ" is no more suitable than "glioma retinæ" for the class of tumors to which these terms have been applied.

Clinical Department.

CLINICAL MEETING OF THE STAFF OF THE MASSACHUSETTS GENERAL HOSPITAL, APRIL 10, 1903.

(Concluded from No. 16, page 431.)

RÉSUMÉ OF DR. F. B. HARRINGTON'S SERVICE.

DR. E. A. CODMAN said: I want to present this leaflet as I did last year, not as a table of statistics, but to give you some idea of all the cases, good and bad alike, which come into one-ninth of the surgical service, with special reference to their results. Please bear in mind that most of the cases we have been able to trace are the least satisfactory ones, and that those that do not report are presumably better.

In using our judgment on a surgical question, we are mainly guided by our individual experience and by what we read of the work of others. Next to our individual experience in value comes the experience of our colleagues, the character of whose work we know. In the records of results found in surgical literature we are often ignorant of the degree of ability and standard of veracity of the author, so that the nearer home we get our facts, the more faithful prognosis can we give our patient.

The weakness of our hospital régime is in the failure to record ultimate results. This résumé which I have passed about is only of real value to one who has seen the individual cases, but if each of the nine staff surgeons presented annually such a report as this, the aggregate result would be worth reading.

A RÉSUME OF THE RESULTS OF DR. HARRINGTON'S SERVICE, FROM JUNE 1 TO OCTOBER 1, 1901, AS SEEN IN THE FOLLOWING JUNE OR LATER.

DISEASES.	Total number treated.	Number traced.	Perfect result.	Good result.	No improvement.	Bad result.	Died.	Died after leaving hospital.

Explanation. — Most of the results were seen personally by Dr. Harrington or by Dr. Codman. A few who replied by letter are included. The results of cases as seen at the time of discharge and not heard from later are not given, because such figures can easily be obtained from the annual report.

Perfect results are not discussed in the remarks at the end, because they are perfect and speak for themselves. Good results include those cases which, while they showed some benefit from the operation, were, nevertheless, not completely relieved. In what respects these lacked perfection is explained in the remarks.

REMARKS ON THE CASES IN WHICH THE RESULTS WERE NOT PERFECT.

General peritonitis from appendicitis. — One of these which was not operated on died. Another drowned suddenly a week after the operation from the perforation of a subphrenic abscess into a bronchus. The one considered "good" had later an abscess in the abdominal wall, and is now well. Two or more successful cases which might justly be considered general peritonitis are included under the next heading.

Appendicitis; wound drained. — The fatal case died of post-operative intestinal obstruction; three other cases had successful operations for this condition shortly after their first operation, and though they are now well are classed as good results instead of perfect. Of the six other good results, three are well, except for hernia in the scars. The other three complain of occasional pain or constipation; one died after leaving the hospital (cause unknown).

Appendicitis; wound closed. — The six good results have more or less complaint of constipation, distress from wind and indefinite pain. In one case it is hard to see what good the operation has done except to eliminate the appendix.

Hernia. — Two deaths were in cases of gangrenous strangulated hernia, in which resection was done. One was due to exhaustion following an operation for repair of a large ventral hernia, consequent to an acute appendicitis the year before. One patient with double inguinal hernia has had recurrence on one side. A patient with femoral hernia writes that she still has pain in her wound.

Miscellaneous laparotomies. — One case of fibroid in which hysterectomy was done still flows regularly for only one day at a time. One case of pelvic abscess of unknown origin died under chloroform when in a moribund condition; the other died a year later of cancer of the stomach. An ovarian cyst (the size of a full term uterus) with a twisted pedicle and a large fibroma of the ovary were reported well, but were not seen. One fecal fistula still has a small sinus. In this case a large round worm was removed incidentally by enterostomy at the operation. The other case of fecal fistula had had four previous operations for salpingitis, broad ligament cyst and abdominal sinuses. At the last operation two fecal fistulæ were closed. She is now well. Two cholecystotomies have hernias in the scars, but are otherwise well. One has not been "quite strong" since the operation. One was well for six months, had recurrence, then the morphine habit and died last summer from persistent vomiting following cholecystectomy. One case of gangrene of gall bladder died of general peritonitis. One died of shock. A case where hysterectomy was done for advanced cancer of the cervix uteri was free from signs of recurrence for eighteen months. It has now recurred (March, 1903). A case of resection of several feet of intestine for tubercular stenosis died of pneumonia (tubercular)? while convalescent. Of the six other cases, five were exploratory laparotomies. In one, gastro-enterostomy for cancer of stomach gave considerable relief, and the patient died nearly a year later. In a case of probable chronic pancreatitis, and in one of peritoneal cancer, nothing was accomplished. In a case of cirrhrosis of the liver, very little was accomplished. A case of gunshot wound of the kidney, liver and lung died. A case with symptoms of acute appendicitis, but in which the appendix did not account for the peritonitis, has been well since.

Gynecological cases. — The case of extra-uterine pregnancy operated on by vagina has not felt well since. Her symptoms point to adhesions. *Pelvic abscess.* — All four cases of pelvic abscess operated on by vagina were temporarily good results, but all still have symptoms of more or less severity referable to an inflammatory condition in the pelvis. The same may be said of a single case which was not operated on. Of the two cases of cancer of cervix (curetted) traced, one lived in comparative comfort for nearly a year, when she re-entered and again was curetted; the other "suffered untold agony," and died seven months later. *Ventralfixation.* — In five of the seven cases of ventralfixation appendectomy was also performed; two cases were symptomatically well, but were not examined; two others had anatomically perfect results, but their symptomatic improvement was questionable. One extremely neurasthenic patient wrote that she was no better for the operation. *Repair of cervix and perineum.* — The one case which replied is an invalid from severe osteoarthritis of the spine. Probably she should not have been operated on. *Dilating and curetting.* — This operation was of course usually done also in conjunction with the other gynecological operations. In the one case of "no improvement" it was done for sterility. *Complete repair.* — Of the four good results, in one, retroversion has returned; one has had considerable distress during pregnancy; one says she is well but "not quite comfortable"; one has had a great deal of distress from a neglected wick in the uterus, but is now well.

Genito-urinary cases. Prostatic hypertrophy, in which Alexander's operation was done. — One result considered good has a very small perineal fistula, but is otherwise well. One case has a little cystitis and has to wear a urinal because he has not complete control. The case which has not improved was previously operated on, and has since been successfully operated on by Dr. Elliot. One case died from shock. *Strictures.* — Of the two "perfect" results, one was from perineal section, the other from divulsion; of the three "good," one was perineal section and two divulsions; of the *miscellaneous genito-urinary cases*, only one is of interest: a case of orchidectomy for tubercular epididymitis, died three months later from tubercular meningitis.

Head Cases. Compound fracture of skull. — The one "good" began to have epileptic fits in about six months. He has since been in Dr. Warren's service for a fracture of the base sustained during a convulsion. *Fracture of the base.* — One still has a slight facial paralysis and left-sided headache. *Concussion.* — One case of concussion has certain areas of paresthesia and diplopia.

Bone and joint disease. — Perfect results: a typhoid periostitis and a deformity following mal-union of femur. Good results: the case of osteochondroma reported at the last clinical meeting; adhesions of knee joint; plastic on necrosis of tibia; tuberculosis of wrist tendons; fringes in knee joint; tuberculosis of shoulder (excision); necrosis of jaw. The eighth case was one of contracted ankylosed knee joint following gonorrhea. An attempt to break adhesions broke the tibia, and was equivalent to osteotomy in straightening the leg. No improvement except alleviation of pain occurred in a case of osteomyelitis of the tibia and in an osteoarthritis of the hip joint. A case of double hip disease is worse than at discharge (operated on in a later service).

Empyema. — A thoraco-plasty for old empyema was partially successful. The patient still comes to the O. P. D. with a large cavity. The other case later had an abscess of the lung, which was operated on successfully.

Cancer of the breast. — Two had been operated on in the summer of 1900 and returned for recurrent nodules. In one case these proved to contain no cancer, and the patient is still free from signs of recurrence (February, 1903). In the other case the patient has lately had recurrence. In two cases there was a large amount of growth in both breasts, and it was known at the operation that all disease was not removed. One of these died some months later, and Dr. Wright found that the disease was probably metastatic from the ovary. The two results considered "good" had small nodules of recurrence.

Hemorrhoids. — One case has a serious cicatricial contraction. The case was a very bad one with ulceration. It could not be properly reduced after operation, and the patient was very ill with alarming abdominal symptoms.

Miscellaneous malignant cases. — The three perfect results were: an epthelioma of the lip; a case supposed to be metastasis of lung (which proved to be phthisis) following an amputation of arm for sarcoma the year before; a case supposed to be a recurrence from a partial resection of the jaw the year before. (This proved to be an inflammatory gland.) The good results were in a large nevus of the face, a parotid sarcoma, and a myxosarcoma of the dorsum of the foot. All three showed small areas of recurrence. The case of parotid sarcoma was first operated on eighteen years before. Of the twelve cases which did not report, radical operation was not attempted in six.

Accident cases. — Two cases only were of much interest. A heavy man slid down a sand bank with his legs apart and struck on an upright crow-bar. The bar entered the ischiorectal fossa beside the anus and passed through the sacrum, appearing on the back near the posterior-inferior spine of the ilium. The wound was douched and drained by a wick passing through it. A year later he was well except for a small sinus. A stout woman with irreducible dislocation of the shoulder was sent in for resection of the head of the bone. It was thought unwise to do this. A year later she returned with a very serviceable arm. The deformity was scarcely noticeable and the motions were good, except in putting the hand to the back of the neck or the back of the waist.

Amputations. — All seven complain of slight pain in stump.

Fractures. — Twenty-six of the forty-nine were of the lower leg. Three results were perfect, one of the thigh, one of the tibia and one of the jaw. The latter was not examined, but reported by letter. He was treated with Dr. Moriarty's splint after leaving the hospital. Each of the good results had some slight complaint; for example, flat foot, pain on long standing, swelling of leg, stiffness of ankle joint, etc. The bad result was the fracture of the neck of the femur in a huge woman. She is still helpless. Three good results were in cases of fracture of the patella, which were sutured with chronic catgut. All had slight limitation in extreme flexion.

The following cases died during or after the service:

Cases which died unoperated: general peritonitis, two cases of compound fracture of skull, carcinoma of rectum, multiple burns, gunshot wound of chest, delirium tremens, ruptured spleen, multiple injuries, fracture of pelvis, multiple fractures.

Cases in which death was probably hastened by operation: appendix abscess, ventral hernia, gallstones, intestinal tuberculosis, cancer of sigmoid, partial obstruction from adhesions, prostatic hypertrophy, sarcoma of thigh.

Cases in which death was probably not hastened, or not more than a few days, by operation: five cases of general peritonitis, two of strangulated hernia, pelvic abscess, general peritonitis from gangrene of gall bladder, mesenteric thrombosis, sarcoma of intestine, gunshot wound of liver, etc., two skull fractures, abscess of cheek, osteomyelitis of humerus (septicemia).

Cases which died after leaving the hospital: appendix abscess (cause unknown), pelvic abscess (cancer of stomach), papilloma of ovary, gallstones (cholecystectomy), cirrhosis of liver, cancer stomach, cancer of peritoneum, cancer of cervix, tubercular epididymitis (meningitis), two of cancer of breast, cancer of larynx, cancer of penis, sarcoma of nose, epithelioma of cheek, tuberculosis of kidney.

Dr. Codman also showed three cases illustrating points in the surgery of the knee joint.

CASE I. I show this patient to demonstrate a point for which I am indebted to Dr. Tenney of the City Hospital.

The point is this, that in some, probably in many, dislocations of the semilunar cartilage, the posterior portion is folded over the anterior so that the whole cartilage lies in front of the bearing of the joint. Thus when the joint is extended locking occurs.

This patient entered the accident room on the 8th of last September, with the cartilage dislocated, and with a history of many previous dislocations during the preceding seven months. I therefore did not reduce it, but the next day opened the joint under ether, and found the cartilage dislocated exactly as shown in this model. I excised the whole cartilage, and the patient left the hospital well in three weeks. The joint is apparently perfect, and gives him no trouble. Usually in these cases the operation is done when the cartilage is back in place, and nothing is seen but a cracked or damaged portion in the middle where the bend occurs. In such cases it is important to fish out the whole posterior half. Perhaps this can be more easily done by first dislocating the cartilage.

CASE II. This patient illustrates a wholly different form of lesion, which is often confused with the type found in the other patient. This is a case of "loose cartilage," or "joint mouse."

In this patient *certainly* the "mice" were chips of articular cartilage, and his case proves to me a point which I have long suspected. I think that most men would say that these mice arose from several different sources, and that few would speak of their being actual pieces of articular cartilage with a little of the underlying bone. The sources commonly mentioned are: Concretions of fibrin, bits of semilunar cartilage, fragments of fringes or fat which have become free in the joint and calcified, or marginal osteophites which have been broken off.

In 1895, when assisting at an operation for this condition, I noticed a stellate scar on the articular surface of the internal condyle. This scar was a little smaller than the "mouse" removed. Since then I have seen the same thing in the cases of other surgeons a number of times. In 1900 I operated on a case in which the mouse nearly fitted the scar.

In this patient before you I found two mice in the right knee and four in the left. One was still hung to the articular surface by a hinge of cartilage. Another had evidently just come out, and could be accurately fitted into its former bed, the base of which was bare bone. A third had been free some time, was crusted, and was considerably too big for its former place.

These bodies are on the card which I hand about. There are also a few other specimens which other surgeons have removed, which show the same structure and therefore probably had the same origin. The first two pieces on the card were taken from the joint of a cadaver after striking a blow with a mallet; on opening the joint these pieces were found still *in situ*, and resembled the depressed fragments of a skull fracture. I picked them out with a director. They resembled very closely the pieces found in this patient.

The point of all this is that when a joint is opened to remove a mouse, it is best to put your finger in and feel of the articular surface of the internal condyle to see if there are other mice in the process of formation. In this case the

patient would not have been cured had I not done so, and as it was, the fourth mouse was removed at a second operation.

I believe that the origin of these bodies is, as a rule, primarily traumatic, and due to a fall on the flexed knee. The articular cartilage on the internal condyle is not protected in flexion. A depressed fracture occurs, followed later by loosening of the chip (perhaps by granulations growing up in the cracks). When the chip is free, it still continues to grow, either by actual growth or by accumulation of fibrin.

Dr. Whitney has kindly made some sections for me of similar bodies removed by Dr. Cabot. On one side you may see articular cartilage, on the other cancellated bone.

I may say that in looking up the question of origin of these bodies, I find a voluminous literature, and that the manner of growth after the body becomes free in the joint is of especial interest. The fact that the growth seems to be chiefly in the cancellated portion, and that in some cases the cellular elements are still capable of staining, seems to point to actual activity of the osteoblasts. *A priori*, however, one would think that growth by concretion and the slow deposit of lime salts would be more likely.

Case III. My third case I take a good deal of pride in, because I freely disobeyed surgical rules in not operating.

This boy entered with a punctured wound of the knee joint discharging pus containing streptococci and staphylococci. I contented myself with enlarging the wound to about half an inch and washing the joint out with salt solution. Believing that the natural discharge of serum would constantly tend to drive out the bacteria, I did not damage the joint by the introduction of tubing or gauze drains, and merely kept the lips of the wound apart with protective. In spite of a picket fence temperature, of a great deal of pain and tenderness and septicemic symptoms, I maintained the same policy without even irrigating the joint again. The resulting practically free joint justifies my conservatism in this one case.

Dr. Whitney: The question of the growth and development of these foreign bodies in the knee joint is certainly very interesting. These cells stain very well, but whether they are still capable of producing bone is a question. It will be only by very careful examination of future cases that we shall find out.

Medical Progress.

REPORT ON PROGRESS OF SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D., BOSTON.

(Concluded from No. 16, page 433.)

THE VALUE OF ENTEROSTOMY IN SELECTED CASES OF PERITONITIS.

F. B. Lund[8] gives the following summary as to the indications for this operation: Enterostomy is indicated for obstruction or paralytic distention of the intestine from whatever cause, after the ordinary means for relief of such distention have failed. It is especially applicable for distention after operations for acute appendicitis or general peritonitis. Under such circumstances it may restore to life cases in which death seems inevitable. Secondary ileostomy is the operation of choice. Local anesthesia is to be preferred. The subsequent operation for closure of the fecal fistula is usually safe and successful.

[8] Journ. Amer. Med. Ass., July 11, 1903.

THE EPIDEMIC NATURE OF APPENDICITIS.

A very complete monograph on appendicitis by Rostovtzeff forms an important contribution to the subject. He does not recognize the epidemic nature of the disease, contrary to N. Golouboff,[9] who in 1897 put forth the view, as based on clinical data, that inflammation of the vermiform appendix was an epidemic infectious disease. In this opinion he is supported by no less an authority than the famous French surgeon Lucas-Championniere, who considers appendicitis as a new disease of an undoubtedly epidemic character and especially prevalent in England and in the United States. Professor Charrin of Paris considered the subject important enough to conduct a series of laboratory experiments, the results of which he embodied in a "Report on Experimental Epidemic Appendicitis." There is no doubt that many of the most prominent surgeons seem to be inclined to consider appendicitis as an epidemic infectious disease, and the more the disease is being studied, the stronger becomes this view. Dieulafoy goes so far as to call appendicitis *maladie toxi-infectieuse*. The author finds that in appendicitis, as in other infectious diseases, there occur icterus, acute nephritis, multiple arthritic inflammations, etc.; he even observed in two cases enlarged spleens. In concluding, the author draws the following: (1) Appendicitis is an infectious disease; (2) in many of the cases appendicitis appears as a primary independent affection of the appendix, in the way that tonsillitis represents an inflammation of the tonsillary glands; (3) during the last eight to ten years the number of appendicitis cases has increased progressively, taking the character of an epidemic, or even endemic prevalence; (4) this prevalence is of a distinct, undoubted nature, as observed by Sonnenburg in 1899, in certain localities in Berlin and Frankfort.

[9] Prakt. Vrach., No. 29, 1903. Med. News, Sept. 12, 1903.

NOTES ON EXPERIMENTAL SURGERY: A MODIFICATION OF THE MCGRAW ELASTIC LIGATURE.

Maury, J. W. Draper,[10] gives a report of experimental work which he did by the authorization of the Department of Surgery of Columbia University. In April last he began a series of laboratory experiments which aimed at finding a method so to place the elastic ligature that it would "punch out." He states that from his too small and confessedly incomplete series of experiments the following conclusions suggest themselves:

[10] Med. News, Sept. 12, 1903.

(1) The McGraw elastic ligature can be so inserted as to " punch out " as large an area of the juxtaposing walls as may be desired, with at least as much certainty and with greater safety than the Murphy button.

(2) That the margins of such openings are smooth and not unduly cicatrized.

(3) That the elastic ligature may remain *in situ* after punching the openings, although this is less likely to happen if tied with iodized catgut.

(4) That such retention in the mucosa of so soft a material is not apt to be harmful or permanent.

(5) That the time required is not sufficiently increased to render the use of this technic impractical.

(6) That perhaps enough has been suggested to stimulate further research by others, so that the actual facts in these most interesting problems may shortly be brought to light.

TREATMENT OF FISSURE AND PROLAPSE OF RECTUM.

Czerny [11] describes a case of prolapse treated by operative intervention through a parasacral incision exposing the rectum and taking a lengthwise tuck in it with a row of button sutures. The stitches did not pass into the mucosa, and the tuck projected toward the lumen of the intestine. The rectal wall was sutured at the same time with several catgut stitches to the severed fibers of the ligaments. By these procedures the wall of the rectum was made smaller and stiffer and it was suspended, thus completely counteracting the tendency to prolapse. He treats fissure by excision in profound anesthesia, uniting afterward the tip of the wound in the mucosa with the opposite point of the wound in the skin, drawing it out for the purpose by a suture passed through the mucosa at the tip of the incision. The rest of the wound is united with two to four stitches. The fissure is thus radically extirpated and the defect left is lined with sound mucosa. He has found the operation a success in his six cases treated in this way.

COLITIS.

C. L. Gibson [12] redescribes his method suggested in 1902. It consists particularly in reproducing the technic of Kader's gastrostomy, making a valvular opening into the intestine and introducing a drainage tube through which treatment can be carried on. When it is removed the valvular arrangement completely closes it and to obtain permanent closure of the fistula when required it is only necessary to discontinue the treatment by omitting to pass the catheter into the gut. The Weir modification of this, with the use of the appendix, has the apparent advantage of making the simple operation still simpler, but the valvular formation is wanting and the after-treatment is less agreeable. Gibson says that the results of this operation have been such as to justify the hope of marked amelioration or cure of the symptoms, while it offers the advantage that it is devoid of every disagreeable feature of an artificial anus. It calls for only a short confinement to bed. If a prolonged course of treatment is required, it may be carried out if necessary by the patient himself. A change of climate, so often beneficial, is made possible. Its performance is perfectly simple and safe. The intermuscular incision greatly reduces the risk of a subsequent hernia, and the prompt closure of the fistula is certain and spontaneous.

GALLSTONE DISEASE.

Mayo [13] remarks on the success of gall-bladder surgery. In 582 operations, he has had but 17, or 3%, that required a secondary operation. It is possible, however, that others may have operated on some of his cases, so this figure is not absolute. Experience has taught him how to get over the defects of his earlier work and avoid the causes which lead to subsequent troubles. He remarks in this connection that a few patients who have had cholecystotomy performed will have a colic or two and transient jaundice within the first month or two after the operation, but usually these do not recur. They are probably due to the non-emptying of the crippled gall bladder with sufficient promptness. Unless there is more than a single spell of pain after closure of the fistula a secondary operation may not be required. The common cause of secondary symptoms is incomplete removal of stones. This, however, is avoidable with sufficient care. Stones in the cystic duct may escape attention, hence the importance of great care in its exploration. In such cases if the stone completely obstructs the duct he clamps it below the obstruction and cuts it off and then performs cholecystectomy from below upward. It may be done almost without cutting by simple traction. It is important to explore the ducts with the fingers before opening the gall bladder in every case, as stones are sometimes overlooked in the common duct, where they may lie quiescent for years. One cause of failure from cholecystotomy is from secondary obstruction of the cystic duct, possibly eventuating in a mucous fistula or repeated attacks of colic; hence the advisability of generally excising the gall bladder whenever the cystic duct is involved. In this way he has in his later practice eliminated this most common cause of secondary trouble. In septic cases long-continued drainage is necessary; severe symptoms may follow too early closing of the fistula. Cancer may be said to be secondary to stone formation and may occur after operation or, if present, be mistaken for inflammatory conditions. All thick-walled gall bladders should be looked on with suspicion. As they are functionally useless, cholecystectomy is better than cholecystotomy. Chronic pancreatitis may exist at the time of operation and require long-continued drainage. The condition of the pancreas should be observed at the same time as that of the ducts. If disease is present there is the choice of cholecystenterostomy with the Murphy button in addition to removing the stone, or of draining for a long time. In the one uncomplicated case in his experience

[13] St. Paul's Med. Journ., August. Journ. Amer. Med. Ass., Sept. 19, 1903.

which required a secondary operation, the gall bladder was very large and the fistula did not close. On dissecting out the gall bladder it was found that by low attachment to the abdominal incision it had formed a channel in which, in certain positions of the body, bile would gravitate outward. After cholecystotomy the gall bladder should be attached as high up in the incision as convenient. Persistent biliary fistula usually means obstruction of the common duct. He holds that every one understands the importance of not attaching the gall bladder to the skin. In earlier days persistent biliary fistula was usually due to the mucocutaneous suture, the evils of which he does not need to point out. The turning in of the margins of the incision in the gall bladder and the tying of a purse-string suture closely about the drainage tube, as in Kader's gastrostomy, hastens the healing of the fistula. Two possible or rather common causes of failure to effect a perfect cure that cannot always be avoided are post-operative adhesions — those to the stomach and duodenum are the most common and may require secondary separation with the use of Cargile's membrane — and hernia, which is not usually troublesome. It may follow a long incision in obese people. While the adhesions usually relieve themselves by stretching, he does not allow the gauze drains to come in contact with the stomach and duodenum on account of their possible development, but interposes a piece of rubber tissue and leaves it from six to eight days, until the adherent films surrounding the drains become organized. To avoid hernia, he makes a secondary opening outside the working incision in cases where it is at all likely to occur, close to the ribs, and through this the drainage matter may be brought out. This enables us to carefully close the full length of the original incision. The necessity of this is increased if the opening has been extended downward to remove the appendix.

SHOULDER DISLOCATION.

Beck [14] reports a case where, on account of a recurrent humeroacromial dislocation of the shoulder, he operated by exposing the acromial surface of the capsule, which was found to be so much relaxed that a fold could be taken up and contracted by making a purse-string suture in it. At the same time a hole was drilled into the head of the humerus and into the acromion, and a medium silver wire carried through it to ensure retention of the head by adhesion formation. There was no evidence of rupture of the supraspinatus muscles, or infraspinatus, causing rupture of the capsule or any abnormality of the joint. The operation was followed by no reaction and when the wire was removed five weeks later the result was good. Six months after operation it appears perfect.

DANGERS OF THE TRENDELENBURG POSITION.

Professor Kraske (Freiburg) [15] said that although the Trendelenburg position was attended by manifold advantages under numerous conditions, it might nevertheless occasionally lead to serious accidents. Instances of paresis of the peritoneal muscles and emphysema of the abdominal walls had already been recorded. These were only temporary lesions and their after-effects were of little, if any, consequence, but the interference with the circulation which attended the production of anesthesia in the Trendelenburg position was of much greater importance. In two cases of myocarditis the administration of ether as an anesthetic led to a fatal issue, which, in Professor Kraske's opinion, was due to acute dilatation of the heart, the result of increased blood pressure caused by the Trendelenburg position. In a third case the patient suffered from ileus for four days but recovered on the fifth day. In a fourth case in which the symptoms of ileus became very alarming, he reopened the abdominal wound and found that the omentum was doubled up and lying above the liver, the effect being to cause obstruction of the transverse colon. He freed the omentum, but the patient died. Similar observations had been made by Professor Schauta of Vienna, who found that after the intestine had undergone displacement, in consequence of the employment of the Trendelenburg position, it did not spontaneously return to its normal place when the patient lay horizontally; he therefore recommended that the surgeon before closing the abdominal wound should correct any displacement of the intestines there might be. Professor Kraske was of opinion that the hematemesis observed after laparotomy was due to distention of the gastric veins.

Professor Trendelenburg said that he doubted whether the cardiac embarrassment in the case of myocarditis mentioned by Professor Kraske was really caused by the elevation of the patient's pelvis and lower extremities. Such patients were not good subjects for the inhalation of an anesthetic, in whatever position they might be. With very corpulent patients he did not employ elevation of the pelvis for more than five or ten minutes at a time.

LYMPHATICS OF ESOPHAGUS REGION.

K. Sakata [16] writes as follows: Injection of the cadavers of children by Gerota's method showed that the lymphatics of this region originate in two separate sets, with no direct communication between them. The first set is arranged lengthwise in the lower layer of the mucosa, while the second is not so large nor so regular and forms a network on the surface of the perimysium. The lymphatics communicate directly with those of the pharynx above and those of the stomach below, although the intervening vessels may run a long way in the submucous tissue or against the wall before reaching them. The close clustering of glands around the recurrent nerve explains the paralysis of this nerve frequently observed in cases of carcinoma of the esophagus. He noted

it in 18 out of 236 cases, and in 13 it was unilateral. The glands may, therefore, be grouped as the near and the distant. The latter are represented by the deep, lower cervical glands, found in the angle formed by the subclavian and internal jugular veins.

Reports of Societies.

THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

SEVENTEENTH ANNUAL MEETING, HELD MAY 12, 1903, WASHINGTON, D. C.

(Continued from No. 16, p. 437.)

REPORT OF A CASE OF COMPLETE AVULSION OF THE SCROTUM, THE SKIN OF THE PENIS AND THE LEFT TESTIS.

DR. ALFRED C. WOOD of Philadelphia related the instance of a man thirty-three years old who was engaged in making an adjustment of a ball upon a revolving shaft. His clothing caught, and he was taken around a few times and dropped upon the floor. He was taken to the hospital, and the doctor saw him within half an hour after the accident. The scrotum was found to be entirely absent, and the skin of the penis was dissected off as clean as could be, well up to the muco-cutaneous junction. The left testicle was absent and the right testicle was left exposed in the wound. Hemorrhage from the torn cord was readily controlled. It became a problem to know how to cover the testis. Flaps were finally taken from either thigh and utilized. The patient remained in the hospital about one month, when the testis was well covered. The Reverdin method of skin grafting was employed to cover the penis, small fragments of skin being taken from time to time from the thigh, with the result being all that could be expected. His sexual relations appeared to be perfectly normal.

DR. RAMON GUITERAS of New York cited the instance of an Italian who had gangrene of the scrotum. The scrotum had entirely sloughed away, leaving both testes exposed. An artificial scrotum was made by taking flaps, two from above the pubes and two from below on the inner side of the thigh, all four flaps being egg-shaped and brought together somewhat like the cover of a baseball.

A NEW METHOD OF PERFORMING PERINEAL SECTION WITHOUT A GUIDE.

DR. CHARLES L. GIBSON of New York presented this communication. A description of his method has already appeared in the report of the Section on Genito-Urinary Surgery, New York Academy of Medicine.

THE CONSERVATIVE TREATMENT OF CASES OF TUBERCULOSIS OF THE GENITO-URINARY TRACT.

DR. GEORGE CHISMORE of San Francisco read this paper. He said that improved methods of diagnosis and a clearer recognition of clinical symptoms had brought us to the conclusion that tuberculosis of the genito-urinary tract was far more commonly encountered than was formerly believed, and that such cases were always prolonged in duration, rebellious to treatment and very grave in character. He gave the histories of several cases that had been under his observation for some time, intending to show that it was possible for a person afflicted with undoubted tuberculosis of the genito-urinary tract to live for years a useful life, without surgical attempts to remove the infected organs. In three of these cases the exciting causes were traumatic, falls and muscular strains. Heredity was not at all marked. In one case there was no tubercular history. One of his children married a man who had tubercular epididymitis, for which he had been curetted a year before with apparent recovery. He died in a year of tubercular perforation of the intestine, verified at autopsy, and his widow soon began to void urine frequently; tubercle bacilli were found in her urine, proven by culture, for several months, although she suffered only from frequent micturition. She married again after two years, and soon returned to perfect health. In three of the cases, frequency in micturition was the marked early feature. In all the kidney or bladder, or both, were involved. In other cases the disease seemed to be limited to the scrotal contents, but never when the urethræ were not invaded by instruments or irritants. Such an observation had led him to abstain from all local measures that were not imperatively demanded in cases of suspected tuberculosis of the genito-urinary tract. This explained to him why so many of these cases had the prostate gland affected.

DR. HUGH H. YOUNG of Baltimore did not think we should or could expect so much in the way of conservative treatment as Dr. Chismore, because of climatic differences.

DR. ARTHUR T. CABOT of Boston believed that the hygienic treatment of certain cases was better, especially when the tuberculosis was disseminated through a complicated series of channels or organs. Now and then the disease would locate itself in the epididymis, for instance, and then operation would be called for. He believed that if we operated at all we should be forced to do so, and not select such a course as the best for the patient. Where tuberculosis started in one kidney, and he found such a condition before the bladder became involved, he believed in the thorough removal of that kidney, and had seen brilliant results follow such a procedure.

DR. W. K. OTIS of New York said that no cases appeared alike in genito-urinary tuberculosis, and, therefore, we were unable to tell what was going to happen when any one method of treatment was employed. He had never been able to find any satisfactory agent for local treatment of a tubercular cystitis. He much favored the let-alone treatment in all cases of genito-urinary tuberculosis. However, when surgical treatment was deemed advisable, it should be done most thoroughly.

Dr. John Van der Poel of New York reported a case of tuberculosis of the left testis with secondary involvement of the prostate as he then thought. An abscess which had occurred in the epididymis of the left side had taken care of itself, but an absolute diagnosis could not be made by that alone. Massage of the prostate showed tubercle bacilli, and an operation was advised. The testis itself did not seem to be involved, but the epididymis was removed, thinking it alone was infected. Upon a microscopical examination it was shown that the incision was made directly through diseased tissues, though the testis itself seemed normal. Subsequently operation was necessary to remove the testis as well as that of the opposite side. This case he said demonstrated how careful one should be in advising a partial operation. The case was drained through in the groin of the left side, and the ultimate result was good.

Dr. Paul Thorndike of Boston said that in cases of more or less advanced tuberculosis, where it seemed advisable to make a palliative operation for the patient's comfort, one would necessarily be deterred from so operating because of the possibility of not removing all the diseased tissue. He said that you may not expect to get all the diseased tissue, but that in nineteen-twentieths of the cases you would place the patients in better conditions. He would even go further than Dr. Cabot and take out a badly tuberculosed kidney even when the other kidney was involved, providing he was sure of doing the patient some good by this procedure. He emphasized the point that we should not be deterred from operating because of fear that we could not remove all the diseased tissue.

A CASE OF CALCULUS ANURIA RELIEVED BY OPERATION.

Dr. Arthur Tracy Cabot of Boston read this paper, and said that these cases were so rare and fraught with such serious consequences that it was of the utmost importance to accurately study and report those that came under observation. The patient was a strong, vigorous man of fifty-seven years of age who, for fifteen years, had suffered from severe pain in the right lumbar region, the pain shooting down into the right groin and into the penis. These attacks occurred about once a year, and were accompanied by nausea, vomiting and a bloody urine. Frequently they were followed by the passage of stones from the bladder, some being one-third of an inch in diameter. Two years ago he had an attack occurring upon the left side. During the past year he had had these attacks upon the right side about once a week. For the past three weeks he had persistent, almost constant, pain in the right side with nausea and vomiting each day, but no stones were passed. Only 2 or 3 oz. of urine was voided in twenty-four hours. Burning pain occurred in the glans penis. There was great tenderness and rigidity in the right lumbar region, and a sense of great and deep resistance over the right kidney. No prostatic enlargement existed. A skiagraph showed no calculi in the bladder or kidney. He saw the patient twenty-four hours after his admission to the hospital, during which time no urine could be withdrawn by the catheter, and it seemed probable that the right kidney was stopped by a calculus, and that the left kidney was practically useless. The severe attacks in the right kidney were supposed to account for its inactivity. The right kidney was cut down upon, and was so large that it was with difficulty lifted out of the wound. It was dark purple in color and dotted with little yellow spots, strongly suggesting miliary tubercles. One of these little abscesses contained a few indeterminate crystals. The pelvis of the kidney was opened and explored, but nothing was found. The ureter was followed down into the bladder, but nothing could be felt. A drainage tube was introduced into the renal pelvis, the capsule was split along its convexity, and the wound was closed so far as drainage would allow. Within the next twenty-four hours the patient passed 900 cc. of urine; in the next, 1,500 cc., and as much more was supposed to have escaped into the dressings. On the fourth day the urine suddenly ceased coming through the bladder, and a proportionate amount escaped through into the dressings. Some hours later urination by the bladder was resumed and drainage through the tube then diminished. On the eighth day the tube was removed, and leakage through the wound quickly stopped. On the fourteenth day the bladder was washed out, and two stones of about the size of a grain of wheat were obtained and a larger stone was felt to click against the Bigelow evacuator. This stone measured 1 cm. in diameter. This was crushed and pumped out on the twenty-fourth day. From this time recovery was practically uneventful. After convalescence the bladder was examined by the cystoscope. The right ureter was three times the normal size, and the urine could be seen coming from it in nets. The left ureter was occupied and filled by a string of thick pus, which was not moved or stirred by any urine escaping alongside of it. Cystoscopic examination on the following day showed the left ureteral orifice occupied by this plug of pus. With this orifice kept in view, an assistant made pressure over the left kidney, and at once a gush of thick pus was seen to come from the ureter. As a result of this observation, and from the fact that the right kidney ceased to send its urine into the bladder, it seemed to be proved beyond question that the left kidney was practically destroyed. This case, taken in connection with the case of calculus reported by the speaker in 1893, showed the importance of thoroughly stripping the ureter in these cases where the stone cannot be felt.

Dr. Ramon Guiteras of New York reported the case of a Canadian who sufferred from hematuria. From his past history he thought of stone in the ureter. A local x-ray worker denied the existence of stone, but Dr. Leonard of Philadelphia said one was present just where the

ureter passed over the pelvic brim. Operation was performed, and just at the point named by Dr. Leonard there was a bulging of the ureter of fusiform character. Palpation of it revealed no stone. It was incised, but no stone was found, but a large mass of thick yellow pus of the consistence of Camembert cheese was noted. The ureter was stripped down into the pelvis. The patient's hematuria ceased. Although no stone was seen, he thought the probabilities were that there had been one which had passed down into the bladder and escaped through a large perineal opening which the patient had.

(To be continued.)

Recent Literature.

How to Keep Well. An Explanation of Modern Methods of Preventing Disease. By FLOYD M. CRANDALL, M.D. New York: Doubleday, Page & Co. 1903.

This is a small octavo of 500 pages, and is designed more especially for the use of readers without a medical education. It is divided into nineteen chapters, preceded by an introduction. The author admits that much light is nowadays offered upon medical subjects, but, in his opinion, the quack usually holds the candle. Moreover, he thinks that the medical profession is to a certain extent to be blamed for this state of affairs, in that it has frowned upon the public discussion of medical subjects by its own members. It is to remedy this situation that the author has written this book.

The American Illustrated Medical Dictionary, including much collateral information of an encyclopedic character. By W. A. NEWMAN DORLAND, A.M., M.D. Third edition, revised and enlarged. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Dorland's excellent medical dictionary we have previously reviewed at length. It appears now in its third edition, with such revisions as the short time intervening between the second edition and this have necessitated. The binding of flexible leather remains the same, and is to be commended.

A Thesaurus of Medical Words and Phrases. By WILFRED M. BARTON, M.D., and WALTER A. WELLS, M.D. pp. 534. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

A somewhat new departure in the way of medical books of reference appears in Barton and Wells' "Thesaurus of Medical Words and Phrases." The idea embodied in this unique book is to reverse the process of an ordinary dictionary and to attempt to supply a fitting term or phrase to express an idea when merely the meaning or idea is in the mind. We can easily see the value of such a plan, and can certainly commend the book to our readers. It also is bound in flexible red leather covers, and is most attractive in appearance.

THE BOSTON

Medical and Surgical Journal

THURSDAY, OCTOBER 22, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

EYESTRAIN: AN OVERWORKED THEORY.

IN our issue of Oct. 1 we printed a brief editorial comment on the theory of eyestrain as a cause of various nervous affections, apropos of a paper which we had recently published from the pen of Dr. George M. Gould relative to the "Ill Health of Francis Parkman." Dr. Gould takes exception to our position, as may be seen by reference to his letter in our issue for Oct. 15. This we regret; we certainly had no intention of criticising our "guest" in any but the friendliest spirit, nor can we see in our well-meaning effort an "anomalous condition." We modestly reserve the right of comment on our contributors' productions, nor does the fact of allowing space in our columns commit us to agreement in any views which may be expressed.

We must, therefore, reiterate our opinion that Dr. Gould is an extremist in his advocacy of a theory which unquestionably stands on a basis of scientific fact. That eyestrain is causative of many distressing symptoms we gladly admit; that it is causative of so vast an array of affections as Dr. Gould maintains we as firmly deny. We regard Dr. Gould's method as scientific in that he has drawn renewed attention to and collected many facts bearing upon one important element in the production of certain nervous disorders; this service should be recognized and appreciated, and we are entirely ready to acknowledge that there is much practical utility in the theory. There are those who find truth in the uric acid theory, to which many of the ills of human life have been attributed. As a theory it has claim to scientific consideration, but its application in the hands of its advocates has at times gone quite beyond the bounds of scientific common sense. And so

of many another excellent medical theory. Dr. Gould must recognize that the worth of a theory and the manner of its advocacy are quite distinct. Darwinism, heredity, degeneracy, to mention but three, have all suffered grievously at the hands of their too ardent advocates, and we are forced to say that the eyestrain theory has similarly suffered from extreme claims.

Dr. Gould asks why we regard him as an extremist. We quote a few of his own statements in explanation. In his paper on "The Ill Health of Richard Wagner," he says:

> Wagner's clearest symptom was "sick headache;" migraine, megrim, hemicrania, nervous headache or bilious headache are other names for this terrible affection. It causes a large number of other symptoms, and is itself of an infinitely varied type, according to the kind of near-work required and the kind of organism of the patient. I have had thousands of patients with this disease, and ninety-nine out of one hundred were cured by spectacles alone.

No one who has had experience with migraine will deny that this is, at least, a radical statement, and one which, in the present state of our knowledge, could be made only by an extremist. And again:

> In Wagner's passport he is described as "wearing glasses." Outside of that simple statement no one ever seems to have seen him doing so, or spoken of the fact. Mr. Ellis has proof that seems to him pretty good that he did not wear them. It is of no consequence. Any spectacles he could get would not have neutralized his eyestrain. Were he living to-day he would in all probability not find any oculist or physician in Germany that would help him or care to help him in the one possible and effective way.

Such an arraignment of German physicians as a class does not savor of scientific fairness. The following remark also lacks the judicial quality:

> There is no greater cruelty, no greater crime against humanity, than this of non-recognition and scorn of eyestrain.

Writing of Jane Welsh Carlyle, he scores his professional brethren in the following words:

> The old physicians of forty years ago were excusable, perhaps, although we marvel to-day at their stupidity, At best they could say their parrotlike, everlasting "Take a trip to Italy or to Switzerland;" the silliest whispered "gingerbread," or twiddled their fingers. They had not yet learned the pompous pseudoscience that cries, "She is a neurotic, afflicted with climacteric melancholia, the victim of heredity, mental dyspepsia and masked insanity." The favorite word of this pseudoscience is *stigmata*. If it could only progress so little as to make the addition of a single letter to its lore! If it could only learn one-hundredth as much of *astigmatism* as it affects to know of *stigmatism*, less *stigma* would there be, and infinitely less suffering in the world! In the last twenty years any physician who does not know the true nature of such a case as that of Mrs. Carlyle and cure it instantly should be deprived of his medical degree.

This, also, we hold, transcends the limits of unprejudiced statement. We leave it to our readers to determine whether or not these excerpts from many which might be made are the language of an extremist.

As a matter of fact we have long been deeply interested in the theory of eyestrain as a causative factor in many nervous disorders. As Boston is smaller than Philadelphia, so our experience is, no doubt, smaller than Dr. Gould's, but such as it is, we confess again that it prohibits us from following him to the end of his theory. We are willing to go with him part way on his journey, but if we part from him before he has reached its end may we not, weighing all the facts, claim some justification for our timidity?

THE LEGAL STATUS OF FAITH HEALING.

A CONSIDERABLE amount of light has been thrown upon the mooted question of the relation of faith healing to the law by a recent decision of the New York State Court of Appeals. Within a few days a decision has been handed down in a case which has long been before the public, of the People *vs.* a man named Pierson, by profession a faith healer.

The original difficulty arose from the fact that in 1901 this Pierson treated by prayer an infant of sixteen months who was suffering from pneumonia. The child died; the incident became generally known; the legal authorities took the matter up; and Pierson was finally arrested and charged with a misdemeanor under a statute of the penal code which provides that a person is guilty of a misdemeanor who wilfully omits, among other things, to provide medical attendance for a minor.

At the trial of the case the prisoner admitted the facts, but contended that, inasmuch as he believed in healing by faith rather than by the art of medicine, he had not been guilty of wilful neglect. He, in the language of such people, failed to cure because "something was lacking in him." By such arguments it was attempted to exonerate the offender. He was, however, found guilty and sentenced to pay a fine. On legal technicalities the case was carried to a second court, which held that no criminal offence

under the statute had been proved. The prosecution then carried the case to the highest court in the state, whose decision we have already alluded to.

Without going into details regarding the final argument of Justice Haight of the Court of Appeals, which may be found elsewhere in this issue, it suffices to say that he held that liberty of religious profession and worship, which it is claimed had been infringed, could not be used as an argument for the defence, inasmuch as "acts which are not worship" fall within the jurisdiction of the penal code. By the construction of this final court it was held that the meaning of the statute was that minors could not legally be refused what is ordinarily understood as medical treatment on any ground whatsoever.

It was further stated that this decision does not apply to adults, who, if they desire, may refuse medical or any other aid in sickness or may call upon whomsoever they wish in the hope of relief. Naturally this decision makes no attack upon any special form of faith healing, whether it be known as Christian Science, Dowieism or any other of the subdivisions of this type of thought. It simply, in a common-sense way, deals with the law as originally enacted, and insists that the law must be maintained in individual cases.

It is said that this is the first decision of the sort which has been made in the United States by so high a Court, and it is generally conceded that the interpretation of the law is eminently just. What the outcome of this and other decisions, which are sure to follow, may be, we have no means of knowing, but we are strongly of the conviction that the final reasonableness and common sense of the people, as expressed in their courts of law, will ultimately lead to a proper appreciation of the limits of these irregular types of healing, and that the agitation which now periodically appears will gradually subside as the courts, and particularly the higher courts, are called upon more and more for a final expression of legal opinion.

THE BOSTON DISPENSARY.

THE annual meeting of the managers of the Boston Dispensary has recently been held, and the reports indicate a year in the work of the institution of unusual efficiency. There were treated during the year at the dispensary in the various departments upwards of 29,000 new patients, and in the districts under the general jurisdiction of the dispensary upwards of 11,000 new patients. It was furthermore stated that since the establishment of the institution in 1796 more than one and a half million persons have been treated, certainly an excellent record of work accomplished.

We have from time to time commented on the part played by this dispensary in the medical work of the city. Situated as it is in a crowded region, it forms the center of a large amount of medical work, and, furthermore, as is generally known, extends the scope if its usefulness by an admirable system of medical districts under the charge of young physicians and experienced nurses. This system, which has been elaborated to a very considerable degree, is not only eminently useful to the persons treated, but is also of the greatest value as a perfectly legitimate training school for many of our best younger medical men. There are at present thirteen of these district physicians, whose fields extend now over large portions of the city. Many of the physicians associated with the dispensary are also teachers in one or another of our medical schools, and the value of the institution as a place for teaching has certainly grown year by year. Unfortunately, like all successful enterprises, the work of the institution has expanded beyond the capacities of the buildings up to this time provided.

It will be remembered that not many years ago an extensive addition was made, but now again it is felt that the work is being seriously hampered by lack of adequate space and equipment. The expense of conducting a modern hospital is usually not properly appreciated by the general public. While it is perfectly evident that in certain cases unnecessary expenditure is made for internal fittings, it is nevertheless true that with our increasing knowledge and increasingly diversified methods of treatment, new apparatus and new arrangements of rooms are constantly required to fulfill the completest modern demand. The Boston Dispensary apparently finds itself in this position, and needs at least $65,000 for the enlargement of its facilities. Experience in Boston would lead one to the assurance that this amount of money will be forthcoming for so worthy an object. The dispensary, with its excellent record of more than one hundred years, will certainly not be allowed to lapse or in any way curtail its usefulness.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Oct. 21, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 67, scarlatina 24, typhoid fever 27, measles 56, smallpox 0.

Bequests to Hospitals.—By the will of the late Dr. George Haven of Boston, the Harvard Medical School receives $25,000 and a share in a residue to become available on the death of certain relatives. The Lying-In Hospital of Boston receives all books and instruments, together with a bequest of $20,000, and ultimately shares equally with the Harvard Medical School in the residue.

Additions to Perkins Institution for the Blind. — After a considerable delay work on necessary additions to this well-known institution were begun last spring, and the new building is now practically completed. The new section is four stories high and commodious. It will add very much to the efficiency of an institution which has long held an enviable place in its work for the blind.

Diphtheria.— A somewhat exaggerated report has apparently been spread abroad of the dangerous prevalence of diphtheria in certain regions of the city. The facts show that the total number of cases in the entire city is but very little above what it was during the same period last year, and does not equal what it has been in several previous years. Every precaution has been taken to insure the health of school children, so that nothing approaching an epidemic is to apprehended.

The Opening of a Ward for Skin Diseases at the Massachusetts General Hospital. — Proper special hospital facilities for the treatment of patients suffering from cutaneous affections that confine them to their beds, or prevent them from following their usual occupations, have not hitherto existed in Boston or New England. By the gift of Dr. Charles G. Weld a very complete ward has been added to the Massachusetts General Hospital, especially built and equipped for the care of cutaneous cases, to be under the charge of the dermatologists on the staff of the hospital. The ward contains twenty beds in separate rooms, the male and female patients being quartered at either end, a wide open space occupying the center. Special arrangements for baths and other features necessary for the treatment of skin diseases have been added. Of the twenty beds in the ward, four have been reserved for the use of the departments of the nervous system and of the throat and nose, thus giving to all of the special out-patient departments a certain representation in the wards.

NEW YORK.

Unlawful Practice of Medicine. — At a meeting of the Society of Medical Jurisprudence held Oct. 12, Justice Julius M. Mayer read a paper on "Criminal Procedure against the Unlawful Practice of Medicine." He reviewed the subject from the standpoint of a justice of the Court of Special Sessions, where cases of alleged unlawful practice are tried, and among his conclusions were: That a statute should be enacted defining more clearly what is the "practice of medicine," that there should be no minimum punishment provided in the law; and that some method should be devised to prevent the newspapers from publishing the advertisements of palmists and clairvoyants, whose real occupation is the practice of medicine illegally. In speaking on the latter point he said: "The worst agency in New York to-day that helps the man who sells either real or pretended abortion medicine is the newspapers, for they make it possible to ensnare the unwary, the superstitious and the fearful. I suggest that in the new school of journalism at Columbia there be a chair of advertising, and let it be taught to the young men of the newspaper profession that the first duty of a great newspaper is to censor its medical advertising. Many persons who advertise as palmists and clairvoyants advertise simply to cover the giving of medicines of the kind I have mentioned."

A Legal Decision on Faith Healing. — It is a gratifying fact that just on the eve of the descent upon wicked New York of "Elijah" Dowie and the cohorts of Zion, the Court of Appeals handed down its decision in the case of People *v.* Pierson, declaring dependence upon faith healing to be criminal negligence. J. Luther Pierson, a follower of Dowie, living at White Plains, Westchester County, early in 1901 was sentenced to $500 fine or 500 days' imprisonment for criminal neglect in failing to provide medical attendance for his adopted daughter, an infant of sixteen months, who died from pneumonia. The conviction was secured under the penal code, which states that "a person who omits without lawful excuse to perform a duty

by law imposed upon him, to furnish food, clothing, shelter or medical attendance to a minor, is guilty," etc. The conviction was reversed by the Appellate Division of the Supreme Court, Justice Goodrich of Brooklyn dissenting. Justice Bartlett, in the prevailing opinion, held that the "medical attendance referred to in the statute does not mean exclusively the attendance of a medical practitioner in the generally accepted sense of that term. The case was then carried to the Court of Appeals, and in rendering the decision of this highest court Judge Haight says: "It would seem that the legislative intent is reasonably clear, although possibly more precise language could have been employed. The section of the code under which the indictment was found contemplates that there are persons upon whom the law casts a duty of caring for minors. . . . Sitting as a court of law for the purpose of construing and determining the meaning of statutes, we have nothing to do with variances in religious belief, and have no power to determine which is correct. We place no limitations upon the power of the mind over the body, the power of faith to dispel disease, or the power of the Supreme Being to heal the sick. We merely declare the law as given us by the legislature. We find no error on the part of the trial court that called for a reversal." District Attorney J. Addison Brown of Westchester County, in commenting on this decision, stated that as far as he knew — and he had carefully investigated the matter — this is the first time in the history of New York or any other state where the law has been made certain by the decision of the higher courts. The higher courts of England have upheld convictions in similar cases, the prisoners there being found guilty of manslaughter. "The decision," he said, "is of the highest importance, and means absolutely that these faith curists and others of the same sort must obey the law compelling them to call in regular physicians in the event of dangerous illness of minors in their families. The fact that they have called in 'readers' of their churches, layers-on-of-hands and others will not shield them from the law." Referring to the case of John Carroll Lathrop, the reader of one of the Eddyite churches in New York, the attendant of the Quimby child at White Plains who died of diphtheria, Mr. Brown said: "It would seem in the light of the decision that his trial would be brought up very soon before County Judge Platt. Counsel demurred in this case eight months ago, and it is possible that the judge delayed the trial until he could hear the decision of the Court of Appeals." Lathrop was indicted by the Grand Jury at White Plains on a charge of manslaughter.

Miscellany.

THE PROTECTIVE EFFECT OF ANTITYPHOID INOCULATION.

DR. A. E. WRIGHT, late professor of pathology at the Netley Army Medical School, contributes further statistical records, supplementary to those previously offered by him, in regard to the protective effect of antityphoid inoculation.

One statement (Table I) refers to the incidence of typhoid fever and the death-rate from the disease in the inoculated and uninoculated soldiers in India during the year 1901:

TABLE I.

	Average Strength During Year	Cases of Typhoid Fever	Deaths from Typhoid Fever	Incidence Rate Per cent	Death-Rate Per cent
Uninoculated	55,955	744	199	1.33	0.36
Inoculated	4,883	32	3	0.66	0.06

The incidence rate was reduced one-half and the death rate five-sixths by antityphoid inoculation, according to these returns made to the war office.

The second statement (Table II) gives the incidence rate among a column of troops during a limited period of three months (December, 1899–March, 1900) of the South African War:

TABLE II.

	Number Cases of Typhoid Fever	Incidence Rate
Uninoculated	10,981	2.3%
Inoculated	2,535	1.0%

The incidence rate was reduced more than one-half.

The first table, as interpretated by Dr. Wright, who is personally familiar with the inoculation work in India, suggests that the protective effect of inoculation continues for a minimum of three years.

IS REGISTRATION AND DISINFECTION A SUCCESSFUL METHOD OF COMBATING PULMONARY CONSUMPTION?

IN a paper read before the York meeting of the Pennsylvaina State Medical Society, Sept. 23, 1903, and published in the *New York Medical Journal*, Sept. 26, 1903, on the death-rate of acute pneumonia, Dr. Thomas J. Mays of Philadelphia expresses surprise to find that instead of decreasing, consumption has increased in most of our large cities during the last five years. This has led to an inquiry whether registration and disinfection of consumption in vogue in many of our cities are as efficient in "wiping out" this disease as we have been led to believe. In order to throw light upon this question he collected data showing the death-rate of consumption and pneumonia in twenty large cities and two prominent states, namely, Philadelphia, New York, Chicago, Boston,

St. Louis, Buffalo, Washington, D. C., New Orleans, Richmond, Baltimore, Louisville, Reading, Milwaukee, Hartford, New Haven, Cleveland, Haverhill, Worcester, Cincinnati, Indianapolis, and New Jersey and Rhode Island, representing a total of nearly thirteen million inhabitants, or about one-sixth of the entire population of the United States. These statistics are arranged in twenty-five charts, and in many instances cover a period of thirty years.

One of the striking characteristics of these charts is that the consumption tracing pursues a general descending course, while that of pneumonia rises in most instances. Another one is that during the last five years consumption increased in Philadelphia, Boston, St. Louis, Buffalo, Washington, Rhode Island, New Jersey, New Orleans, Richmond, Baltimore, Louisville, Reading, Milwaukee, New Haven, Cincinnati and Indianapolis; and decreased during the same time in New York, Chicago, Hartford, Cleveland, Haverhill and Worcester, the total increase being 184.71% and the total decrease 38.86%, leaving a net increase of 145.87% in these localities.

On examination of the charts it will be found that with perhaps one or two exceptions they may be divided into two classes; namely (1) those in which the phthisis and pneumonia tracings touch or cross each other during the last ten years, as is the case with Philadelphia, New York, Chicago, Boston, Buffalo, Baltimore, Hartford, New Haven, Cleveland, Worcester and New Jersey, and (2) those in which the same tracings remain apart a good distance, the latter below the former, as is true of St. Louis, District of Columbia, New Orleans, Richmond, Reading, Milwaukee, Haverhill, Indianapolis and Rhode Island.

Now on investigation, it turns out that in all the localities of the first class, registration and disinfection of consumption are enforced, or these subjects are or have been largely agitated; while in the localities of the second class these measures receive no consideration whatever. If we compare the death-rate of phthisis and pneumonia for the whole period between the first class, or prevention localities, and the second class, or non-prevention localities, it will be seen that the decrease of phthisis is about 1,000% greater in the prevention than it is in the non-prevention localities; while on the contrary pneumonia increased over 600% in the former over the latter localities.

Now what is the interpretation of these figures? How can the difference in the death-rate of pneumonia be accounted for between these localities which practice prevention and those which do not? Is this mere chance, or is it coincidence, or a connection between cause and effect? Without inquiring into the specific nature of this relationship, if any exists, it is enough to know that the pronounced decrease of phthisis in the prevention localities is largely supplemented by the excessive rise in the pneumonia rate in the same. Indeed it seems as if from the early nineties until the end the phthisis and pneumonia lines had become confounded in many of the prevention localities, and as if a certain large proportion of deaths had been deducted from the former and bodily transferred to the latter.

It might be asserted that the greater decrease of phthisis in the prevention over the non-prevention localities during the last ten years is direct proof of the efficacy of disinfection measures. Standing by itself it might be regarded as such, but when taken in connection in the first place with the simultaneous enormous rise of the pneumonia column in the same localities and in the second place with the fact that no rise but even a decline occurred in the pneumonia rate of the non-prevention localities, it will be seen that its force as such is greatly impaired. It is perfectly clear that the decrease of phthisis is intimately interlinked with the increase of pneumonia, and it is very probable that both of these phenomena are dependent on the influence of registration and disinfection, because in localities like New York and Boston, in which these measures have been carried out most effectually and for the longest periods, the death-rate of pneumonia attains by far the highest average during the last ten years.

Now when we reflect that all the prevention localities, with possibly one exception, may be recognized by a high pneumonia death-rate; that the decrease of phthisis in the same localities is largely supplemented by a marked rise in the pneumonia rate; and that in eight out of the thirteen prevention localities, there has been a total increase of 88% of phthisis during the last five years, it is sufficient proof to show that registration and disinfection have not thus far shown themselves a success in the "wiping out" process of consumption.

Correspondence.

ETHER.

Boston, Oct. 16, 1903.

Mr. Editor: In connection with the opening of the new Out-Patient Department of the Massachusetts General Hospital which occurred to-day and has been called "Ether Day," I am reminded of the account of the first exhibition of ether as an anesthetic for surgical purposes in Great Britain. The first use of ether in Boston, and the announcement of its wonderful effect in relieving pain which was thus made to the world, was followed by a speedy trial of its properties there. The account of the first operation performed by Mr. Liston was written by Mr. William Cadge (F.R.C.S.), England, and appeared in the *British Medical Journal* of Oct. 17, 1896, almost exactly fifty years after the first demonstration of anesthesia in Boston, Oct. 16, 1846.

Mr. Cadge died recently, and in an extended obituary notice an allusion is made to the fact that he was probably the last survivor among those persons who witnessed the introduction of painless surgery into British practice. Under the caption, "The First Operation under an Anesthetic in this Country," an abstract of the former paper is included (*British Medical Journal*, July 4, 1903, p. 54). In both articles the credit of the first *information* concerning the anesthetic properties of ether is unrestrictedly given to "Dr. Bigelow of Boston," who had sent "definite and authentic information" to Dr. Boott of Gower Street in December, 1846. * * *

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, OCT. 10, 1903.

CITIES.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 2,949; under five years of age, 926; principal infectious diseases (smallpox, measles, scarlet fever, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 890, acute lung diseases 281, consumption 336, scarlet fever 21, whooping cough 14, cerebro-spinal meningitis 10, smallpox 11, erysipelas 3, puerperal fever 7, measles 6, typhoid fever 50, diarrheal diseases 252, diphtheria and croup 80.

From whooping cough, New York 5, Baltimore 1, Pittsburg 1, Cambridge 2, Boston. Fall River, New Bedford, Chicopee and Hyde Park 1 each. From erysipelas, Chicago 1, Philadelphia 1, Providence 1. From smallpox, Philadelphia 3, Baltimore 1, Pittsburg 7. From measles, New York 4, Philadelphia 2. From scarlet fever, New York 6, Chicago 5, Philadelphia 2, Baltimore 3, Pittsburg 1, Boston 1, New Bedford 3.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Sept. 26 the death-rate was 16.3. Deaths reported, 4,707; acute diseases of the respiratory organs (London) 134, whooping cough 57, diphtheria 54, measles 23, smallpox 3, scarlet fever 40.

The death-rate ranged from 5.3 in Hornsey to 24.7 in Merthyr Tydfil; London 15.4, West Ham 14.6, Brighton 14.1, Portsmouth 19.3, Southampton 15.2, Plymouth 15.4, Bristol 14.6, Birmingham 18.2, Leicester 14.2, Nottingham 14.6, Bolton 17.1, Manchester 19.4, Salford 20.3, Bradford 13.6, Leeds 16.1, Hull 23.2, Newcastle-on-Tyne 21.4, Cardiff 14.8, Rhondda 13.5, Liverpool 20.9, Handsworth 8.2, Middlesbrough 22.5.

METEOROLOGICAL RECORD.

For the week ending Oct. 10, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING OCT. 17, 1903.

C. H. DELANCY, assistant surgeon. Detached from the "Hancock" and ordered to the "Petrel."

R. K. MCCLANAHAN, assistant surgeon. Detached from treatment at the Naval Hospital, Mare Island, Cal., ordered home and three months' sick leave.

S. W. DOUGLASS, pharmacist. Detached from the Navy Yard, Portsmouth, N. H., and ordered to the Naval Magazine, Iona Island, N. Y.

W. F. ARNOLD, surgeon. Detached from treatment at Naval Hospital, Mare Island, ordered home with three months' sick leave.

W. R. DUBOSE, medical inspector. Commissioned medical inspector with the rank of commander from June 20, 1903.

D. H. MORGAN, passed assistant surgeon. When discharged from Naval Hospital Mare Island, granted sick leave for three months.

C. H. DELANCY, passed assistant surgeon. Commissioned a passed assistant surgeon, with rank of Lieutenant, from June 7, 1903.

SOCIETY NOTICES.

FIRST MASSACHUSETTS STATE CONFERENCE OF CHARITIES. — Meetings of this Conference will be held in Boston, in Huntington Hall, Massachusetts Institute of Technology, Nov. 4, 5 and 6, 1903.

NATIONAL ASSOCIATION FOR STUDY OF EPILEPSY. — The National Association for the Study of Epilepsy will hold its third annual meeting in the Hall of the College of Physicians in Philadelphia on the afternoon and evening of Nov. 5. The program includes, papers by Drs. Wharton Sinkler, Everett Flood, Wm. N. Bullard, H. M. Weeks, Charles K. Mills, A. H. Halberstadt, J. Chalmers DaCosta, John C. Munro, L. Pierce Clark and W. P. Spratling. The Association extends a cordial invitation to all persons interested in charity, and especially in the care and treatment of epileptics, to attend its annual meetings.

RECENT DEATH.

JEAN F. CHAUVEAU, M.D., one of the best-known French physicians in New York City, died on Oct. 17. He belonged to a French-Swiss family and was graduated at Geneva in 1853. He had practiced in New York for many years, and until compelled by poor health to retire was a visiting physician to a French Hospital there. His son the Dr. Jean F. Chauveau, Jr., a graduate of the College of Physicians and Surgeons, New York, in 1891, was associated with him in practice.

BOOKS AND PAMPHLETS RECEIVED.

The Practical Medicine Series of Year Books, comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Issued monthly, under the general Editorial Charge of Gustavus P. Head, M. D. Vol. X. Chicago: The Year Book Publishers. September, 1903.

Introduction to the Study of Malarial Diseases. By Dr. Reinhold Ruge. Translated by P. Edgar, M.B., C.M. (Edin.) and M. Eden Paul, M.D. (Brux.), M. R. C. S., L. R. C. P. Illustrated London and New York: Rebman Company. 1903.

Address.

THE RELATION OF LABORATORY RESEARCH TO THE GENERAL PRACTITIONER OF MEDICINE.[1]

HORACE D. ARNOLD M.D., BOSTON,

Professor of Clinical Medicine, Tufts College Medical School; Assistant Visiting Physician, Boston City Hospital.

THE recent passing of the century mark has given medical addresses of the past few years a retrospective aspect. It has been an appropriate and opportune time to review the progress of Medicine. As viewed in the large perspective of a century, that progress has been truly wonderful. The advance in one hundred years, or even in fifty years, was greater than that of the whole previous history of Medicine. Toward the end of the century the rate of progress increased until it was well-nigh impossible for a single mind to keep in touch with even the important advances being made along the whole line of medical investigation.

The improvements in the microscope in this period made possible a study of the minute structure of the tissues of the body. About the middle of the century originated the conception of the cell as the unit in the structure of each organ, and hence the unit of organic life itself.

Anatomy advanced by the development of microscopical anatomy, or histology. Pathology advanced by bounds with the study of the changes in the individual cells and groups of cells in disease. The discovery of bacteria and their relation to disease became possible. We not only developed a new branch of medical science,— bacteriology,— but the application of the knowledge thus obtained made possible the remarkable advances in modern surgery, and threw new light on and profoundly modified our conceptions of infectious diseases.

The study of the functions of the individual cells has added much to physiology. Even more is due to animal experimentation. But the problems of physiology and of disease have also shown the need of study of the chemical changes occurring in the body. Many important advances have already been made along this line, and much more important developments are to be looked for in the near future, based on the researches of the chemical laboratory.

I have briefly rehearsed some of these well-known facts that we may clearly appreciate that the advance in Medicine of which we are all so justly proud is chiefly due to laboratory research — using the term in a broad sense. The debt which the medical profession and which humanity owes to these skilled and tireless workers in the laboratory can never be fully repaid. They are the leaders in the advance which is being made in our warfare against disease, and as such we should give them due meed of honor.

What I wish to particularly consider to-day, however, is not the extent of the advances thus made in Medicine, but the question of how far the general practitioner is applying these improvements in his battle with disease. Medical advance is to be measured not alone by the attainments of the generals of the medical army, but by the efficiency of the rank and file. As we found in our recent war, the "man behind the gun" is a very important factor.

Is our medical private — the general practitioner — equipped with the best form of rifle? Is he using the modern smokeless powder? Or does he obscure his view of the enemy with an opaque cloud from his obsolete ammunition? Has he had sufficient drill in the use of his arms and ammunition to make his aim reliable and accurate? Better give us a sharp-shooter armed with a muzzle loader and black powder, than a man who has an up-to-date equipment but has no skill in its use!

My answer is that the medical army is a motley assemblage; that it is lacking in organization and consequently lacking in the most effective coöperation of the different branches of the service; that the equipment of the individual (both in arms and ammunition) varies from the most modern to the very obsolete; and that the training of the individual in the use of his equipment varies widely and generally needs improvement.

The personnel of this medical army is, however, excellent. The individual soldier is courageous, animated by high motives, self-sacrificing and earnest in his work. Often, by the intelligent and resourceful application of available means to the problem in hand, he does much to make up for the deficiencies in his equipment and training. The results obtained by the profession are on the whole good. The essential point I wish to make is that the results might be better.

We may improve by a wider application in general practice of the knowledge furnished by the laboratory worker; by adopting his more scientific methods of investigation in the clinical study of disease; and by a more cordial coöperation between the laboratory worker and the practicing physician in the study and cure of disease.

Some, perhaps much, progress has already been made in this direction. It is because this progress must depend on the effort of the individual physician that this question is worthy of our consideration on such an occasion as this, when by common consent a body of general practitioners pause at the end of a year's work as a society to cast a broad look over the whole field of medical progress.

That the advances made by the laboratory workers have not been fully utilized is not entirely the fault of the medical practitioners. The fault lies partly with the laboratory workers themselves. Having frankly acknowledged our deep indebtedness to these investigators, it is our right to criticize them and to point out how their discoveries may, by better coöperation with us, be made more available for the benefit of humanity. For after all, the benefit of humanity

[1] Annual Oration before the Norfolk District Society of the Massachusetts Medical Society, delivered May 12, 1903.

is the ultimate goal at which the medical profession aims, and it is right to measure the work of any member of the profession by the degree to which he attains this goal, directly or indirectly.

It is always well to look facts squarely in the face, and not to ignore their existence because their contemplation is not entirely pleasant. In this connection it is an unpleasant fact that there is too often a lack of sympathy and frequently, even, a feeling of hostility between the laboratory worker and the general practitioner. The latter criticizes the laboratory worker as being "too scientific," as carried away by the pure spirit of investigation and not caring for the practical result of his work. He considers the laboratory worker impractical because so much of his investigation has no immediate application in the treatment of disease.

The laboratory worker replies that his work cannot be judged by any such standard; that science should be pursued for itself, being a search after truth, and must not be judged by its utility. He further points properly to the fact that many important advances in medicine have been based on scientific facts thus discovered which at first seemed to have absolutely no bearing on the practical problems of Medicine. The great need of Medicine has been and still is, a scientific foundation. To the taunt that he is unpractical he retorts that the medical practitioner is unscientific; that his observations are carelessly made; and that the practice of medicine based on such observations is empirical and unreliable.

Both sides in this controversy are partly right and partly wrong. We must admit that the condemnation by the laboratory investigator applies justly to many of us who are practicing medicine. Perhaps it is as well for our self-esteem and for the reputation of the profession that we should not try to learn too accurately to how many it does apply. But, admitting this, it is equally true that many of the laboratory workers are so lost in the scientific side of their investigation that they apparently forget any question of its practical value. Some even glory in the fact that it has no apparent practical value. These are impatient of any questions as to the utility of these very interesting observations, and are annoyed by the efforts of physicians who try to garner from these riches something which they may carry as a gift to the sick. Such extreme instances are few, but they make a bad impression.

I know that in general the laboratory worker is more willing to welcome the practitioner in his realm than the physician generally supposes, and is more patient and courteous in such reception than we have just reason to expect. It is hard for him, however, not to show a certain feeling of toleration rather than interest, when the utility of a given point is examined.

Notwithstanding appearances, the laboratory workers are at heart just as earnest in their desire to benefit humanity as any memebrs of the profession. The more the pity, then, if they become so engrossed in their studies that they forget the necessity of occasionally summarizing their work, and of interpreting it so that the average medical mind can grasp its significance. This they certainly neglect to do.

It is not enough to make the studies. It is not enough to publish the results in their technical form. If the general practitioner is to make use of this information, somebody must translate it into terms which he can thoroughly understand, and this process of interpretation should be begun by the laboratory workers themselves. Such action on their part will not only bring their work to better fruition, but will remove from the mind of the general practitioner the unjust feeling that the laboratory worker is indifferent to the ultimate practical application of his discoveries.

The first step, then, toward the better utilization of scientific medical facts is for the discoverers of those facts to put them in a form in which they may be digested and assimilated by the medical body as a whole, and let them remember that its digestive powers are weak and that it needs simple nutriment.

But if some of the blame for the present condition of medical practice lies with the laboratory workers, much more — and the greater part — lies at our own door. Granted that much of the output of the laboratories has no immediate application in the practice of Medicine; granted that much of it needs interpretation before we can comprehend its utility, we, medical practitioners, are not yet using our best endeavors to apply that part of the scientific discoveries which has a manifest application in the diagnosis and treatment of disease. Until we do this we fully deserve the criticism of the scientific investigators, and we, the greater sinners, have little right to criticize them.

We have criticized them as too little interested in the benefit of humanity. Are we true to this aim? Alas, many are not! How many, I dare not estimate. And the worst of it is that it is not the zealous pursuit of truth that distracts our attention, but the zealous pursuit of the dollar!

Commercialism, the pursuit of medicine as a trade, explains altogether too much of the indifference of a large number of medical practitioners to the scientific advances of medicine. So long as these traders are a little ahead of the laity and can impress upon them an acknowledgment of their superiority and thus get a good financial return, they care nothing for the advance of medical science. You cannot reach such men by appeals based on the ideals of the profession. The only practical way to reach them is to educate the public. When the public knows enough to see that they are poorly equipped, they will be driven in self-defence to increase their equipment.

To you, members of the Massachusetts Medical Society, this does not apply. You are actuated by higher motives than the pursuit of medicine as a trade. And yet even with us the question

of the financial return to be made from scientific medicine must be considered.

We cannot, then, dismiss this aspect of the application of scientific medicine with a condemnation of commercialism. Actuated, as we are, by high ideals of the profession, we are yet dependent on the practice of Medicine for our financial support. Whatever our duty to humanity, I believe we have an equal or higher duty to our own families, and perhaps to ourselves. We have a right to consider how this question affects our pocket books without being accused of having a sordid aim in so doing. I shall devote some time to the consideration of this topic, because it has a very practical bearing, and because I believe there is a general hesitancy among physicians about adopting such methods because they think they cannot afford the time or money for it.

I have heard the objection urged that the people cannot or will not pay more for this extra work, and that the doctor cannot afford the time for it without recompense. Both assertions are, I believe, wrong.

If our patients actually cannot afford to pay us for this work, it is still our duty to perform it when it will be an essential aid to the diagnosis or treatment of the disease. In treating a needy patient, our only right question should be, Is it necessary? If so, it is our duty to do it. If we are unwilling to give a charity case the essential treatment, we should withdraw from the case. There are in our neighborhood charitable institutions, if not charitable doctors, who will do it.

If the case is not one of absolute charity, but one that can make only a poor return for whatever we do, still the same rule applies. Only we are even more culpable if we take from such patients the best they can afford to give, and do not in return do our best in treating them.

But the important class of patients are those who pay their bills, who make no objection to paying the customary fees for the ordinary medical attendance, but do object to paying more for extra investigations made by their regular attendant. The doctor, knowing their feelings, is reluctant to charge for such work, fearing they may take offence and that he may loose good-paying patients. On the other hand, he objects to doing this extra work free of charge for patients who ought to pay.

If the examination is essential in these cases, it should be made. The doctor should make a reasonable charge for such work, and I believe it can be done not only without losing these patients, but with added respect for his reputation. The necessity or utility of the examination must be explained to the patient, and the fact that it takes time and requires skill. Then he will understand that it is service of value to him and will be willing to pay.

In other words, many doctors are afraid to do the work and charge for it in the present mental attitude of the public. The remedy lies in educating the public to know that such researches are valuable. Then they will not only pay for them, but will demand them.

Some care is necessary, however, in deciding when to recommend such measures. If such investigation is really essential, we should not hesitate to urge it. It is, of course, the patient's privilege to refuse to follow our advice in this respect as in all others, but that should not affect the nature of the advice given. But if the investigation is not essential, but only desirable, then we should take the patient's pocket book into consideration. We should not cause him extra expense merely because the investigation would be of interest to us. In many such cases we would perform the tests and count the resulting satisfaction a sufficient recompense.

I am very far from urging that laboratory investigations ought to be inaugurated in all our cases. That is very well in the hospital, which is, as it were, a laboratory for the complete study of disease; and the more complete the investigation, the more reliable are the results. Such investigations as do not injure the patients are only a fair return for the benefits gratuitously received by them from the institution. Moreover, they are directly benefited by the results of these investigations.

In private practice, however, the relation of the patient to the physician is an entirely voluntary one. His wishes must be consulted. We may offer him certain opportunities, but he may decline them if he chooses. It is not fair to criticize the work of the general practitioner because it is not always done with all the thoroughness of hospital work. For he is handicapped by the fact that the public often fails to appreciate the necessity or the advisability of such measures.

Suppose a patient comes to us with an apparently slight gastric disturbance. We could perhaps prescribe with more certainty if we investigated the exact condition of his gastric juice and his power of digestion. Perchance the investigation of the stomach contents might reveal the existence of trouble of unsuspected gravity. But can you blame the patient if he prefers first to try such remedies as your skill would suggest, even if the diagnosis is not perfectly clear? Would not you, in his place, try the remedies first, instead of at once embracing the opportunity to swallow the stomach tube? If the symptoms are grave, if serious trouble is suspected, or if the remedies fail to relieve, that is another matter. But the routine use of the stomach tube is not practicable for the treatment of every case of gastric disturbance, whatever may be the scientific aspect of such cases.

This is but an illustration of the general principle that in private practice the patient has the right to determine how far he cares to avail himself of the opportunities offered by medical science. Provided the investigation we have in mind is not absolutely assential for his welfare, we should do the best we can with the limited means he puts at our disposal. It is part of the art of the practice of medicine to decide when it

is wise to urge, and when it is wise not to mention the measures that the theory of scientific medicine suggests. Except where such measures are essential, the successful physician is properly a practitioner of the art of medicine first, and secondly a scientific investigator.

Before leaving the consideration of the financial aspect of laboratory investigation, I wish to say a word about the indirect benefit that may be derived from such work, even though it may bring no immediate money return. It is not so unusual to find the ordinary practitioner contrasting his lot with that of the more successful man who has hospital or other large clinical opportunities. Not that these men are always the most successful financially in practice, but in general the experience gained by such work is a valuable asset in winning financial success. The less succesful man is apt to overlook the fact that such experience is gained only by the expenditure of much time and energy in gratuitous service. Is he willing to make the same sacrifice? Does he make the best use of similar opportunities that lie at his hand? If, instead of refusing to do scientific work in his practice when it cannot be paid for, he accepts all such opportunities for the sake of the experience he may gain, — I do not say that he can equal the improvement gained at the hospital, with its greater opportunities, but at the expenditure of much less time he may add materially to his own experience and ability, and he can to an important degree acquire that asset for successful practice which he envies in the hospital physician. Thus not only consideration of our duty, but self-interest, should lead the general practitioner to a much wider application of laboratory methods than is now the case.

An indirect benefit, but one of great imporance, attends the use of the laboratory methods of examination, in that it tends to make our clinical examination of the patient more careful and accurate. The mere consideration of whether such a test is desirable means a careful analysis of the symptoms of the case. We cannot do this laboratory work successfully without methods of precision and intelligent thought, and we return to the clinical side of the case with keener mental faculties as well as with facts that aid in diagnosis. Thus the thoroughness and accuracy necessary in laboratory technique lead to better methods in the ordinary clinical examination and study of cases.

What may we reasonably expect of the general practitioner in the way of laboratory work in connection with his practice? Certainly not a fully equipped laboratory, nor the ability or time for exhaustive researches. But we may expect the possession of a suitable microscope, and those simpler forms of laboratory apparatus and the reagents that are required for the practical clinical tests, and the ability to apply these tests with sufficient accuracy to be of value as an aid to diagnosis. The equipment is not prohibitive in cost, and if properly utilized will bring fully as good a financial return as many forms of equipment that the general practitioner willingly makes. The skill required in making these examinations is within the reach of any medical man of average ability.

One reason why the general practitioners have not more generally adopted these methods is, I believe, that the teaching of these subjects in medical schools has been unnecessarily complicated from the physician's point of view. In teaching medical students we must aim not only at showing them these practical tests, but at giving them at the same time a thorough scientific training in methods of investigation. Much that is thus valuable for training is of little or no value in its practical application. Now the men in general practice may need this training in method fully as much as the students, but few of them feel that they can spare the time for a course based on such lines. It is better to put within their reach a course which will teach them just the practical points they can apply, than to offer only courses which are theoretically more complete but which they will not avail themselves of. If such courses are inconsistent with the thorough scientific spirit of the medical school, they could be given by competent men outside, especially at the hospitals. There are plenty of opportunities for such work, but generally they have not been properly utilized for our object. As a rule, such courses have either been modeled too much after the exhaustive school course or they have been clinical courses in which the laboratory work has held too subordinate a place. The untrained physician needs for laboratory work more time and patience from the instructor than is given in the ordinary clinical course. He gets an unsatisfactory amount of laboratory instruction only at the expense of a lot of time on other clinical work, which, though most excellent in itself, is not exactly what he desires at the time.

Post-graduate medical work is different from undergraduate work. The physician who takes post-graduate work has a pretty definite object in view. I think we should be more willing than we are to meet just that object in the individual case with the least possible waste of time. We should not treat him as an undergraduate, to whom we properly say that in studying a given subject he must learn at least so much and in just such a manner. If the general practitioners want such courses, they have but to ask for them. If the demand is made, some of the many competent men who have clinical facilities can easily arrange such courses and would do so. That such courses are not more common is due chiefly to the indifference of the general practitioner.

There is yet another means for the busy practitioner to acquire this skil . We are sending out from the medical schools every year many graduates who have had excellent training in these methods of investigation. They are thoroughly "up-to-date" in methods, but lacking in clinical experience. The general practitioner has the clinical experience, but is rusty or behind

the times in methods. Here are two sets of men who have much to teach each other, but the opportunity for mutual benefit is seldom made use of. In the coöperation of the man of large clinical experience with too little time for laboratory work, and the present graduate with plenty of time for such work and too little practical experience, is a most promising field for the benefit of both these practitioners as well as the patients.

Such coöperative work in private practice is an excellent substitute for the school or hospital courses I have spoken of. The time can be arranged more conveniently for the practitioner than in a clinic, which usually comes at the busiest time of his day, and thus one of the greatest obstacles to his study of such subjects is removed. Nor is the benefit all on his side. He can provide the equipment for their common use, which the young practitioner can perhaps ill afford to buy. And an intelligent discussion of the clinical, as well as the laboratory, aspects of the case cannot but be full of benefit to the young graduate.

Indeed, one of the faults of our medical education at the present time is an exaggerated view in the mind of the medical student as to the importance of laboratory work in general practice. His view is commonly as one-sided as that of the general practitioner who undervalues such methods. In these days of the triumphs of laboratory research and of our zealous pursuit of "scientific medicine," it requires some courage to say that this side of medical education is overdone in the schools; but a careful observation of students and recent graduates has convinced me that such is the case.

The student to-day shows too great a tendency not to think about a case until he has it in some way under the microscope, and then his diagnosis must fit his microscopic findings. Is our technique so perfect that this is always the crucial test? Are we to make a diagnosis of tuberculosis only after the tubercle bacilli have been found?—or of typhoid fever only after the Widal reaction is positive? And especially are we to decide that the patients cannot have these diseases because the laboratory investigation is negative? If we determine our treatment on this basis, we shall make grave mistakes. I have often seen the man whose accurate technique I have envied fail to recognize a case of tuberculosis when "phthisis" was written on the patient's aspect in indelible lines. His view of the case, as a whole, was as limited in extent as the field of his microscope.

I have seen the wise general practitioner (who, however, could not use an oil immersion lens) and the thoroughly trained recent graduate on the same case. The former said the case "looked like typhoid," and insisted on treating it as such. The latter was all at sea because the Widal reaction was delayed, and he didn't know what to do for the case. In a few days his doubts were removed by the appearance of the Widal reaction, but in the meantime the patient had had the best treatment from the old family physician.

Indeed, the young laboratory expert has much to learn from the general practitioner about clinical medicine. He has a better foundation, to be sure, but to-day when we turn him loose with a degree of M.D. to practice, he has laboratory astigmatism and needs glasses to correct his vision. The proper material for these glasses is "common sense," and the glasses should be ground on the stone of experience. For correcting this form of astigmatism the general practitioner is an excellent oculist.

Of course there is the other side. For example, how many times does the general practitioner saturate his patient with quinine for the supposed chills of malaria, when an examination of the blood, showing the absence of plasmodia and the presence of leucocytosis, would demonstrate a septic or suppurative process hidden somewhere in the body. Knowing that it is present, though hidden, it may be sought out and properly treated. Examples might be multiplied on either side to show what may be accomplished by the coöperation of the older and the younger practitioners.

Naturally we must look to the older practitioners to take the initiative in establishing such coöperation. To some extent the services of the younger men are already utilized in this way, but it is not done enough, and it is not usually done in the right way. Generally the younger man is given a specimen and merely asked for a report. He thus gets no opportunity to know the clinical bearing of his work, while the older man holds himself aloof from the investigation and its technique, a better knowledge of which would enable him to better understand both the advantages and the limitations of such work. This complete separation of the clinical and the laboratory side of the investigation is undesirable. It is too prevalent even in our best equipped hospitals. Neither the clinician nor the pathologist gets the best results from his work unless both sides are considered together.

Let us then coöperate. Let us drop our prejudice against the young man who settles in our midst. We cannot justly look down on him as an inexperienced youth, for in many respects his experience and equipment are superior to ours. Nor yet need we view him as a dangerous rival who is likely soon to usurp the professional position we have established. Rather is he a useful aid, from whose enthusiasm, as well as knowledge, we may gather the stimulus which will preserve the vitality of our medical work. Unless by our own initiative or by such outside stimulus we keep our medical work vital and fresh and abreast of medical advance, it stagnates and then retrogades. In these days when the strenuous struggle for existence is more and more apparent in our crowded profession, the consideration of self-interest, if no higher motive, should lead us to make a better use of the opportunity offered by contact with the recently trained

medical graduate. The man is not unknown in our profession whose best work was done in the few years following his graduation, when he was perforce "up-to-date." We must keep up with the procession or fall by the wayside. There are plenty to fill our places, and the public, on whom we depend for our livelihood, are getting more exacting in expecting of the doctor the best skill attainable.

Let us ask once more: What may be reasonably expected to-day of the general practitioner in the way of laboratory investigation? This work is not concerned with the examination of the patient as a whole; that is clinical. It is concerned only with such parts of the patient or such products as may be safely and conveniently carried away for more careful examination than is furnished by our unaided senses. Specimens of tissue which may have undergone pathological change belong generally to the pathologist as a specialist. Few of us may hope to deal successfully with such matters.

One tissue, however, easily comes within the range of the general practitioner, and for our purposes it is a very important one, namely, the blood. The counting of the red and the white corpuscles is not difficult, and often gives most valuable information. The microscopical examination of the character of both kinds of corpuscles, both in the fresh and the stained dry specimens, is often of even greater importance. Neither this nor the examination for the plasmodia of malaria are beyond the reach of the general practitioner. The estimation of the hemoglobin by means of the Tallquist paper and scale is no more difficult than taking the temperature. By it we get most valuable information as to the degree and progress of a case of anemia, yet how few physicians make use of this simple measure!

The Widal test for typhoid fever, necessitating the use of a fresh culture of the typhoid bacilli, is hardly within our reach, but we have access in this vicinity to the aid of public laboratories, and our part in furnishing the material is easily performed but frequently neglected. The examination of the blood for bacteria is seldom necessary and involves too intricate a technique for the general practitioner.

Of the products of health or disease the physician may to advantage examine the urine, sometimes the feces, the sputum, pus, vomitus, and the gastric contents. All of these may in suitable cases give most valuable information. And yet too many of us make none of these examinations but the testing of the urine for albumen, and some even neglect that when it should be done.

Another laboratory test is the bacterial diagnosis of diphtheria. This is more advantageously done by the aid of the public laboratory. It is of the utmost importance in any suspicious case. Fortunately the utility of this aid to diagnosis has been so clear that it has been generally adopted by the profession. Yet even this test is not always resorted to as early as it should be. If we cultivated what I may call the laboratory habit of mind we should neglect fewer cases and thereby prevent suffering and save some more lives.

In our vicinity easy access is had to the public laboratory, not only for aid in the diagnosis of diphtheria and typhoid fever, but for tuberculosis and malaria. There can be no excuse for the physician who does not have these tests made when they would benefit the patient.

I may sum up my argument as follows: What may be called the laboratory method in clinical medicine is of acknowledged value as an aid to accurate diagnosis and hence to the successful treatment of disease.

Such measures are not employed by the general practitioner as fully as they should be.

The wider application of these measures is desirable, and is our duty, first, because it will be of benefit to our patients. Secondly, the ability to perform such work is becoming more and more a necessity for the successful practice of medicine, and motives of self-interest should urge the general practitioner to catch up with the line of progress.

Of the man who has plenty of time and does not choose to thus equip himself little need be said, save that he is short-sighted and will sooner or later suffer in competition with his better-equipped fellow practitioners.

To the man who thinks he is too busy to enter upon this work, it should be said that the requisite skill may be acquired (if not already possessed) at a less expenditure of time than is usually supposed, and that, if necessary, a little sacrifice of time for this object would be one of the best investments he could make.

To the practitioner who is really too busy with routine practice to do such work himself, it should be said that nevertheless this work should be done where necessary. The services of the public laboratories and of less busy but thoroughly equipped practitioners should be utilized.

We should all remember that a wider application of these methods is our duty as enlightened physicians.

PNEUMOTHORAX ASSOCIATED WITH FRACTURE OF THE RIBS. REPORT OF TWO CASES.

BY FRED T. MURPHY, M.D., BOSTON.

THE two cases which I have to report illustrate the extreme degree of that common complication of fracture of the ribs, pneumothorax. Stabs and gunshot wounds of the thorax, perforation of the lung or pleura by malignant disease or suppurative process may lead to a similar condition; also gas formation by the Bacillus aerogenes capsulatus [1] or coli communis.[2] Concerning the great classes of pneumothorax, namely, those secondary to the removal of the chest wall with the parietal pleura as in operations, and the

tubercular and so-called non-tubercular types, a brief mention would seem appropriate. From the varying opinions and conflicting case reports the conclusion is warranted that an opening of the parietal pleura is not the dangerous procedure it was once considered. On opening the pleural cavity the lung will collapse, but if the pneumothorax be created slowly there is, as a general rule, no extreme shock.[3] Even if the dyspnea does become alarming, inflation of the lung by the Fell-O'Dwyer apparatus, or by drawing up the lung and fixing it in the pleural opening, the respiratory difficulty is at once relieved.[4] Hence the preliminary production of adhesions or a moderate degree of pneumothorax by the injection of air, as has been advised, is not necessary before performing an exploratory operation on the lung.

The great variations which have been recorded must be explained by the personal idiosyncrasy of the patient and the suddenness of the compression. The tubercular type accounts for about 80% of all cases in any tabulation of large numbers.[5]

So far as the treatment of the actual pneumothorax with tuberculosis is concerned, it has but little interest, as the prognosis depends rather on the general condition than on the amount of air within the pleural cavity.

A sufficiently large number of cases have been recorded to prove that a non-tubercular type does exist.[6] Here the onset is without violent trauma and often without any apparent cause.

In both of the above classes puncture of the chest wall to relieve pressure has been advised if the dyspnea becomes rapidly alarming.

That the parietal pleura should be torn and the lung lacerated in fracture of the ribs would appear to be a natural sequence. The force of the blow is from without inward, and the periosteum and pleura can offer but a feeble resistance in case the jagged end of the rib overrides at all. Doubtless the spongy, yielding character of the lung tissue protects it to some extent, yet it must be often injured. Also a blow received in full inspiration might easily rupture the pleura covering the lung without other injury to the thorax. Recognizing simple fracture of the ribs as one of the common injuries, it is difficult to explain the rarity of a serious pneumothorax.

In the Massachusetts General Hospital records for twenty years there are catalogued but these two cases, and Murphy [7] states that only twice in twenty years of hospital work has he seen an extreme collapse from this cause.

He also mentions the common occurrence of a slight degree of pneumothorax as a sequel of fractured ribs. With the chest wall intact or nearly so, given a rupture of the lung and its pleura and an increase of the intra-tracheal pressure above that within the pleural cavity and a pneumothorax is possible.

These conditions are repeatedly present without symptoms, since the amount of air is too rapidly absorbed, or the edges of the wound agglutinate before the degree of pressure is severe enough to cause collapse, or the formation is too slow, or the patient shows a personal tolerance.

As preventing a pneumothorax adhesions have been mentioned, but it is in the condition most prone to adhesions that the vast majority of all cases are found, and Duplant [8] reports an autopsy with the bands drawn tense across the cavity. Plainly they play no important part. The adherence of the pleuræ is too weak to offer resistance, and it is counterbalanced by the elasticity of the lung, which equals 7 mm. of mercury. The formation then of this closed type with which we are concerned is simply a question of forcing air from one reservoir — the lung — into a second — the pleural cavity.

In quiet respiration the combination of the adherence of the pleuræ, the elasticity of the lung and the intra-pleural pressure balance so that the lung follows by expansion and contraction the vacuum formed by the changes in the size of the thoracic cavity due to the action of the respiratory muscles. Strong inspiration gives a negative pressure in the trachea of 30–74mm. mercury; strong expiration a positive pressure of 62–100mm.[9] Forced within the pleural cavity by the strong positive pressure in strong expiration, if a return of the air is not possible the accumulation will go on until the intra-tracheal pressure is equalled. Therefore a pneumothorax of the closed type is not simply a collapse owing to the atmospheric pressure as in the open type, but the lung may be actually compressed. In reference to the return of the air from the pleural cavity, the doctrine of a valve formation, more or less complete, has been generally accepted. Autopsy findings have not substantiated this view.

Bard,[10] working on animals and experimenting with the human lung suspended within an air-tight jar provided with manometers, has demonstrated that the passage of air, from the nature of the lung tissue, is from the lung to the pleural cavity and not *vice versa*. This is independent of any evident valve formation. With a resection of a portion of the lung 9 x 5 x 10 cm. he found that pressure in the trachea increased that in the jar to an equal degree, but the air could not be forced back through the open lung. This was substantiated by numerous other tests. Accepting this conclusion, in a case of rupture of the lung, not involving a bronchus, the increase of the intra-tracheal pressure is the vital factor. This we see produced by the coughing and straining with and after the injury.

To account for the shock seen in the serious cases of too rapidly formed pneumothorax of either the closed or open type many views have been advanced. The irritation of the pneumogastric filaments by the sudden contraction and the displacement of the mediastinal organs, causing obstruction to the venous return, may have some influence. Hence a right-sided pneumothorax which would have the more effect on the vena cava is the more serious. Also the decrease in the capacity of the other pleural cavity from the pushing over of the mediastinum may be a

factor. As the circulation is such an elastic apparatus it is hardly possible that the increase of blood from the contracted lung is important. The sudden change in the respiratory mechanism, cutting off a large amount of active lung substance, thus dimishing absorption, as in embolism, is the important fact regardless of the exact method of reaction. With the mediastinal partition displaced Murphy thinks that the piston action of the diaphragm is lost and to this he would attribute mainly the distress.[7]

Laennec [11] gave a clinical description of pneumothorax to which little or nothing has been added. Tympanitic resonance, diminished or lost fremitus, decrease or absence of respiratory sounds, metalic quality of voice and rales, displacement of the heart and immobilization of that side of the chest with possibly bulging of the intercostal spaces, combined with dyspnea, make an unmistakable picture. In the chronic cases there may be but little evidence of intrapleural pressure, and the character of the percussion note may be misleading. Hippocratic succussion may be obtained when fluid is present.

As an acute condition secondary to injury of the chest wall there is nothing else with which it might be confused.

The subcutaneous emphysema of the thoracic wall is due to the escape of the air under pressure through the wound of the parietal pleura; that in the neck from the escape along the bronchi and trachea. When the dyspnea is only moderate, treatment consists of morphia and immobilization of the chest wall to control the forced expiration. Ordinarily these measures will suffice, but if the collapse becomes alarming, puncture of the chest wall and possibly aspiration are indicated. Contraindication to either procedure is the danger of reopening a partially agglutinated wound, hence they should be delayed as long as possible. Aspiration theoretically is especially dangerous on these grounds. Complicated by hemorrhage the question of open exploration comes up and is favored by the majority of operators. For the attendant emphysema subcutaneous incisions may be necessary to relieve the tension. After the recovery from the collapse, if there is no serious organic complication, the lung returns to its normal position within a comparatively short time. Experimentally any increase in the tracheal pressure after the repair of the wound hastens the absorption of the air.

The following abstracts from reported cases give an idea of the character of the injuries. Hamilton [12] records a case of simple fracture of the ribs followed by pneumothorax and emphysema. He comments on the infrequency of the complication in a degree to cause alarm. His patient was relieved by subcutaneous incisions. Regarding treatment, he quotes Mr. Erichsen as being in favor of puncture and Professor Spence as advising simple subcutaneous incisions. Stewart [13] presented at a clinical meeting the account of a greenstick fracture with pneumothorax. As the child died later an autopsy was obtained and the lung was found collapsed. Here aspiration gave no permanent relief, but free opening of the chest wall did. In the discussion which followed, pneumothorax under such conditions was considered to be not a dangerous complication.

Laurens and Darcanne [14] report a case with autopsy findings. There were multiple fractures of the ribs, and the lung was found with a large tear and collapsed. Nothing had been done to relieve the dyspnea.

Morris [15] has given an account of a man who, after a fall of twenty feet, developed emphysema and a pneumothorax of the left side. The lung was evidently collapsed and the pressure was sufficient to change the pericardiac dullness, yet there was no extreme dyspnea, and the man recovered in five days without treatment. There developed a peculiar click over the cardiac area which the writer attributes to the rubbing of bubbles of air between the pleura and pericardium.

Le Boutillier [16] has published a case of pneumothorax in a boy of fifteen who was run over by a wagon. Aspiration gave only temporary relief, and at autopsy two days later two large ruptures of the lung communicating with bronchi were found. There was no fracture of the rib.

Phalip [17] mentions a case in which the pneumothorax developed after thoracentesis.

The two cases which have come under my observation were admitted to the accident room of the Massachusetts General Hospital on the service of Dr. S. J. Mixter, and to him I am indebted for the privilege of reporting them.

CASE I. J. E. G., fireman, forty years of age. Patient was brought in late in the evening with the history of having been thrown from the truck and run over by the hind wheel. Examination showed a strong man in a mild state of shock. The pulse was good at ninety to the minute and the respirations were not markedly accelerated. Heart was normal. Lungs were normal except for a few râles in the right axilla; no dullness, no diminution of respiration or fremitus. There were multiple bruises on the legs and body. The left shoulder was dislocated and the ribs on the right side from the second to the fifth or sixth fractured in the anterior axillary line.

In the right axilla there was some emphysema. Across the back in the upper lumbar region was an abrasion about the width of the tire of the wheel. The belly was negative and the urine free from blood. Color and respiration were good enough to warrant giving ether for the reduction of the dislocation. Double swathe of adhesive plaster was then applied to the chest and the patient sent to the open ward. In the ward he was given morphia grain 1-6 subcutaneously. During the night he was seen by the house officer in charge of the upper wards and the morphia repeated, as he was apparently suffering much and the color was bad.

The next morning his condition was so bad that he was transferred to a single room. When I saw the patient for the second time the picture had completely changed. The face was cyanotic, the respirations rapid and labored. Examination of the chest now showed a tympanitic resonance over the right side with loss of respiratory sounds and fremitus. The heart was slightly displaced to the left. The pulse good. One-fourth grain morphia was given subcutaneously without relief. By this time the condition had become really alarming, and the friends had been gathered at the bedside. After a confirmation of the examination and diagnosis by the medical attendant the chest was punctured below the angle of the scapula. At once with the outrush of the air the extreme dyspnea ceased and the color returned. Aspiration

seemed to afford even greater relief, so it was kept up for one half hour. Then there was some coughing and a discharge of a small amount of blood. Respiratory sounds were present well down on the right side and the cyanosis completely relieved at the end of the aspiration. The heart returned to its normal position.

From that time on the patient complained only of pain in the arm, which was due to a fracture of the clavicle which had not been noted on admission. On the next day the lung had expanded to the level of the eighth rib in the back, and the patient was resting comfortably

Two days after the injury and one after the aspiration there was a sharp rise in the temperature, pulse and respiration, but no discomfort or cyanosis. There was an immediate cessation, however, of all symptoms, and on the ninth day he was discharged well.

Five days after aspiration the lung had returned to the normal position. The emphysema cared for itself.

Case II. J. Q., nine years old. The child was seen in the accident room about 4 P.M. He had been thrown from a bicycle by a team, but whether he had been run over or not no one knew. Examination showed a strong boy in poor condition. Color was bad, the respiration rapid, thirty-five to the minute and labored. Pulse 135. Both sides of the neck and the left back were markedly emphysematous. The chest was resonant all over but on the left there was absence of breathing and fremitus. The belly was not remarkable, and there were no marks of injury except to chest. In fact there was no definite fracture of the rib, only a marked tenderness on the left under the emphysema.

As the condition was rapidly becoming extreme no further examination was made, but a large trochar was inserted on the left at the angle of the scapula. A rush of air followed the insertion, and the dyspnea was immediately relieved and the cyanosis disappeared.

The child announced that he no longer felt as if he was suffocating. After the first escape of air considerable blood ran out. The trochar was kept in for five minutes, during which time the lung had expanded over the upper three-quarters of the chest. The chest was immobilized and $\frac{1}{12}$ gr. of morphia given subcutaneously and the child sent to the ward. As far as symptoms and treatment went he might as well have been sent home. On the second day there was a rise in the temperature of two degrees, but not once did he complain of pain or dyspnea. All but a trace of the emphysema and pneumothorax had disappeared by the fourth day.

In the case with the more serious injury we see the symptoms developing after hours and in the other immediately. That a slight degree of pneumothorax was present on entrance to the hospital is proven by the subcutaneous emphysema, but why the dyspnea should have been so long delayed I can explain only on the assumption that in the manipulation of reducing the dislocation or the vomiting on coming out of the ether or during a fit of coughing the wound, primarily closed, was forced open. Possibly either patient might have recovered without relief by puncture, but the condition seemed to offer a very bad prognosis.

Experience has proven that interference is rarely necessary to relieve the intra-pleural pressure after fracture of the ribs. In the type of case illustrated by the above reports it certainly gives relief, and may be a life-saving measure.

SOME OBSERVATIONS ON X-RAY THERAPEUTICS IN SKIN DISEASES.

BY FRED'K S. BURNS, M.D., BOSTON.

Assistant in Dermatology in the Massachusetts General Hospital,

The following observations on x-ray therapy are drawn from one hundred and fifty cases of skin disease treated at the Massachusetts General Hospital during the past year in connection with the routine work of the skin department. From the outset of the work, the number of cases of epithelioma continually coming to the clinic has considerably handicapped the treatment of a greater variety of diseases. In fact, a majority of the time has been spent in the treatment of epithelioma and tuberculosis; in the beginning according to a fairly well-conceded technique established by observers in this country and Europe, and later by such modifications as subsequent experience suggested. The great influx of cases soliciting x-ray treatment may well be compared to the number of lupus patients appearing for treatment soon after the advent of tuberculin, while the variety of ills for which persons have come would be absurd to enumerate.

That an estimate of the number of cases and variety of diseases treated may be readily made, a table was made indicating the disease, site and character of the lesion exposed, the total number of exposures, the average duration of the exposures and the average distance of the lesion from the anode. The quality of the rays sought and used as constantly as possible will be hereinafter mentioned. Patients with localized lesions have all been protected by means of lead foil covered on either side with adhesive plaster, in which an aperture was cut corresponding to the size of the lesion exposed. This protection has in all cases been sufficient, no evidence of reaction over the protected area having been seen. Diffuse lesions, as psoriasis, have usually been treated with only the head protected when it was in range. The possibility of a harmful x-ray dermatitis occurring during treatment has been constantly in mind, but I have yet to see ill result from a properly guided exposure. In this series of cases no ill effect was obtained. Occasionally an hyperæmia of the exposed area occurred, accompanied by a sensation of burning, but such reaction has always been temporary, except when prolonged intentionally, and by omitting exposures invariably subsided.

Most observers concede that the Roentgen rays are not an isolated variety of radiations, but aggregations of radiations of varying penetration, intensity and absorbability. No one, I think, who has attempted x-ray therapy and used tubes of various potentialities can help acknowledging the truth of this theory. The different degrees of vacuum show plainly varying degrees of penetration and quality as demonstrated by the fluoroscope, the photographic plate and reaction on the normal and diseased skin. I am corroborated, I believe, by most observers in this work in the opinion that tubes of low vacuum are best adapted to therapeutic use.

The quality of rays that has seemed to be best for cutaneous use are those showing black bones of the hand with the fluoroscope at a distance of a foot from the tube; this degree being generated by 1.5 to 3 amperes of primary current and induced by a coil with a maximum spark distance of twelve inches, the frequency of interruptions varying between twenty and thirty thousand per minute. Desiring a more accurate gauge for routine work, I have adopted for present purposes and convenience the penetrability of aluminum as a standard of measurement.[1] In a block of aluminum one inch thick and four inches long a series of eight holes were bored, the first hole leaving a remaining thickness of an eighth of an inch, the second two-eighths of an inch, and each succeeding one-eighth inch thicker, till the eighth, which had a thickness of one inch. This block, fastened to a fluoroscope and adjusted before a radiating tube, shows a certain degree of potentiality according to the thickness of the aluminum penetrated. The degree of radiations that has been found to give the best results in the treatment of cutaneous diseases, such as epithelioma, tuberculosis, etc., is that penetrating a two-eighths inch thickness of aluminum, while the succeeding degree of three-eighths remains quite opaque.

In advocating the above-mentioned quality of rays, I do not by any means assume such rays to be the solitary factor which achieves the results, but I do think that tubes generating such rays are either most potent in themselves or best allow the activity of other contributing factors. The static discharge is certainly greatest from tubes of low vacuum, and reaction analogous to the actinic rays is most readily brought about. Until the conflicting elements are successfully eliminated from tubes as at present used for purposes of treatment, or the separate action of each of the elements is better understood, we are justified in speaking of x-ray therapeutics only in the popular sense of the term.

Of all the diseases treated epithelioma has given the most constant and encouraging results. Most of the lesions were of the rodent ulcer type and situated on the face. A few cases of deeply seated carcinoma involving the skin were treated and gave entirely different results from the superficial epithelioma. These graver cases were exposed daily and tried with both low and high tubes with completely negative results. A temporary cessation of pain in some cases was all the good attained. In three of these cases a pathological examination showed the subcutaneous involvement. In the total number of fifty-five cases of epithelioma treated, twenty-seven were discharged healed, with no visible evidence of the disease left but the scar; nine progressed favorably but failed to continue treatment, and nineteen are at present under treatment, reacting similarly to those already healed. Each patient was treated at an average interval of twice a week, such changes being made in each case as seemed advisable, either on account of individual susceptibility of the patient or the reaction of the particular tube used at the time.

A quite constant evolution in the healing of epitheliomata seems to occur. When the lesion is ulcerative, as a majority of them are, a dryness of the ulcerated surface is noticed after two or three exposures to the rays; this dryness increases until a thin crust is formed, which gradually thickens as the exposures are continued, until it attains a thickness varying in different cases from one eighth to one half inch, the latter thickness presented a prominent and disfiguring appearance, which frequently suggests to patients that they are getting worse rather than better. While the crust thickens above the healing in beneath the surface occurs. The edges of the ulcer gradually contract, lessening the area of ulceration, until when or usually somewhat before healed, the crust falls spontaneously or is so slightly adherent that it is unavoidably removed by the patient. I have thought that healing might be accelerated by removing the crust when it became prominent and thick, but I have found that early removal has almost invariably been followed by a repetition of crust formation, and in comparison with cases whose crusts have been allowed to remain intact throughout treatment, I believe healing is not shortened by their early removal. In some cases several crusts are formed before final healing. In non-ulcerative epitheliomata the change in healing is not so constant, and the course of treatment is a good deal more protracted. After a varying number of exposures, these lesions either become ulcerative by erosion of their surfaces, and in which case they react in a similar manner to the ulcerative variety, or after long continued exposures gradually shrink until all that is lift is a firm scar. A preliminary curettage or cauterization facilitates healing of this variety of epithelioma.

A class of epitheliomata of the face in which I have been particularly interested is that involving the nose, the eyelids and canthi. Such cases are usually ulcerative; those involving the eyelids and canthi are a menace to the eye, causing great disfigurement by ulceration and subsequent ectropion of the lids, while the lesions of the nose and other portions of the face are always a cause of progressive deformity. Cases of this class have all done remarkably well; they have almost uniformly responded to treatment and have healed, leaving a soft scar with no contraction of the cicatricial tissue. No ill effect to the eye from exposures of lesions in its neighborhood has been seen. Frequently when the ulcerated lid rendered it impossible to completely protect the eye, and where the conjunctiva was exposed beneath, not more than a mild and transient conjunctivitis was remarked. Scars in general following healing by the rays are soft, smooth and non-contractile, a softening effect seems even to be often exerted on previously formed scar tissue.

[1] This standard was suggested to me by Mr. Dodd of the Massachusetts General Hospital.

From the favorable effect of x-ray therapy on a large majority of cases of epithelioma treated, I cannot help concluding that it at present offers the best relief to a certain class of epitheliomatous lesions. Many cases are much better and quicker treated by excision, and it is waste of time to treat very small lesions for weeks with the rays when they can be effectively destroyed in a few minutes with curette and cautery. Epithelioma and carcinoma below the cutaneous surface and even lesions which have become deep by infiltration from the skin, should not be treated by the x-rays with the hope of curative effect. All of the deep cases which I have attempted have proved uniformly failures, though treated by rays of various potentialities; and in a large number of carcinomata of the breast that I have had opportunity to observe under treatment, any permanent benefit was equally negative. There is almost a constant temporary relief from pain and occasionally considerable improvement in the general condition of the patient. The permanency of cure of epithelioma may yet fairly be questioned, though relapse has not been seen in any case discharged by us. There are at present under observation several cases who have been healed from eight months to a year. One case shows a soft scar of the cheek of thirteen months' duration. The control of lesions is at least remarkable and sufficiently satisfactory to encourage the continued use of the rays for the treatment of epithelioma.

Twenty-one cases of tuberculosis of the skin were treated by the rays, including lupus and scrofuloderma. Of the last mentioned types of tuberculosis, lupus has proved the more resistant and difficult variety to cure. Compared with epithelioma, the treatment of lupus is much more protracted and intenser exposures are required. Nine cases of lupus were healed, and as far as can be judged at present, cured. In all these cases the desired benefit did not begin until a decided dermatitis of the exposed area occurred. The reaction was usually accompanied by considerable pain, marked redness of the skin, and after a few days beginning sloughing of the lupus tissue. After varying periods of time, from a few weeks to months, depending upon the extent of the disease and its resistance to treatment, the lupus areas were replaced by cicatrices which were of the character of most x-ray scars, — soft and smooth.

While the treatment of lupus has seemed discouragingly long in some cases both to patient and physician, the ultimate result attained fully repays the patience and time expended. In no disease treated has healing been more rapid and more remarkable in its general effect than in scrofuloderma. The healing process seems to consist in a destruction of the tuberculous tissue, followed under the stimulating effect of the rays by rapid healing. The first three or four exposures should be of moderate intensity until the ulcerations begin to slough; at this stage to one not familiar with the evolution of healing the disease would appear to have been made worse, but as the treatment is continued by exposures of three to five minutes twice a week, the ulcerations rapidly heal and soon are replaced by cicatrices. Simultaneously with the improvement of the local lesions frequently there is betterment in the general health. I have in mind a case of a little girl of six years with extensive scrofuloderma of the right leg. During the treatment she gained ten pounds and changed from an anemic and scrofulous to a healthy appearance.

Folliculitis of the beard has responded to treatment with remarkable constancy. Eight cases were entirely healed and none attempted failed to improve. The disease, as is the case with other treatment, has a liability to relapse. I have seen two recurrences, one at the end of two and the other after six months. Cases accompanied by itching are soon relieved of that discomfort; the follicular pustules gradually dry until their resulting crusts are desquamated and all symptoms of inflammation have subsided. In several cases the treated portion of the beard fell, but in no case was the alopecia permanent, although often return did not occur for six or eight weeks.

The test of the value of the rays for psoriasis has been a rigid one. All the cases treated have been those who have come to the clinic for months or years and have been refractory to other methods of treatment. Not a lesion treated by the rays has failed to disappear under their influence. Two cases with generalized lesions have, after a great many exposures, been completely healed. One of the above-mentioned cases has been cleared nine months, and the other six months without return. In the other cases put down as healed only portions of the body have been cleared sufficient to ascertain the efficacy of the rays in each case. Considering that all the cases of psoriasis treated have been those not improved after a thorough trial by other means, the x-rays compare not only favorably with other methods of treatment, but are able to heal cases of psoriasis not otherwise influenced. Eczema, especially chronic cases with epidermic thickening, responds quickly under the rays. All the cases attempted have been healed. That the x-rays have definite therapeutic value in certain cutaneous diseases is at present quite generally accepted. They have been found to be like many therapeutic agents — of distinct value in a few diseases, palliative for the relief of pain in many affections, and of no benefit, if not distinctly harmful, in an unknown number of others. It was only after observation over a considerable period of time, on a large variety of cases, and after thorough treatment, that I became impressed by the fact that no radical curative effect is exerted by the rays subcutaneously.

Tuberculous Teachers Barred. — The State Board of Health of Indiana has issued orders forbidding the reemployment in the public schools of 250 teachers who are affected with tuberculosis.

RECORD OF PARASITIC INFECTIONS IN THE PHILIPPINES.

BY W J. CALVERT, M.D., ST. LOUIS, MO.,

Department of Clinical Medicine, Missouri State University.

THE following reports represent the findings in one hundred and thirty-six autopsies performed while on duty in the Board of Health, Manila, P. I., during 1900 and 1901:

Intestinal parasites:

TABLE I.

Total infection		53	38.97%
A. L.[1]	29		
Ank.	10		
Tri.	13		
T. S.	1—53		
Of these there were single infections		40	29.41%
A. L.	25		
Ank.	5		
Tri	9		
T. S.	1—40		
Double infections		5	3.67%
A. L. and Ank.	2		
A. L. and Tri.	1		
Ank. and Tri.	2—5		
Triple infections		1	0.73%
A. L., Ank. and Tri.	1		
Total cases		46	33.82%

As these cases came from various localities the percentages given fairly accurately represent the parasitic infection among the natives.

The following table represents the age and sex of the cases coming to autopsy:

TABLE II.

Adult males	74	54.40%
Adult females	31	22.79%
Male children	20	14.70%
Female children	11	8.08%
	136	99.97%

Ascaris lumbricoides were usually found in small numbers, varying from one or two to eight or ten; in two cases larger numbers were present, in one of these sixty-nine worms were counted. Usually the worms were found in the intestines, but in two cases a number had migrated to the stomach; in one case a large worm had entered the common bile duct, and in one case several were found in the posterior nares. In one case the worms had formed a firm ball which was lodged in the upper portion of the ileum and sufficiently large to practically obstruct the gut.

Distribution of A. L. with regard to age and sex:

TABLE III.

Male adult	13	44.82%
Female adults	5	17.24%
Male children	7	24.14%
Female children	4	13.79%
	29	99.99%

If the figures in Table III are proportionately raised so as to represent a number of autopsies in each sex and age equal to the maximum number of autopsies for any sex or age, which is 74 for adult males, the following table may be had:

TABLE IV.

Infectious.

Adult males	74	13	16.72%	32.01% adults.
Adult females	74	11.9	15.29%	
Male children	74	25.9	33.29%	67.99% children.
Female children	74	27	34.70%	
	77.8		100.00%	

Consolidating the above table gives:

TABLE V.

Cases.

Adults	148	24.9	16.8%	1:6
Children	148	52.9	35.8%	1:3

Table IV shows that proportionately 32% of those affected are adults and 68% children (under fifteen years), or that a little more than twice as many children as adults are affected; and in Table V it is seen that about 17%, or 1:6, of total adults and 35%, or 1:3, of total children are affected.

All of the infections with ankylostoma duodenale were light; eighteen worms was the largest number counted. Distribution was from duodenum to ileo-cecal valu. In all ten cases were found 7.3%, distributed as follows:

TABLE VI.

Male adults	8	80%
Female adults	1	10%
Male children	1	0 %
Female children	0	00%

If the figures in Table VI are converted as above, the following table may be had:

TABLE VII.

Cases.

Adult males	74	8	56.73%	73.75% for adults.
Adult females	74	2.4	17.02%	
Male children	74	3.7	26.23%	26.23% for children.
Female children	74	0.0	00.00%	
	14.1		99.98%	

Consolidating Table VII gives:

TABLE VIII.

		Cases.	
Adults	148	10.4	7.02%
Children	148	3.7	2.5%

From Table VII it may be seen that 74% of infections occur in adults, 26% in children and 83% in males. Of total adults, 7% and of children 2%, were infected, or three adults to one child.

Thirteen infections with Tricocephalus dispar were noted, distributed as follows:

TABLE IX.

Adult males	6	46.15%
Adult females	4	30.76%
Male child	2	15.38%
Female child	1	7.69%
Total	13	99.98%

[1] A. L.— Ascaris lumbricoides; Ank.— Ankylostoma duodenale; Tri.—Tricocephalus dispar; T. S.— Tenia solium.

If the figures in Table IX are converted as above, the following tables may be had:

TABLE X.

		Cases.		
Adult male . . .	74	6	20.27%	52.36% for adults.
Adult female . .	74	9.5	32.09%	
Male children . .	74	7.4	25.00%	47.63% for children.
Female children	74	6.7	22.63%	
			29.6%	99.99%

Consolidating Table X gives:

TABLE XI.

		Cases.	
Adults	148	15.5	10.4%
Children	148	14.1	9.5%

From Tables X and XI it is seen that males, females, adults and children are equally affected and that about 10% of the inhabitants harbor this parasite.

Considering the customs of the natives, especially as regards the opportunities for the contamination of their water supply, etc., the figures above, although high, are not so high as one would at first suppose. The relatively small number of Tenia is the more surprising when it is known that 4% of all hogs killed in Manila were heavily infected with cysticercus. Trichiniasis was not observed in any of the autopsies; a light infection was found in two hogs. Five cases of filariasis were found, all from the island of Luzon.

Clinical Department.

CLINICAL MEETING OF THE STAFF OF THE MASSACHUSETTS GENERAL HOSPITAL, APRIL 10, 1903.

(Concluded from No. 17, page 461.)

DR. C. A. PORTER spoke of two cases of

ADENO-CARCINOMA OF THE RECTUM.

The next two cases are almost identical with each other. Both of them suffered from an adeno-carcinoma of the rectum, about the size of a silver dollar, situated on the anterior wall in the prostatic region.

The first case I operated upon two and a half years ago, making an incision in the median line posteriorly through the sphincter ani, along the posterior rectal wall, for a distance of four inches. The coccyx and lower portion of the sacrum were removed to give greater room. The rectal walls were retracted, disclosing very clearly an ulcerated growth beneath. This was removed with a wide margin; the base of the bladder and prostate could be clearly seen. Two small glands were removed and upon examination were found to be non-malignant. The circular opening left after the removal of the growth was sutured horizontally, the posterior incision in the rectum longitudinally. The sphincter was carefully united with buried catgut sutures. Most of the skin incision was closed with silkworm gut. Two gauze drains were inserted on either side of the rectum, to the point of suture. Recovery was complicated on the fourth day by a slight fecal discharge which persisted for a week. From that time, convalescence was uninterrupted. At the end of a year the patient acquired perfect fecal control, but up to the present time, if the bowels are very loose, slight moisture is noticed, requiring a T bandage. Careful examination shows no evidence of recurrence. The man has gained twenty pounds.

The second case was operated upon six months ago for a similar growth on the anterior wall. A segment of the bowel was removed, through the same posterior incision without division of the sphincter. This case had no fecal discharge through the wound and had a perfectly normal convalescence. At present the man has perfect control of fecal matter, but imperfect control of gas. There is a slight eversion of the mucous membrane at the anus. In both cases a large rectal tube was kept in position for ten days. I think such cases show well the advantage of retaining the sphincter. In neither case could anything be gained by removing it, as the lower margin of the ulcer was at least two and a half inches from the anus. I have recently had two other cases in which a similar operation was done without incising the anus or sphincter.

DR. ARTHUR T. CABOT: I do not know whether the experience of others is like that of Dr. Porter and myself, but I have often found these adenoma-carcinomas on the anterior wall. In three cases I have removed them by a Kraske operation in which the posterior wall of the rectum was opened. The growth on the anterior wall was pulled through this opening, and it was then possible with a shoemaker's stitch to tie off the growth and then cut it beyond the sutures. In all of these cases the posterior opening through which the growth was removed was closed tightly by sutures, and the defect in the anterior wall where the growth was removed healed perfectly without gaping or giving any trouble whatever. These adenomas and adeno-carcinomas of the rectum are interesting growths, for there is a considerable period in their early history when they seem to be purely local, and during this time a thorough removal may be expected to work a cure; whereas, if neglected, they later inevitably take on malignant characteristics and lead to death.

DR. J. C. WARREN: I remember a case of this kind. The woman has reported from time to time. She has never had any recurrence. Dr. Elliot saw the case when I operated on it and Dr. Whitney pronounced it carcinoma. I think it belonged to the type discussed here to-night. The mucous membrane containing the growth was cut out and the sphincter and part of the rectum was left. I cannot help thinking, however, that the more radical operation is the better.

DR. C. A. PORTER showed a case of

PERONEAL PROSTATECTOMY

for Dr. J. W. Elliot.

The patient, aged sixty, male, tailor, Russian, entered Dr. Elliot's service on March 3, 1903. A year ago he had had acute retention, without known cause. Catheterized by physician for three months, after which he passed his urine without difficulty and with a good stream. Three months ago he had another attack of retention, after which he used the catheter himself. He now complains of severe pain at the end of the penis and in the back. He has never passed gravel. Two days ago, after catheterization, he passed a little blood, which continued until the time of admission. He has passed no water without catheter for three weeks. Rectal examination showed a small, firm prostate. No. 12 Coudé passed into the bladder without difficulty. Constant drainage. On March 13 operation was decided upon, since the patient would not allow catheter to remain in position. No blood in urine, odor foul in spite of frequent irrigation.

On the 14th operation was done by Dr. Elliot. A two-inch incision through the perineum into membranous urethra was made. The bladder entered by finger, and prostate found to consist of two lateral and one larger middle lobe. These three tumors were removed by finger dissection through the perineal wound. Bladder washed out; bleeding moderate. A stricture was found three inches from the meatus, which was divulsed. A large rubber drainage tube was inserted into the bladder through the perineal wound. On the 16th convalescence was good, drainage excellent, tube diminished in calibre. On the 17th tube removed and No. 13 gum elastic catheter passed into the bladder through the penis. On the 22d gauze was removed from perineal wound, which was granulating well. On the 28th, catheter removed and the bladder drained wholly through the perineal wound. On the 29th passed about six ounces of urine at a time per urethra. On the 31st, catheter passed to bladder, which was much cleaner after irrigation twice daily. On April 4 he was catheterized after passing six ounces of water. One and a half ounces of residual urine were found. On April 7 little pain, passes urine himself at two hourly intervals. Upon catheterization, only six drachms of urine found. Perineal wound occasionally leaks a little, but is granulating rapidly. Great improvement in general condition. Dr. Parker also showed a second case which had been operated on by Dr. Elliot. In this case Dr. Elliot had opened the bladder by a suprapubic operation and had removed two large, ovoid, smooth masses of the size of eggs. These masses were elastic and not connected with the bladder. On section of one of these ovoid masses, a small stone was found in the center, surrounded by layers of laminated fibrin.

DR. W. F. WHITNEY: As far as I know these are certainly very unique concretions. They consist apparently of a series of fibrinous lamellæ in the center of which is a stone. It has occurred to me that the formation was due to defibrinating of the blood, which formed the layers of the concretions. It is remarkable that it does not occur oftener. Why it should have occurred in this case I have no solution to offer. Nothing I have ever seen approach these in character.

DR. BEACH: I had a case this winter where the stone was covered with a thinner fibrinous deposit than is the stone mentioned in the discussion tonight, but it was sufficiently covered so that no click was heard when the sound came in contact with the stone. The specimen is in my possession now, and when it is shaken about in the bottle, there is no click when it comes in contact with the glass.

DR. BENJAMIN TENNEY read a paper on

THE CAUSE OF CERTAIN KNEE JOINT INJURIES.

In going over a series of knee joints from the dissecting room some time ago, I found a considerable number which showed damage to the internal semilunar fibro-cartilage.

The most common form of damage found is well shown in these photographs of cartilages, the posterior half of which show the effect of crush and wear. In order to produce this form of damage the internal condyle of the femur must over-ride this part of the fibro-cartilage and settle down behind it while the knee is being flexed. As the knee is extended again the cartilage may either slip back into its normal position with something of a snap, or it may be partially torn from its attachment to the back of the capsule, remaining attached to the internal lateral ligament, as in the case which Dr. Codman has described, or it may be torn from its capsular attachment for its entire length, being held at its two extremities and turned wrong side up into the intercondylar notch. An example of this last injury, I show you this evening.

In searching for a means of producing one of these injuries, I tried 24 undissected joints, flexing them with the foot strongly rotated outwards. In one, the internal semilunar caught and snapped back during this manipulation. This joint showed a marked increase in lateral motion. After rupture of the internal lateral ligament in the other 23 joints, it was possible to catch the semilunar in the same fashion. This indicated to my mind that the slipping internal semilunar cartilage was connected with previous damage to the internal lateral ligament of the joint.

Another one of my specimens shows a partial splitting of both semilunars from the posterior part of the capsule without any evidence of crush or friction. In this joint there was a complete rupture of the anterior crucial ligament. It is possible that this injury may also allow of some over-riding of the condyles on the cartilages, but experimental y it has not been possible to produce such over-riding without injury to the internal lateral ligament as well. If my conclusions are correct, the history of a case should show some injury to the internal lateral ligament of the joint, which results in increased motility at this point. At some time after this the joint is flexed with the foot rotated outwards, and the internal condyle over-rides the semilunar and settles down behind it. If this occurs frequently and without great violence, the results will appear in the shape

of cartilages such as shown in these photographs. If the over-riding occur suddenly, and with great muscular action, the condition as found by Dr. Codman may appear. If this persists without operation, the cartilage may be entirely torn from its capsular attachment as in this specimen.

Dr. Robert B. Greenough reported the following cases:

SKIN GRAFTING FOLLOWING A BURN.

Case I. H. C. (hospital No. 129,663), a young woman of twenty-four, entered the hospital on Oct. 31, 1903. Three weeks before she caught her left hand between the roller of a steam laundry mangle and received a burn over the palmar surface. The wound was dressed in the Accident Room and subsequently in the Out-Patient Department.

On examination it was found that the palmar surface of the left hand was a granulating surface from the wrist line to the last joint of the fingers. A part of the skin of the outer aspect of the thumb was intact. No tendons exposed except over the articulation of the first and second phalanges of the little finger. Operation, Nov. 5, 1902; R. B. Greenough; ether. The granulating surface was cleaned with permanganate and oxalic, peroxide and corrosive. It was then thoroughly curetted and the skin edges freshened. It was then douched with salt solution and bandaged with gauze compresses. A model of the flap needed to close in the defect was then made of gauze, about one-third being allowed for shrinkage. The skin under the right breast was cleaned with solutions and a flap of the desired size and shape dissected up, having its base downward. All of the subcutaneous tissues were included in the flap, which was about 4 x 5 inches in extent. The flap was then laid back on the abdomen and protected with gauze, while the bare space from which it had been raised was closed in by a modification of the plastic operation devised by Dr. Warren for closing the incision in extensive operations for cancer of the breast. In order to bring no strain upon the base of the hand flap the incision into the axilla was carried deep and the flap from the axilla made large and dissected up freely. By this means the defect was closed in entirely. The hand flap was then sutured in position on the palm, the arm being held at rest across the body. A protective dressing was applied and a plaster bandage of the Velpeau pattern was then put on to immobilize the parts. The wound was dressed on the second day and at frequent intervals after that time. There was considerable oozing from the granulating surfaces of the fingers, but the flap became firmly adherent and was well nourished when its pedicle was cut on the eleventh day. The wound then healed rapidly and the further convalescence has been uneventful. The present condition of the flap can probably be improved at a later date by the removal of the superabundant fatty subcutaneous tissue. The little finger promises to be of little value on account of the involvement of its tendon. The case is shown particularly on account of the ease with which the defect from which the flap was taken was closed in by a plastic operation; by this means the use of Thiersch grafts was avoided.

PERFORATING GASTRIC ULCER — RECOVERY.

Case II. L. P., a young man of twenty-one, tailor by trade, was brought to the hospital at 10 P.M. on Dec. 31, 1902, with the following history: Well until three weeks ago, when began to have indefinite symptoms of ill health, without localization in any organ. Lost appetite but did not vomit. Ate usual dinner of meat and soup at noon on day of entrance and was at work in the afternoon, when, at 4:30 P.M., on drinking a cup of tea and eating two crackers, was suddenly seized with intense pain in epigastrium. Rolled on floor with the pain and vomited several times, quantity small and no blood noticed. Pain increased in severity until entrance; no jaundice, no chill, no cough or lung symptoms and bowels had been moving regularly.

On examination, a fairly nourished young man, with an anxious expression of face and considerable color in cheeks. Respiration 36 and labored pulse 100 and of good character, medium tension. Temperature 101. Leucocytosis of 21,000. Heart and lungs negative. Abdomen very rigid and board-like, especially in epigastrium and right hypochondrium. Some tympany. Slight area of shifting dullness in right flank. Liver dullness markedly diminished. Rectal and urinary examination negative. The probable diagnosis of perforation of a gastric ulcer was made by the evidence of perforative peritonitis, the seat of symptoms in the upper abdomen and the diminished liver dullness.

Operation, six and a half hours after onset of pain; ether; Dr. R. B. Greenough. A median incision was made from ensiform to umbilicus. On opening the peritoneal cavity, gas and turbid fluid escaped. Cultures were taken, but showed no growth of bacteria; probably owing to some fault in technique; inasmuch as the stomach contents was free in the abdominal cavity, the stomach was explored, and on its anterior wall, close to the pylorus, a round perforation was found one-eighth of an inch in diameter, from which exuded fluid and gas. Considerable fibrin surrounded this opening, and the walls were thickened and of softened consistency. A purse-string suture was used to close the opening and a row of Lembert stitches were used to cover in the purse string until leakage no longer occurred. By this method of closure the lumen of the pyloric end of the stomach was so much obstructed that it was decided to perform a gastro-enterostomy, since the patient was in sufficiently good condition to bear the operation. The stomach was raised and an opening made in the transverse mesocolon, exposing the posterior wall of the stomach. To this the jejunum was united, at a point about four inches from the duodenum, by means of the McGraw elastic ligature. This anastomosis was protected by a row of Lembert stitches, and the stomach allowed to return to its normal position.

While this part of the operation was being done, the abdomen was thoroughly flushed out with gallons of salt solution until the turbid serum was entirely washed away. Two counter incisions in the flanks were made and cigarette wicks of gauze and rubber dam were introduced in all directions, two in each flank dan three in the central incision. A rubber drainage tube was also introduced, covered with gauze, to the bottom of the pelvis. A Mixter tube was then tied into the cecum, which was drawn to the umbilicus for this purpose and the wounds were partially united with silkworm gut. The patient stood the operation well, and was at no time in an alarming condition of collapse. The operation consumed less than forty minutes.

After the operation the drainage tube was emptied by a catheter and suction syringe, at intervals of every half hour in the day and every two hours at night. One to two drachms of fluid were usually obtained during the first week. On the day after operation an enema through the colostomy tube was followed by a good result. The patient was fed on nutrient enemata until the 9th day, when small doses of milk and lime water were allowed. On the sixth day all of the wicks and the rubber drainage tube had been removed, and the Mixter tube had come away, leaving a fecal fistula. On the thirteenth day the wound was drawn together with straps, and in two weeks the fistula had closed. At the present time, just over three months after the operation, the wound is solid and the patient is eating well and feels in perfect health.

INJURY OF INTESTINE; OPERATION; RECOVERY.

CASE III. P. S. (hospital No. 411-199), a hostler, fifty-eight years of age, was brought to the hospital on Aug. 28, 1902, in the afternoon, and entered the serviice of Dr. S. J. Mixter, by whose permission I report the case. The history was as follows: Previous history of a negative character; an hour and a half before entrance the patient was kicked in the abdomen by a horse. He apparently did not lose consciousness, but fell and was unable to rise and suffered excruciating pain.

On examination there was found a man of large frame and well nourished, face pale and with an anxious expression, moist with perspiration. Pulse of 84, of good quality and medium tension. Temperature 98.2. Respiration 22, shallow and chiefly costal. Lungs negative. Heart not enlarged, soft systolic murmur at base, not transmitted. The abdomen was markedly retracted in upper portion and of boardlike rigidity. This was most marked in the upper left portion of the left rectus muscle, which was so retracted as to form a transverse depression. There was a small area of shifting dullness in the left flank. Tenderness was present over the whole abdomen, becoming exquisite in left upper quadrant. Rectal examination was negative. Urine drawn by catheter was normal. Patient vomited undigested food after entrance; no blood. Liver dullness not diminished. Leucocytosis of 19,000. The diagnosis of probable injury to the intestine was made by the absence of signs of hemorrhage and the extreme rigidity of the abdomen.

Operation three hours after injury by Dr. R. B. Greenough; ether. A median incision six inches long was made from ensiform to umbilicus. Turbid fluid escaped and blood stained omentum presented. A culture of this fluid showed the presence of a mixed growth of bacilli, cocci, diplococci and streptococci. On exploration of the entire intestinal tract, the following lesions were found: There was extravasated blood in the omentum. There was a tear two and a half inches long in the transverse meso-colon, perpendicular to the gut, and not involving any large vessels. The anterior surface of the transverse colon was denuded of peritoneum over an area of one and a half by three inches, leaving apparently uninjured muscle exposed. At a point about ten feet from the duodenum the jejunum presented a transverse tear through all its coats on the side opposite to the mesentery. This tear involved about one-half the circumference of the gut, and from it liquid feces were escaping into the peritoneal cavity. A punctured wound of small size, extending only through the peritoneal and muscular coat, was found at the junction of jejunum and duodenum. The peritoneum was dull and covered with fibrin flakes in several regions, most marked at the position of the tear in the jejunum. The torn jejunum was sutured with continuous catgut, which was reinforced by two rows of silk Lembert stitches. The slit in the meso-colon was closed with a continuous catgut stitch. The rent in the peritoneal coat of the colon and the punctured wound in the duodenum were closed with continuous silk stitches. The abdomen was thoroughly irrigated with gallons of hot salt solution, and wicks were placed in contact with the sutured wound of the jejunum and against the weak place in the transverse colon. The wound was then closed with silkworm gut. The patient was under ether about two hours, and was taken to the ward in good condition.

The convalescence of the case was uninterrupted and the temperature did not go above 100. The wicks were removed on the fifth day and the wound closed rapidly by granulation. The patient considers himself in perfect health at the present time, seven and a half months after the injury.

Reports of Societies.

THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

SEVENTEENTH ANNUAL MEETING, HELD MAY 12, 1903, WASHINGTON, D. C.

(Continued from No. 17, p. 466.)

CONSERVATIVE PERINEAL PROSTATECTOMY. PRESENTATIONS OF NEW INSTRUMENTS AND TECHNIQUE.

DR. HUGH H. YOUNG of Baltimore read this paper, giving a brief résumé of his work and the

problems which presented themselves to him. The principal objection to the perineal route was the necessity of the suprapubic incision to push the prostate down into the perineum where it could be enucleated. After several months of experiment he had constructed an instrument which could be used from below to draw down the prostate. It consisted of two fenestrated blades attached to shafts, one of which revolved around the other. When the two handles near the outer end, which regulated the rotation, were brought together, the blades were approximated and in position for insertion into the bladder through the opening in the membranous urethra. Once introduced above the intravesical limits of the prostatic lobes, the blades could be made to separate by rotating the external blades away from each other, when the instrument would be ready for any traction on its shaft that was necessary to drag down the prostate well into the perineal wound. The fact that many of the cases requiring prostatectomy were vigorous men in the fifties, with sexual powers well preserved, rendered it important that nothing should be done to injure their manly vigor, and care should be taken not to injure or remove the ejaculatory ducts. Evidence of injury to these ducts was that Petit reported that twelve cases in thirty suffered with epididymitis after the Albarron operation. The doctor then presented some drawings which showed the position of the ejaculatory ducts and vesicles, and stated that their position depended largely upon the character, size and disposition of the enlargements. As a result of his study of the course of the ejaculatory ducts, he summarized as follows: In the normal prostate the ejaculatory ducts lie for the most part just beneath the posterior capsule, considerably below the level of the vesical neck, and were separated from it by the pre-spermatic group of glands. In the hypertrophied prostate the same statements were true, the only difference being that the ducts enter relatively lower down, and the vesical neck was separated from them by much more tissue, especially if the pre-spermatic group of glands have taken on growth with the resulting median lobe enlargement, when the vesical orifice was lifted high up above the level of the ducts. The prostatic tissue immediately adjacent to the ducts was beneath the urethra, and played no part in the obstruction, which was caused entirely by the lateral and median enlargements, both of which were well above the ejaculatory ducts.

Technique of operation. — He considered the exaggerated dorsal lithotomy position the most satisfactory. The perineum should be elevated until it was almost parallel with the floor. He used the median perineum incision, about 6 cm. in length, the posterior limit being quite near the anus in thin patients; if the patient be large, with the prostate situated deeply, he generally used the inverted "V"-shaped incision. The apex of this incision was just over the posterior part of the bulb, and the two branches were each 5 cm. long, the posterior limit being about midway between the anus and ischial tuberosity. After exposing the superficial muscles by blunt dissection, the central tendon was caught by a clamp near the bulb and divided. This at once freed the sphincter and the levator ani from the anterior attachment, and exposed the rectum drawn forward by the recto-urethralis muscle. In order to reach the membranous urethra and the apex of the prostate this muscle should be divided. This at once exposes the "*espace decollable retroprostatique*," so well described by Proust. When this muscle was divided the rectum dropped back and one entered the space surrounding the posterior surface of the prostate. Next the membranous urethra was opened upon a sound, and a sound of considerable size passed through the incision into the prostatic urethra and bladder. Then the prostatic retractor, already described, was inserted; so soon as the beak was free in the vesical cavity the thumb screw which fixed the blades in position was loosened, the blades rotated 180° by means of the external blades, and then was fixed by tightening the thumb screws. Each blade projected laterally so as to engage the intravesical surface of the lateral lobe. As a result of this a splendid exposure of the entire posterior surface of the prostate was obtained. Next an incision was made on either side of the median line for almost the entire length of the posterior surface of the prostate and about 1 cm. deep; the two lines should be convergent. The bridge of tissue which was contained between the two incisions contained the ejaculatory ducts, whose preservation was of the utmost importance.

Enucleation of the lobes. — He believed the separation of the capsule from the lateral lobes was best done with a blunt dissector. Capsules were of varying thickess and contained several layers of cleavage. It was important to start not too deeply, going into the prostatic substance, nor too superficially, so as to be outside most of the capsule. After the stripping up process had been started correctly it was easily continued by blunt dissectors until first the lateral and then the anterior surface of the lateral lobes had been freed from the capsule. Internal enucleation required considerable care to prevent tearing into the urethra. When the enucleation of the lateral lobe had progressed fairly well on each side, he found it advantageous to have traction made upon the prostate itself, in order to facilitate the separation of the deeper portion. He devised a pair of fenestrated instruments which could grasp the entire lobe, and which presented such broad surfaces that no tearing or cutting of the capsule could result. After shelling out the lateral lobes, attention should be directed to the median portion of the prostate. The prostatic retractor can be used now with great advantage, and should be handled as follows: Push the retractor backward until it is free in the bladder cavity; depress the handle so that the shaft can be on top of the

middle lobe; rotate the instrument 90° so that one of the blades will project downward behind it. After the median lobe has presented in the left intracapsular cavity, it can be readily and rapidly enucleated. By this technique he said that he had been able to enucleate several median hypertrophies and without tearing the mucous covering. Abundant vesical drainage should be provided for, as a small tube may easily become plugged by blood clots and cause great annoyance. He deemed it advisable to keep up continuous irrigations while the patient was being returned to his room, so as to prevent clogging of the drainage tube with blood clots during transit.

After treatment. — If the patient had a cystitis, and such patients usually do have, a continuous irrigation of the bladder was kept up, often for a week, and with great benefit to the vesical inflammation. A submammary infusion of 1,000 cc. salt solution was given either on the operating table or after return to bed. This prevented both shock and anuria, and was also a cure for the post-operative thirst. At the end of a week in bed the drainage tubes were withdrawn. After passing a catheter on the ninth day it was held there by straps. Permanent drainage was maintained for five days, the bladder being irrigated twice daily with boric solution. He had never had a stricture following this operation.

Results. — He had now operated upon twelve cases with the prostatic retractor, and generally by the technique described. All these cases were living and well. All could empty their bladders completely, and none used the catheter. Incontinence of urine had never been more than a temporary affair, and the perineal fistula had closed in all, except the recent cases. One case, sixty-nine years old, with a tremendous prostate, who had led a catheter life for ten years, was now, seven weeks after the operation, voiding urine at intervals of from three to five hours. He had determined that the power of erection was present, that ejaculation was apparently normal, and that the semen obtained by ejaculation contained actively motile spermatozoa and the lecothin bodies found in normal prostatic secretions. Their presence showed that the bridge of prostatic tissue surrounding the ejaculatory ducts was furnishing a part of the fluid ejaculated. This was possibly of great importance, as it was supposed that without the mixture of prostatic secretion, the spermatozoa were non-motile and apparently lifeless. It was possible that only a very small amount of prostatic secretion was necessary to vivify the spermatozoa. He said that although a longer period of time must elapse before the effects of the operation can be thoroughly realized, he felt convinced from the cases already studied that the sexual powers would be perfectly preserved, and that the ability of these men to procreate would remain unchanged. The instrument which he called his "prostatic retractor" had transformed the operation of prostatectomy for him. Now, with its use, the entire field was cleared, the operation was performed in a shallow wound accurately under visual control, proper regard being now made to the urethra and the ejaculatory ducts.

DR. RAMON GUITERAS of New York showed some plates demonstrating his operation of perineal prostatectomy.

DR. EDWIN C. BURNETT of St. Louis did not believe that tearing or severing the ejaculatory ducts would always interfere with the sexual power so far as erections were concerned. At a meeting at Niagara Falls last year he reported a case of division of the ejaculatory ducts done upon a child when four years of age; this occurred during an operation for stone. When this child grew to manhood he had perfect virility with normal erections, and the only thing abnormal was the fact that he never had an ejaculation.

DR. ARTHUR T. CABOT of Boston expressed much admiration for the operation as performed by Dr. Young, which removed an objection to the perineal operation, the injury to the ejaculatory ducts, which so often happened by other methods.

DR. HUGH H. YOUNG of Baltimore said that in a case he operated upon five or six years ago, doing the Alexander operation, he removed two enormous lobes of the prostate and severed the ejaculatory ducts, yet that man afterwards was able to have an ejaculation.

SECOND DAY — MAY 13.

ACUTE VESICULITIS — ESPECIALLY TREATMENT.

DR. JAMES P. TUTTLE of New York read this paper. The chief object of his paper was a prophylactic one, to call attention to the harm often done to the rectum by unwise efforts to treat vesiculitis through that organ. He said that the onset of acute vesiculitis was usually in the course of an acute posterior urethritis. It might be due to gonorrhea, colon bacillus, tubercular or simple pus infection. It had been rare, in his experience, in those cases which had not been subjected to instrumentation or forcible irrigation of the posterior urethra. It seemed possible to him that the hydrostatic pressure exerted by the Valentine method on the deep urethra in cases of spasm of the neck of the bladder might easily distend the ducts and carry the infectious secretions up towards the vesicles. The disease may come from other causes than gonorrhea. Aside from the painful erections and emissions, frequent and straining efforts at urination and sometimes retention of urine, most of the symptoms were referred to the perineum and rectum. There usually occurred aching in the sacrum and pelvis, rectal tenesmus, pain on defecation, shooting down the legs into the testicles and to the end of the penis, just as was often found in ulcer of the rectum. Diagnosis could only be made by an examination through the rectum, and this was best made with the patient in the knee-chest position and with the bladder moderately filled with urine. The finger in the rectum could then make out

an unusual heat, tenderness, swollen irregular masses leading upward and outward from the lateral lobes of the prostate. Usually the prostate was swollen and tender.

Treatment. — After experimenting very largely he found that, in all such conditions requiring prolonged irrigations, two soft catheters of rubber were more satisfactory than the metal irrigators. In the very early stages cold water gradually lowering the temperature from 90° to 50° by putting ice in the reservoir after the flow had begun was best. The bag should not be so high as to cause a forcible injection of the fluid. Prolonged rather than intense cold was to be desired. After the acute symptoms had subsided, one should change from cold to heat, but one should be careful not to raise the heat too high; 110 to 115° F. was as hot as the water should ever be. To this he advised the adding ½ to 2% hydrastis. When the swelling and pain persisted, irrigations over the vesicles through the rectal speculum gave great relief, and would often start up resolution when nothing else would. Temperature was best reduced by the application of guaiacol along the course of the vas deferens. Pain was best relieved by aconite or acetanilid, or phenacetin. Opium should be avoided on account of its constipating effects. Frequent rectal examinations should be avoided. Hydrastis and ergot internally had good effects in chronic conditions.

Dr. Eugene Fuller of New York emphasized the importance of rest, with elevation of the hips, the use of the bed pan, enemata, etc., in the treatment of acute vesiculitis. If such a treatment be pursued, few cases will run on to a chronic conditon.

Dr. George K. Swinburne of New York deprecated the use of forcible urethral irrigations. He used urethral irrigations a great deal, and had never had a case of acute urethritis or prostatic abscess or other bad result from its use because he never used force, and so avoided distending the urethra too much. In acute vesiculitis he had used the Chetwood tube with pleasing results.

A FURTHER REPORT ON THE AUTHOR'S METHOD OF EXPOSING AND DRAINING THE SEMINAL VESICLES.

Dr. Eugene Fuller of New York read this paper. He reviewed this former paper read before the New York County Medical Association and published in the *Journal of the American Medical Association*, May 4, 1901, entitled "A New Operative Method to Expose the Seminal Vesicles and Prostate for the Purpose of Extirpation and Drainage, — a Preliminary Report." In order to facilitate an accurate dissection through the soft, elastic and yielding perineal and pelvic structures, they should be made to assume as stable a position as possible, and that could only be accomplished by making them taut. To accomplish this the patient with his thighs sharply flexed was put belly downward on a Trendelenburg table, the buttocks protruding somewhat over the end, while the flexed thighs straddle the table. The end of the table was then inclined upward quite sharply. The body was maintained in this position by sand bags, strappings and the attention of attendants. An antiseptic lubricated cotton tampon, with a tape attached, was pushed into the previously cleansed rectum, well up into the region of the sigmoid, in order to guard against bowel leakage. No catheter was necessary or advisable, as in the Von Dittel operation, but the bladder emptied before the administration of the anesthetic. The external incision consisted of two somewhat converging longitudinal cuts, which were connected at their dependent and proximal extremities by a transverse cut. The longitudinal cut to the operator's right began a little above the patient's coccyx and just inside his right ischium, and extended downward and slightly inward, keeping just within the border of that bone, passing the tuber ischii and ending somewhat below that tuberosity at a point laterally and about three-fourths of an inch anteriorly to the anterior margin of the anus. The longitudinal cut to the operator's left corresponded exactly to the one just described. The transverse cut connected the converging ends, dividing the perineum transversely about three-fourths of an inch anterior to the anterior margin of the anus. He incised deeply along the longitudinal cuts, through the fatty tissue of the ischiorectal space, and divided above a few of the lower fibers of the glutens maximus muscle. The transverse cut was then deepened, the anterior layer of the deep fascia being cut through. Great care was taken to avoid wounding the sphincter muscle. The forefinger of the operator's left hand was next introduced into the rectum, the ball of the tip turned downward against the anterior rectal wall, while the corresponding thumb pressed against the loosely dissected rectum, the hand at the same time exercised upward traction. With the right hand the operator dissected more deeply, cutting through the levator ani muscle and the visceral layer of the pelvic fascia. The pathway of dissection between the urethra and the rectal wall was very narrow, and the forefinger in the rectum acted as a most important guide. The stroke of the knife was inward and toward the rectal wall. The tip of the finger was moved so that it was just behind the portion of the rectal wall where the dissection was being made. This protected against perforation of the rectal wall, and the urethra escaped damage. In case the lower portion of the lateral incisions have not been made deep enough to sever the levator ani muscle, they can now be made so. Next the operator's right forefinger was inserted along the dissection and kept just below the rectal wall until it passed through the cut in the visceral layer of the pelvic fascia, and entered the lymph space which lies between the prostate and the rectal wall. When this space was reached the left forefinger was passed in alongside the right, and the path of the wound divulsed by separat-

ing the fingers. By this process the loose rectal connections were stripped from the seminal vesicles and posterior bladder wall, leaving those parts exposed to direct surgical attack. The operation having been completed for which the incision was made, the walls of the wound were carefully adjusted by deep sutures, so as to bring the rectum back into its orignial position. A space for gauze packing was left in the middle portion of the transverse cut. If the sutures around the rectal portion of the wound were not deep, so as to allow the sphincter to become firmly attached to the outlying structures, some tendency to rectal prolapse might eventually develop. Temporary retention of urine was apt to develop, especially where considerable gauze packing was left, connecting the deep track of the wound with the surface. As the tissues in these parts were well nourished, first intention was the rule. This operation rendered direct surgical attack feasible in many rebellious forms of seminal vesicular disease, which were formerly left unaided, or which have responded unsatisfactorily to palliative measures. He did not recommend the operation in tubercular seminal vesiculitis. He found this method of reaching and draining deep suppurations either about the seminal vesicles or prostate most satisfactory. If the abscess was back of the prostate his operation avoided injuring that gland or the ejaculatory ducts. He always feared the operation per rectum, lest bowel leakage into the tissues might give trouble, or in case of an abscess just on the verge of spontaneously discharging itself into the bladder, a vesico-rectal fistula might persist. No surgical objections could be raised against the drainage of suppuration by his method, since the dissection employed reached the focus of trouble without injury to any of the adjacent organs. Speedy and safe convalescence ensued, and there was little or no danger of subsequent complications. The only objection to the operation was that it required more skill than a cystotomy, with incision through the trigonum or an incision through the rectum.

DR. JAMES P. TUTTLE of New York, in order to prevent any contamination of the operative field by the rectal contents, recommended that a metal ring with a groove running around it, with four holes in it, be employed in this way: An ordinary condon should first be tied around the groove in the metal ring, which is then fastened just inside the anal margin. The condon is then inverted, and this would prevent the feces coming down as well as protect the surgeon's hand from the fecal contents.

DR. HUGH H. YOUNG of Baltimore believed that too much attention was paid to the vesicles and not enough to the prostate. He said that a chronic prostatitis was more difficult to cure than a chronic vesiculitis, and that it happened very often a cure of both resulted from attention being paid alone to the chronic prostatitis.

DR. E. L. KEYES, JR., of New York always had fancied that a rectal incision was adequate to take care of that kind of cases; he had never found the dangers of infection increased by an incision through the rectum, which was a simpler matter than going through the perineum. He related an instructive instance occurring in a man who was in catheter life. He was called to the country to open an abscess, the incision being made through the rectum. Before operating there was no pus in the urine, but after the operation it became loaded with pus. The parts were irrigated with boric acid solution for eight or ten weeks, and he was reported to be no better. He was still passing urine through his rectum. The irrigation was stopped and, six weeks later, the hole closed and remained closed.

DR. EUGENE FULLER of New York said he had never had infection from the rectum from following the method of operating advocated, but thought the suggestion of Dr. Tuttle a good one. He believed that a greater effort should be made to differentiate between diseases of the prostate and those of the vesicles. He thought the time would soon come when more would be done for such sufferers by operative procedures. One of the dangers of opening through the rectum was from the urine, and an operation which avoided such a possibility would be better than when we obtained drainage elsewhere.

DR. E. L. KEYES, JR., wished it to be understood that he referred only to cases of well-defined perivesicular abscesses when he advocated a rectal incision for drainage.

A VESICAL CALCULUS OF UNUSUAL DIMENSIONS.

DR. ABNER POST of Boston presented this unusual specimen. The patient was a man sixty-six years old. He dated the beginning of his trouble from a urethral hemorrhage which he believed occurred fourteen years ago. Since then he had had almost constant discomfort and frequent micturition. For some time he had been compelled to get up every hour of the night to pass his urine. Sometimes his urine would not come until he had raised his leg. It was evident when the doctor first saw him that he had a stone, the removal of which would relieve him of his symptoms. Suprapubic cystotomy was performed, and the immense stone was disclosed. It filled the entire vesical cavity. With much difficulty the stone was removed from its bed. To gain sufficient room it was found necessary to divide the recti muscles and to make a transverse incision on each side. The stone weighed 660 gm. It was $11\frac{3}{4}$ in its longest diameter and $10\frac{3}{8}$ inches in its shorter. The pathologist reported that it consisted chiefly of phosphate of calcium and triple phosphates, with some carbonate of lime and organized débris. The largest vesical calculus on record was said to be in the possession of the French lithotomist, Morand. It weighed 6 pounds and 3 oz. An enormous stone weighing 51 oz. was long preserved in the hospital of La Charité, Paris. It was extracted after death from the bladder of a poor curate in 1690. Coulson, "On the Bladder and Prostate," said: "The largest calculus

preserved in our collections is the one which Mr. Cline attempted to extract from the bladder of Sir William Ogilvie; it weighed 44 oz., and was 16 inches round one axis by 14 round the other. Numerous cases are recorded where the stone weighed from 5 to 15 or 20 oz., but how small a proportion they bear to the mass of cases operated on may be gathered from the fact that, of the 703 calculi in the Norwich collection, weighed by Mr. Crosse, only two exceeded 6 oz. in weight, and they were between 6 and 7 oz."

Dr. Hugh H. Young of Baltimore said that from a book he had in his possession he learned that Sir William Ogilvie for five years had found it necessary to stand on his hands or back up against a wall in order to urinate; in this way the urine flowed over the top of the stone. The attempt at perineal lithotomy was made in 1816 before the days of anesthesia. It was stated that Sir William bore the operation with great fortitude. With supplies from a blacksmith, a chisel and hammer, etc., 5 oz. of the stone were removed, and then Sir William could stand it no longer. The calculus was now in the Museum of the College of Physicians and Surgeons, and had the marks of the work done upon it during the operation, showing where a hole had been gouged out. Last year Dr. Young had seen two calculi which filled the bladder and prostatic urethra, and were practically as big as the one presented by Dr. Post.

(To be continued.)

Recent Literature.

A Laboratory Text-Book of Embryology. By C. S. Minot, S.D., LL.D., D.Sc. xvii + 380 pp. 218 illustrations. Philadelphia: P. Blakiston's Son & Co. 1903.

Embryology has received such scant recognition in most American medical schools that the majority of teachers of this subject have been forced to devise means for getting the most out of the limited opportunities given them. From this standpoint an excellent body of concise information and of laboratory directions has been brought together by Professor Minot in this "Laboratory Text-book of Embryology." The volume opens with a chapter on the general conceptions of embryology, such as a comparison of the larval and the embryonic types of development, the germ layers, theories of heredity, law of recapitulation, etc. This is followed by an account of the early development of mammals, by which the student is led to a consideration of the human embryo. The chapter on the human embryo is supplemented by chapters on the development of the pig, chick and rabbit, and the volume is concluded with an account of the uterus and fetal appendages in man, and directions for laboratory manipulation.

The novel feature in the treatment of the subject, and one that will attract the attention of teachers, is the attempt to describe the anatomy of the more important stages of developing embryos on the basis of a few well-selected sections in the three planes: transverse, sagittal and frontal. Although this method acquaints the student with the structural relations in only a few planes in the embryo body, it must be confessed that Dr. Minot has been unusually successful in selecting the very best sections and in supplementing them with some remarkably clear and beautiful perspective drawings of solid reconstructions. The method here outlined gives evidence of the work of the experienced teacher, and is carried out with such rare insight as to the precise requirements of the case that its success seems assured.

The illustrations, text as well as plates, represent with remarkable fidelity the natural appearances of the objects from which they are taken. Many of them are indeed works of art, and fully equal the best embryological reproductions hitherto published. The letter-press is remarkably clear, and in Dr. Minot's well-known scholarly style. Embryologists are responsible for a fair share of verbal innovations, and Dr. Minot has kept to this tradition by introducing the verb "to microtome." The word is certainly convenient, though possibly "microtomize" might have been more in accordance with etymological usage.

To the teacher of human embryology the volume is full of suggestions, for it is evidently the outcome of long practical experience, and the school that will instil into its students even a small part of the information contained in Dr. Minot's textbook, and give them even part of the training he implies, will do much in advancing to its proper place the somewhat neglected study of human embryology.

A Text-book of Clinical Anatomy. For Students and Practitioners. By Daniel N. Eisendrath, A.B., M.D., Professor of Clinical Anatomy in the Medical Department of the University of Illinois (College of Physicians and Surgeons); Attending Surgeon to the Cook County Hospital, Chicago, etc. Octavo of 515 pages, illustrated with 153 illustrations, a number in colors. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

In his preface the author states that the primary object of his work is to serve as a bridge for both the practitioner and student from descriptive anatomy, as it is usually taught in the first two years of a medical course, to its daily application at the bedside, in the clinic or in the operating room. The term "clinical anatomy" seemed to the author to be the most appropriate one to use to express the larger field which the subject covers. The illustrations, which are very numerous, are for the most part very clear and serviceable, and the majority are original. The book will be found useful by the clinician, whether medical or surgical.

THE BOSTON

Medical and Surgical Journal

THURSDAY, OCTOBER 29, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published a Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered etter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

REPORT OF THE SURGEON-GENERAL OF THE ARMY.

THE annual report of the Surgeon-General of the Army for the year ending June 30, 1903, is before us. The pamphlet, as is usual, contains a very large amount of information on matters of medical interest relating to the army. It is always of interest to the general medical profession to observe how many men appear for appointment in the medical corps of the army. At various times during the last year medical boards for the examination of candidates have been in session in several cities. From the statistics it appears that 176 candidates were examined by these various boards, that 37 were rejected as physically disqualified, that 99 withdrew during the examination or were later rejected, and that but 40 were physically and professionally qualified for appointment in the medical corps.

In spite of the fact that this appears a rather small number of successful candidates, it is shown that the percentage of approved candidates has continued to increase, and this notwithstanding that the high standard of examination has been maintained. It is less encouraging to note that there is a steady loss by resignation of certain of the best-trained young medical officers, for the obvious reason that prospects for advancement are better in civil life than in the army. Surgeon-General O'Reilly believes that, if the medical corps is to be maintained in the highest possible state of efficiency, its functions should be performed by commissioned officers. Civilian physicians under contract are useful and satisfactory so far as strictly professional work is concerned, but their position as officers is wholly anomalous, and should not be further continued to the exclusion of fully commissioned medical officers.

This periodic discussion of the opportunities for medical men in the army, and particularly regarding the social position of contract surgeons, has before been subject of comment in these pages. We are not prepared forthwith even to suggest a remedy for the existing state of affairs, but it is evident to the unprejudiced observer that the position of medical officers, both on its professional and social side, must be made so attractive that not only will the very best men accept the positions offered, but also that they will remain during life in the service. If a certain number of the best of the younger medical men resign from the army, it is sufficient proof that the conditions there are not such as to meet the highest ambition of able professional men. This should in some way be remedied if the medical corps of the army is to maintain the high place in public esteem which it should.

Regarding contract surgeons, it is stated that there were 273 in service at the close of the fiscal year ending June 30, 1902, and that there remained in service June 30, 1903, 229. Few contracts have been made, except with men the character of whose work was known to be of proved value, and by far the larger number of these are on duty in the Philippines. The number now in service will be still further reduced in the near future.

In February, 1901, Congress approved the appointment of thirty contract dental surgeons. By June 30, 1903, the full complement permitted by law was made. The number of officers, enlisted men, nurses and prisoners of the army treated during the year from Jan. 1, 1902, to Dec. 31, 1902, was 16,161, being 20% of the mean strength of the entire army. This fact alone is sufficient to justify and to continue the improvement of this department of the medical work of the army. It has been shown that dental and oral disease among troops is very common, and it is evident that if perfect health is to be maintained, defects in the teeth as they arise should be properly attended to. Measures are being taken to instruct enlisted men as to proper methods of caring for the teeth and mouth, which should do something towards diminishing the number of cases requiring treatment.

In considering the prevalence of special diseases in the army a large amount of space is given to the always interesting subjects of ty-

phoid fever and malaria. The army offers peculiar opportunities for the study of such a disease as typhoid fever, and the report before us is interesting in this connection, since it traces out with a considerable degree of care the source of various epidemics, together with statistics which should be of general medical value. In the discussion of malaria there is also much of interest, and the whole subject is approached from a modern, scientific standpoint with adequate pathological detail. Tuberculosis naturally claims its victims, and it is interesting to note that the troops in the Philippines now show the greatest prevalence of the disease. No cases of pulmonary tuberculosis are now treated at post hospitals in the United States if it is possible to transport them to the general hospital at Fort Bayard, New Mexico. This gives not only the patient himself the best opportunity for recovery, but also frees his companions from the possible danger of contagion.

In general we find this report, as we have previous ones, worthy of serious reading and study. It offers certain statistics regarding disease, particularly in epidemic form, which are difficult to obtain from other sources. The medical problems connected with an army, or with large groups of persons collected under the same hygienic conditions, are far from being solved, and each published report of the work done by our army medical officers tends at least to simplify the problems which it remains for the future to answer completely.

A YEAR'S MEDICAL BOOK PRODUCTION.

In the current number of the *Medical Library and Historical Journal* is an interesting statistical study of the medical book production of one year, the period covered being from Oct. 1, 1902, to Oct. 1, 1903. In compiling these statistics, serial publications of all sorts, including transactions, year books, government reports, etc., together with graduating theses, have been excluded. With these exceptions the list given is practically a complete record of medical books published during that year. The results afford much food for reflection.

It appears that new books published in America number 367; in England, 250; in France, 288; in Germany, 354; with 25 scattering. In addition to these, 382 new editions were published, making a total of 1,666 new books and new editions. The average price of these books was $1.92 a volume, the American books being on an average the most expensive. In percentages it appears that, including new books and new editions, America leads the list with 30%, Germany following closely with 29%.

A further analysis of these statistics demonstrates the fact that America leads the world in the production of medical books, and that half the medical books published in the world are in the English language. That the cost of American and English books is somewhat greater than that of French and German publications is explained by the fact that German and Frnech books are usually published unbound. This estimate of books published, as stated above, does not include the vastly greater number of periodicals. which in one sense rightly belong to a year's medical publications. The journal from which we quote is of the opinion that the economic waste in the production of this amount of medical literature is enormous, but suggests that there seems to be no disposition, either by publisher or writer, to check the output.

Certain it is that the production of medical books, particularly in this country, has been phenomenal within the past year, a condition which we strongly suspect is due as much to the zeal of the various excellent publishing houses as to the enthusiasm of the individual writers. Several publishers in this country have on their list of medical books a fairly complete library, and it is apparently their design to be able to offer the reading public a book on practically every important subject connected with medicine. This means that the publishers take an active interest in the production of books, even going so far at times as to solicit authors to write on certain subjects.

This tendency on the whole we regret. It certainly does not express the highest aim of medical or any other sort of literature. At the same time we are inclined to think that the evils of overproduction of medical books are not really great. Medical publications. like literature of other sorts, soon find their level, and that more are produced than are needed does not necessarily reflect upon the profession as a whole. The competition which such prolific book production entails is at any rate useful and stimulating.

DOWIE IN NEW YORK.

What with the general ridicule of the secular press, and the somewhat ponderous analysis and criticism of the medical journals, Dowie and his cult seem to have accomplished a decidedly in-

creased notoriety in their invasion of New York. If that alone is what the "prophet" has been aiming at he has certainly accomplished his end, and we are inclined to suspect that he has had a certain inward satisfaction at the success of his somewhat unusual methods. No one questions his shrewdness and his knowledge of human nature; his material success sufficiently demonstrates this. Where a sincere religious enthusiast might sway the mob by eloquence or the contagion of personal faith, Dowie draws the attention of a vastly greater number of people by vituperation and general vulgarity. It is hardly necessary, as our contemporary, the *New York Medical Journal*, has done, to demonstrate the fact that he is a false prophet. This fortunately is apparent to all outside his immediate following. What is of very great interest, however, to students of such movements is the extraordinary means he apparently deliberately takes to extend his influence. His apparent failure to arouse the dormant moral sense of his hearers has been his chief success. He has in no way appealed to the mob spirit as ordinarily understood; no one apparently seriously believes in his mission of reform, and, we imagine, exceedingly few have been led to better things by his so-called preaching. The abuse with which he has treated his audiences has naturally been thrown back at him with redoubled vehemence, with the final result that the details of his visit to Boston, for example, are treated with almost the minuteness which was accorded the advent of Prince Henry. No doubt he will return to Zion well pleased with his descent on New York, and with the reception he there received. However that may be, we must put him down as a remarkable man of his kind.

MEDICAL NOTES.

THE TUBERCULOSIS WORK AT SARANAC LAKE. — By invitation of the Henry Phipps Institute for the Treatment and Prevention of Tuberculosis, Dr. E. L. Trudeau delivered an address last Saturday in Philadelphia on the "Development of the Tuberculosis Work at Saranac Lake." The address was followed by a reception.

THE MEMORIAL TO PROFESSOR VIRCHOW. — The German committee appointed to secure a memorial to the late Professor Virchow has issued a circular, under date of Oct. 13, the anniversary of Virchow's birth, in which they acknowledge previous contributions from abroad and at home to the object which they have at heart, and express the hope that still further and larger contributions will be forthcoming that they may be justified in undertaking the erection of the life-size statue, to be placed in an open street of Berlin in the neighborhood of the site of Virchow's scientific activity, as a permanent memorial to this distinguished teacher, investigator and statesman. Contributions can be sent to the banking house of Mendelssohn & Co., Berlin.

AWARD OF A NOBEL PRIZE. — It is reported from London that Professor Finsen of Denmark has been selected as the recipient of the Nobel prize in the section of medicine.

THE ENNO SANDER PRIZE. — The subject of the competition for this prize for 1904 is "The Relation of the Medical Department to the Health of Armies." The essayist receiving the first place will be given a gold medal valued at one hundred dollors; the essayist securing second place becomes a life member in the Association of Military Surgeons. Competition is open to all persons eligible to active or associate membership in the Association of Military Surgeons of the United States. Essays will consist of not less than 10,000 nor more than 12,000 words, exclusive of tables, and must be submitted on or before Sept. 10, 1904. Further information regarding the conditions may be obtained from Dr. James Evelyn Pilcher, Carlisle, Pa.

A NEW MEDICAL JOURNAL. — It is announced that a new journal, to be known as *The Journal of Infectious Diseases*, will begin publication Jan. 1, 1904. The journal is to be published in connection with the Memorial Institute for Infectious Diseases in Chicago, and is to be under the editorship of Drs. Ludvig Hektoen and Edwin O. Jordan. The object is to publish original investigations dealing with infectious disease and to include in its pages only such contributions as bear with reasonable directness upon this general topic. Attention will be given to prompt publication, and numbers will be issued at irregular intervals as material permits. Conditions of publication are such that the permanence of the journal is assured, as well as the adequate presentation of material submitted.

ALVARENGA PRIZE FOR 1903. — The Alvarenga Prize for 1903 has been awarded to Dr. William S. Carter of Galveston, Texas, for his essay entitled "The Relation of the Parathyroids to the Thyroid Glands."

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Oct. 28, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 73, scarlatina 19, typhoid fever 29, measles 74, smallpox 1.

Bequest to a Hospital. — By the will of the late Mary Putnam Ropes of Salem, the Salem, Mass., Hospital receives the sum of $5,000. This bequest, however, will not become available until the death of her sister.

George Haven, M.D. — The Senior Staff of the Boston City Hospital passed the following resolutions at a meeting held Oct. 19:

"The Staff of the Boston City Hospital desires to record its deep regret at the death of Dr. George Haven. Appointed to the Out-Patient Department in 1889 and later to the position of Junior Visiting Physician for Diseases of Women, he served the hospital with ability for fourteen years.

"With a strong and attractive personality he combined the qualities which compel professional success. Tactful, patient and tireless, a good diagnostician, a skillful operator and a wise counsellor, he gave unsparingly to his patients of the best which was in him."

NEW YORK.

Euthanasia. — At the annual banquet of the New York State Medical Association on Oct. 21, one of the speakers, the Rev. Merle St. Clair Wright of the Lenox Avenue Unitarian Church, attracted considerable attention by advocating euthanasia for hopeless sufferers from disease or injury. In the course of his remarks he said: "I appreciate the practical difficulties in the way of the practical application of the doctrine, but it seems to me that it is not beyond the bounds of possibility. Of course it would be necessary to have the advice and approval of men of the highest scientific attainment. The city might be divided into districts, and every application should be considered most carefully, not merely by physicians, but by some eminent clergymen selected for the purpose. And, of course, there should be the consent of relatives and the consent, even the request, of the patient himself. But where all these conditions are fulfilled, and where the prolongation of life is simply the prolongation of hopeless agony, it seems to me that it would be proper that such a patient should quietly, decently, modestly, be allowed to end the sufferings. It seems to me that such a course would be a step forward in civilization and a step further away from barbarism." Other speakers were John S. Wise, Esq., and Dr. Algernon T. Bristow, President of the Medical Society of the State of New York.

Religious Service for Physicians. — On St. Luke's Day, Sunday, Oct. 18, a special religious service for physicians and medical students was held at Calvary Protestant Episcopal Church, and Bishop Potter officiated, assisted by several clergymen. The Scripture lesson, which was read by a medical man, Dr. D. B. St. John Roosa, was the chapter from Ecclesiasticus in the Apochrypha, which contains the well-known passage commencing: "Honor the physician for the need thou hast of him; for the Most High hath created him." On this occasion addresses were made by Bishop Potter and Prof. William H. Thomson.

A Dentist Sues Shah's Brother. — Dr. M. Wagschal, a New York dentist, has commenced proceedings against Prince Zille Sultan, a brother of the Shah of Persia, for a claim which would apparently seem somewhat difficult to realize upon. When in Persia, some time since, he was called upon to operate upon the mouth of this august personage, and the prince was so much pleased with his services that he made a contract with him, according him the privilege of practicing his profession wherever he liked upon the condition that he should attend on the prince whenever the latter had need of him. In consideration of his thus holding himself to come whenever he was summoned, the dentist was to receive a regular salary of 200 toman a year. He states that he was obliged to leave Persia after the assassination of the shah, but has always kept the prince aware of his whereabouts, so that he might be summoned whenever his professional services were required. For a considerable time past, however, the prince has neglected to pay his salary, and now owes him 1,600 toman, or $2,400 in American money. The contract is in Persian and bears the prince's seal, which is described as "resembling a bird's-eye view of a labyrinth, disarranged by an earthquake." This has been placed in the hands of Dr. Wagschal's attorney, who, after getting a judgment in the local courts, proposes to place the matter in charge of the American consul, and, if the latter cannot collect, to submit the claim to the Arbitration Court at the Hague.

Obituary.

IN MEMORIAM — JOSEPH P. OLIVER, M.D.

THE sudden death of Dr. Oliver in Paris, France, Sept. 11, 1903, although not wholly unexpected to those who knew him best, represents to many a loss nearly irreparable. For several years he had suffered from angina pectoris, the attacks of which had gradually increased in frequency and severity. He continued, nevertheless, to care for his patients with such constancy and equanimity that but few were aware that the physician often was more of a sufferer than the one seeking relief.

Dr. Oliver was born in Boston, March 28, 1845. Previous to engaging in the study of medicine he was employed for a few years in an important brokerage office. He soon became convinced that a mercantile career was distasteful to him, and found in the pursuit of medicine abundant opportunities for the use of the talents with which he was exceptionally gifted.

He was graduated from the Harvard Medical School in 1871. Before beginning the practice of medicine in Boston he served for a year as medical house pupil in the Massachusetts General Hospital, and continued his studies for another year in Europe.

Never of robust health, of a sensitive, delicate organization, he was enabled by a fineness of temper and strength of will to endure the stress of a remarkably busy and eventful life without signs of serious illness until nearly the close of his days.

Gentleness of disposition was one of his prominent characteristics, directly inherited from a loving mother, whose life was a constant exemplification of this charming quality. His early family ties were intimately connected with a large and happy family of growing children, to whom he was more brother and friend than uncle. The experience thus acquired was of the greatest value in enabling him to appreciate the child's point of view, and to attain that skill in the treatment of sick children which was one of the corner-stones of his success as family physician. He early became recognized as an authority in the diseases of infancy and of childhood, and was an instructor in the diseases of children at the Harvard Medical School from 1875 to 1884. During this period he served also as physician to the Boston Dispensary and to the Children's Hospital. He remained connected with the latter institution as consulting physician during the rest of his life.

His fondness for family practice, and the increasing demands of an exceptionally large and influential circle of patients, led him to resign the positions of teacher and of visiting hospital physician for the purpose of devoting himself wholly to the interests of his patients. For years it was his custom to spend his summer vacations in Europe, partly for study and partly for rest and recreation. He thus became a well-known visitor to the leading health resorts of the Continent, and acquired a personal knowledge of the advantages claimed for the various spas, of the comparative merits of the local physicians and of the experiences of their patients. In consequence he was widely known as an authority in such matters, and his advice frequently was sought by his colleagues as well as by his patients.

The qualities which especially distinguished Dr. Oliver, in addition to the gentleness of nature and refinement of disposition, were a warmth of sympathy, uniformity of courtesy, and tact beyond reproach. He was more interested in the practice of medicine than in medical science, and the former became to him an art in the use of which he was pre-eminent. "We need," said one of the ablest of the teachers of the Harvard Medical School, "some such man as Dr. Oliver to teach students how to pratice medicine successfully."

Through his skill, sympathy and almost feminine instinct, his opinion and advice were always a comfort and a consolation if not a more enduring relief. He was, above all else, the beloved physician, gratefully remembered by the distressed mother and by the anxious father. He was welcomed with open arms by the younger of his patients, and depended upon for counsel and relief by the busied man of affairs. Among his patients were the leaders in thought and action in the various professions and in mercantile pursuits, but among the many patients in waiting were those less fortunate who always found a friend in deed as well as a physician for their need. His charity, however, was known only to himself and those privileged to receive it.

The indebtedness of physicians to Dr. Oliver for information with regard to subjects in which he was particularly informed already has been stated. A word should be added relative to the especial obligation of a number of his younger colleagues whose ultimate success has been attained in considerable part through the aid and encouragement given them by Dr. Oliver during the early part of their career. It gave him the greatest satisfaction to follow their progress and to realize that his influence had helped in advancing it.

Beloved physician and enduring friend, unselfish in his devotion to others — may he rest in peace.

Miscellany.

WORK OF NEW YORK TENEMENT HOUSE DEPARTMENT.

A STATEMENT in regard to the work of this department recently published by the secretary of the Charity Organization Society is of interest. In it he says: "The Tenement House Department is unique in municipal administration. So far as the interiors of the houses in which the bulk of the people live are concerned, it virtually is the Health Department. Sanitary inspection, the correction of unsanitary conditions and the vacating of buildings unsuit-

able for human habitation devolve upon it. It brings about the improvements in housing conditions upon which result less sickness, a lower death-rate, greater decency and a nearer approach in many other ways to rational family and home life. When the tenement-house law was passed it was predicted that all building of tenement houses in New York would cease because of the radical changes made by the law. After the law had been in operation a short time, it was found that builders were making greater profits under it than they had made under the old law, and some of its bitterest opponents soon became its warmest supporters. . . . The new-law tenements have proved successful from the tenants' point of view because for the first time many tenants have been able to get apartments with light, air and sanitary conveniences. They have been successful from the landlord's point of view because they have been fully occupied from the time of completion at remunerative rents. The whole lower East Side is being rapidly rebuilt with new-law houses. . . . Under the steady pressure of competition, the demands of business resulting in the replacing of some of the worst of the old buildings by warehouses, factories, etc., and the operation of the new law, there will gradually come about a complete transformation in those tenement-house conditions which have so long been the despair of all who knew them. There is an immense contrast between the old-law dumb-bell tenements, with their foul 'air shafts,' and the new-law tenements, with their large, ventilated inner courts. No house that is built under the present law contains any room that is not adequately lighted and ventilated. This is in striking contrast to the old-law houses, in which ten rooms out of each fourteen were almost totally dark and without ventilation. . . . Another indication of the activity of the department is that in the first six months of 1903 fire escapes have been erected on 1,701 tenement houses and 3,312 unsafe and dangerous wooden slat floors removed from fire-escape balconies and replaced by proper iron floors." Speaking in regard to prostitution, which was formerly prevalent in tenement houses, Jacob A. Riis, in an address on "The Battle with the Slums," said: "Those conditions have been swept away through the powers given to the Tenement House Department. The owners know that there is a fine of $1,000 if they permit such conditions, and also that there is a commissioner who will enforce the law."

THE COMMUNITY AND TUBERCULOSIS.

Dr. Beverly Robinson, in an article on the above subject,[1] makes the following statement:

"Finally, the broad statement still remains true, that without a susceptible soil no tuberculosis will develop in the vast majority of cases. Witness a little experience of my own. I served thirteen years in the Out-door Department of the New York Hospital, where I had the class either of heart and lungs or throat and nose. During that time I had three or more assistants at different times, and several students. I or my assistants passed at least two hours three times a week in the room where the patients were examined, treated and prescribed for. In no instance that I recall was any one among my assistants or students (of course including myself) known to have contracted tuberculosis, and certainly in no instance was our attention directed to the room of the New York Hospital as being the source and origin of the disease.

"So far as I know, at no time in the thirteen years referred to above was the room where I examined and worked over my cases ever thoroughly disinfected in accord with the notions that we now possess of the meaning of the term. Of course, patients coughed, expectorated and frequently tuberculous sputa reached the floor, dried up and were wafted freely later to the respiratory tract of us all."

[1] Am. Journ. Med. Sci., October, 1903.

THE FOURTH OF JULY AND TETANUS.

At the twenty-ninth annual session of the Mississippi Valley Medical Association, held at Memphis, Oct. 7–9, the following resolutions were adopted:

"In view of the fact that more than four hundred deaths from tetanus occurred following the 4th of July celebration of 1903, as shown by the statistical report elaborated by Dr. S. C. Stanton of Chicago, and published in the *Journal of the American Medical Association* of Aug. 29, 1903, the great majority of which might have been prevented had proper precautions been taken; therefore,

"*Be it Resolved*, That the conclusions which follow, as offered by Dr. Stanton in a paper presented before the association, at the above meeting, be endorsed as the sense of the association, and further

"*Be it Resolved*, That the secretary be instructed to forward a copy of these resolutions and conclusions to the Medical Press, Associated Press and the secretaries of the several state medical societies, with the request that they publish same and take suitable action thereon.

"(1) Enforcement of existing laws regarding the sale of toy pistols and other dangerous toys.

"(2) Enactment of laws by the nation, states and municipalities prohibiting the manufacture and sale of toy pistols, blank cartridges, dynamite canes and caps, cannon crackers, etc.

"(3) Open treatment of all wounds, however insignificant, in which from the nature or environment there is any risk of tetanus.

"(4) Immediate use of tetanus antitoxin in all cases of Fourth of July wounds, or wounds received in barnyards, gardens or other places where tetanus infection is likely to occur.

"(5) As a forlorn hope, the injection of tetanus antitoxin after tetanus symptoms have appeared."

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, OCT. 17, 1903.

Deaths reported, 2,861; under five years of age, 923; principal infectious diseases (smallpox, measles, scarlet fever, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 744, acute lung diseases 286, consumption 303, scarlet fever 19, whooping cough 14, cerebro-spinal meningitis 7, smallpox 12, erysipelas 8, puerperal fever 9, measles 6, typhoid fever 58, diarrheal diseases 231, diphtheria and croup 94.

From whooping cough, Baltimore 4, Providence 3, Philadelphia 2, New York, Chicago, Pittsburg, Boston, and Chicopee 1 each. From erysipelas, New York 3, Boston 2, Philadelphia, Pittsburg and Newton 1 each. From smallpox, Pittsburg 8, Philadelphia 4. From measles New York and Providence 2 each, Philadelphia and Boston 1 each. From scarlet fever, New York 6, Philadelphia 5, Chicago 3, Boston 2, Baltimore, Pittsburg and New Bedford 1 each.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Oct. 3, the death-rate was 15.3. Deaths reported, 4,424; acute diseases of the respiratory organs (London) 161, whooping cough 38, diphtheria 52, measles 38, smallpox 2, scarlet fever 31.

The death-rate ranged from 6.3 in Handsworth to 25.1 in Newcastle-on-Tyne; London 14.1, West Ham 14 6, Brighton 12.1, Southampton 17.5, Plymouth 15.8, Bristol 13.8, Birmingham 17.7, Leicester 16.8, Nottingham 15.1, Liverpool 17.6, Bolton 15 6, Manchester 19.8, Salford 21.0, Bradford 15.1, Leeds 12.1, Hull 16.9, Cardiff 10.6, Rhondda 13.5, Merthyr Tydfil 22.6, Swansea 20.2.

METEOROLOGICAL RECORD.

For the week ending Oct. 17, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING OCT. 24, 1903.

B. L. WRIGHT, passed assistant surgeon. Commissioned a passed assistant surgeon from March 3, 1903.

F. M. BOGAN, J. H. PAYNE, JR., and J. J. SNYDER, assistant surgeons. Commissioned passed assistant surgeons from June 7, 1903.

DRS. J. MILLER, JR., E. C. TAYLOR, F. E. CAMPBELL, J. E. GILL and I. S. K. REEVES, appointed assistant surgeons from Oct. 12, 1903.

W. S. PUGH, assistant surgeon. Ordered to the Naval Museum of Hygiene and Medical School, Washington.

J. COWAN, pharmacist. Retired from active service, Oct. 19, 1903, under the provision of Sec. 1453, R. S.

RECENT DEATHS.

DR. MAURICE F. PILGRIM, Professor of Psychiatry in the New York Post-Graduate Medical School and a co-editor of the *Journal of Advanced Therapeutics*, died on October 18, of pneumonia, at the age of forty-six.

ROBERT ABERDEIN, M.D., of Syracuse, N. Y., who was for many years one of the most prominent physicians in Central New York, died after a long illness at the Hospital of the Good Shepherd in Syracuse on October 18. He was one of the original Fellows of the New York State Medical Association.

DAVIDSON H. SMITH, M.D. — Much sympathy is felt for Dr. Andrew H. Smith, President of the New York Academy of Medicine, whose only son, Dr. Davidson Heermance Smith, died suddenly at the Post-Graduate Hospital, New York, during a mastoid operation, on October 23. Dr. Davidson Smith, who was in his twenty-ninth year, was graduated from the medical department of Columbia University in 1902, and since then has been engaged in post-graduate work at the New York Post-Graduate Medical School and Hospital. During the past spring he accompanied his father abroad, and he was one of the delegates of the Medical Association of the Greater City of New York to the International Medical Congress at Madrid.

BOOKS AND PAMPHLETS RECEIVED.

Physician's Pocket Account Book. By J. J. Taylor, M.D. Philadelphia: The Medical Council.

Lessons on the Eye for the Use of Undergraduate Students. By Frank L. Henderson, M.D. Third Edition. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

An Atlas of Human Anatomy for Students and Physicians. By Carl Toldt, M.D., assisted by Alois Dalla Rosa, M.D. Translated from the Third German Edition and adapted to English and American and International Terminology, by M. Eden Paul, M.D. (Brux.), M.R.C.S., L.R.C.P. First Section. Illustrated. New York: Rebman Company. 1903.

Annual Report of the Supervising Surgeon-General of the Marine-Hospital Service of the United States for the Fiscal Year 1900.

Annual Report of the Supervising Surgeon-General of the Marine Hospital Service of the United States for the Fiscal Year 1901.

ON GASTRIC TETANY.

BY B. G. A. MOYNIHAN, M.S. (LOND.), F.R.C.S., LEEDS, ENGLAND.

THE occurrence of tetanoid spasms in association with certain diseases of the stomach, though mentioned by Morgagni, was first prominently recorded by Kussmaul in 1869. His observations referred to cases of dilatation of the stomach in which convulsive attacks had been noticed.

It is now generally recognized that tetany is an occasional complication of several diseases implicating the gastro-intestinal tract. There are, however, widely divergent views as to the frequency and as to the seriousness of the disease, and an attempt has been made to limit the term "gastric tetany" to cases in which there are increased mechanical excitability of the muscles, increased mechanical and electrical irritability of the motor and sensory nerves; a profoundly serious constitutional disturbance and often a fatal termination. Indeed it has almost been made a criterion of the disease that it should end fatally. Frankl-Hochwart, for example, in discussing the records of 40 cases, disallows all but 11, and of these 10 terminated fatally. To restrict the term "gastric tetany" to cases of this type seems to me to preclude deliberately a large number of cases presenting similar, though less serious, manifestations, cases precisely similar in kind, though slighter in degree. The distinction between gastric tetany and tetanoid spasms associated with, and dependent upon, gastric dilatation is one which is arbitrary and irrational. It must, I think, be conceded in the future that the term "gastric tetany" shall include all cases of tetany and tetanoid spasms associated with and directly due to diseases of the stomach.

The occurrence of tetany in gastric disease is more common than is generally known. In the slighter degrees the symptoms are often inconspicuous and are in no way associated in the mind of the patient with the more urgent stomach trouble; it is then not until some leading question is put that he will refer to the "cramps" or "tingling" in the extremities.

In the early stages the patient generally complains of a peculiar numbness or prickling or tingling or a feeling of "pins and needles" in the extremities; in the hands more often than in the feet. There may be also a feeling of coldness or heaviness in the limbs; and drowsiness, or a feeling "as if the head were swelling" has been remarked. More than one patient has spoken of a feeling of fatigue, of infinite weariness in the muscles about to be affected.

The formication frequently follows closely upon the act of vomiting, or upon the washing out of a laden stomach. In not a few cases indeed, the first onset of tetany has been observed after the stomach has been emptied of its contents by the stomach tube. In the severer forms, and in almost all the fatal cases, a history is given of severe and uncontrollable vomiting immediately preceding the attack. As the formication increases, a tetanic contraction of the muscles occurs. In the hand the fingers and the thumb are stiff and slightly flexed, the thumb is strongly adducted and the position of the "accoucheur's hand" is reproduced; the hollow of the hand is deepened, and the thenar and hypothenar eminences exaggerated. The wrists are, as a rule, strongly flexed, but may be extended, the forearm is usually flexed upon the arm; but all the muscles of the forearm and upper arm feel tense and rigid in contraction. During a tetanic seizure some alteration of the position of the limb may gradually occur, the wrist may, from a condition of rigid extension, pass into one of flexion, or from one of pronation into supination, or again, slow, writhing movements may be performed. Occasionally, when the patient feels a tonic spasm beginning in the hand, forcible voluntary movements of the fingers will cause the attack to pass away. As a rule the spasms are symmetrical, but, as Albu pointed out, the one side is almost constantly more profoundly affected than the other. The muscles of the feet and legs may be also, though more rarely, affected; the toes are drawn up into the sole, the ankles and the knees are flexed. The muscles of the face and jaws, of the neck and of the abdomen are all involved at times. The facial exppression is greatly altered, a frowning, anxious or "snarling" appearance being remarked. The muscles of the eyeball are not seldom affected and the sight may be lost for a time; the patient calls out that he "cannot see," or that he is blind. In one of Trousseau's cases the sight did not return for three days. During the paroxysm the patient may mutter or shout unintelligibly, almost as if in delirium; words and phrases are run together unmeaningly. In all the well-marked attacks, the signs of Trousseau, Chvostek, Erb and Hofmann are present.

Trousseau's symptom is described as follows: "So long as the attack is not over, the paroxysms may be produced at will. This is effected by simply compressing the affected parts, either in the direction of their principal nerve trunks, or over their blood vessels, so as to impede the venous or arterial circulation."

Chvostek's symptom is shown by the very great increase in the mechanical excitability of the motor nerves of the part affected; a facial spasm, for example, being produced by tapping over the facial nerve near its exit from the stylomastoid foramen.

Erb's symptom is shown by the great increase in the electric irritability of the nerves and muscles, especially to anodal stimulation.

Hofmann's symptom has reference to the heightened excitability of the sensory nerves, the slightest pressure on which may cause paresthesia in the region of distribution.

In some cases of gastric tetany, but more especially in one case in an old man who had gastric dilatation, the result of duodenal ulcer, I

have noticed during the tetanic seizure a dusky lividity of the parts involved. The face and neck look leaden and suffused, and the forearms and arms, swollen and turgid, have the same appearance as would be produced by the light application of a tourniquet.

As the spasm passes off a return of the tingling in the hands and feet is often noticed, and the patient will rub the hands together, or rub the parts against the bedclothes to obtain relief.

I have almost always found that the agony of the spasm may be relieved by forcibly bending the fingers, flexing or extending the wrist or forearms, or by reproducing passively those movements which would be caused by the active contraction of the muscles involved. Though the first passive movement will often cause an excruciating pain, yet a gentle persistence in the act will cause the spasm gradually to resolve, and will afford the patient great relief.

Intermissions during an attack are often observed. A seizure in which the wrists are flexed may slowly subside, to be presently followed by one in which the wrists are extended. And so the posture of the limbs may vary from time to time. The muscles of the abdomen are affected in the severer cases, the abdominal wall feeling hard, tense and absolutely unyielding.

The general effect produced upon the patient by an attack varies greatly according to the severity and the duration of a seizure. In many cases the tingling or numbness, though frequently noticed, is nothing more than an unpleasant sensation, whose significance is never appreciated. Cramps in the extremities, noticed from time to time soon after the patient gets to bed, are not attributed to their real cause until the surgeon makes pointed inquiry as to their existence. When, however, there is a wide involvement of muscles, and especially when the attack is unduly prolonged, the physical suffering is intense, and the most profound prostration may be witnessed. The pulse at the wrist may be quite imperceptible though the tensely contracted vessel can be rolled beneath the finger. Consciousness may be lost for a time, or the patient's mental balance gravely disturbed by the intensity of his suffering. A severe and prolonged seizure of gastric tetany is, then, almost as serious an ordeal as any patient may experience and live. It is these severer cases which furnish the large mortality recorded by Frankl-Hochwart, Müller and others.

Theories as to the causation. — Three chief theories have been put forward to explain the occurrence of gastric tetany:

(1) Kussmaul, to whom we owe the first description of the disease, attributed the tetany to the general desiccation of the tissues of the body. He considered that the loss of fluid to the body was occasioned in part by the copious and frequent vomiting, and in part by the absence of adequate absorption of fluid from the alimentary canal. Though Kussmaul himself subsequently disclaimed this theory, there have been several who have accepted it, or have thought that the deprivation of fluid might be one among several causative factors. Thus Fleiner[1] states that there is some evidence of inspissation of the blood, and that a fall of blood pressure is probable, and Jürgensen[2] gives support to the theory. Albu thinks, also, that the loss of fluid, if not the final or sole cause, is probably an important predisposing condition. In one case, related by Blazicek,[3] investigation failed to show any loss of fluid to the blood. With few exceptions this theory has now been abandoned by all observers.

(2) Germain-Seé, Berlizheimer and others have suggested that the tetanic spasms are due to a reflex action aroused by the stimulation of the sensory nerves of the stomach. The frequency with which the seizure is immediately preceded by an act of vomiting, or by the passage of a stomach tube, and the fact that a spasm can be elicited by flicking or percussing the stomach, have each lent some support to this reflex theory. It is indeed not to be denied that, whatever may be the ultimate cause making possible the tetanic condition, the stimulus necessary to start the seizure may be derived reflexly from the gastric mucosa. Albu quotes the partly analogous cases of tetanus, and of strychnine poisoning in the frog, in both of which toxic conditions a convulsion is instantly caused by the slightest peripheral irritation. Though this theory has been practically discarded by recent writers, it is, in my judgment, one that we cannot afford wholly to ignore.

(3) The third theory is the theory of autointoxication. It is one that has received the weightiest measure of support from recent authorities, and is that which is most in accordance with the facts. The poison or poisons are generated in the stagnant and putrefying contents of a dilated stomach. Bouveret and Devic separated from the stomach contents of a patient with hyperchlorhydria and gastric retention a poison soluble in alcohol, which produced convulsions in animals. In their opinion hyperacidity is a condition to which considerable importance should be attached. The frequency of its occurrence is attested by the fact that in many of the records it is especially observed that the vomited matters were intensely acid or sour. If this theory of auto-intoxication were correct, it would naturally be expected that the injection of the untreated stomach-contents into animals would produce some convulsive seizures resembling those occurring in man. All such experiments have, however, entirely failed. Carnegie Dickson, who has very fully and very ably recorded a most interesting case of gastric tetany, quotes Müller, von Jaksch, Berlizheimer, Blazicek, Landsteiner, Gumprecht and Albu as all having failed to obtain results. In Carnegie Dickson's case no results were obtained from a series of inoculations into rabbits and guinea pigs. Subcutaneous injections were made of the following solutions:

[1] Münch. med. Woch., March 10, 1903, No. 10.
[2] Deut. Archiv. f. klin. Med., 1898.
[3] Wien. med. Woch., 1894.

(1) Filtrate of unaltered stomach-contents.

(2) Filtrate of stomach-contents evaporated to dryness in vacuo or a strong sulphuric acid at a temperature of 40° C. and extracted with normal saline solution.

(3) Filtrate of stomach contents evaporated as in No. 2, extracted with alcohol; again evaporated to dryness and then extracted with normal saline solution.

No result whatever, either of a paralytic or of a convulsive nature, followed these inoculations, though none were made by the intravenous method recommended by Bouveret and Devic. The auto-intoxication theory, therefore, though plausible and attractive, lacks any proof from the experimental side.

It is possible that in the second and third theories jointly, the true solution may be found. A poison formed in the stagnant contents of the dilated stomach may be absorbed, and both invoke the tetanoid convulsion and make more responsive to peripheral irritation the nerve centers in the brain and spinal cord. It is worthy of emphasis that in many instances an excess of free hydrochloric acid has been present in the stomach contents. To this, as already mentioned, Bouveret and Devic attach considerable importance as a factor in the etiology. Gumprecht and many others have found this condition of persisting hyperchlorhydria, but Blazicek, in one case, was unable to discover any trace of the free acid.

The relationship which may exist between gastric tetany and the condition of the kidneys is in need of further investigation. In many of the recorded cases albuminuria has been present; in some of these no naked-eye existence of kidney disease has been obtained at the autopsy, in others advanced chronic nephritis has been found. If the tetany be due to auto-intoxication, it is possible that the elimination of the toxin may have a damaging effect upon the kidney and be the cause of an inflammatory change. Hemmeter has recorded three cases of nephritis which he thought owed their origin to auto-intoxication. The single case of albuminuria in gastric tetany that I have had under my own care was in the person of an old alcoholic.

Pathology. — In almost all the recorded cases of gastric tetany, dilatation of the stomach has been a pronounced feature. Indeed, only one authority, Albu, has admitted the existence of tetany without dilatation. The dilatation is due to stenosis at or near the pylorus, and is associated with thickening and muscular hypertrophy of the stomach walls. Carnegie Dickson observed in his case that in the height of the seizure, the size of the stomach was greatly increased. As a rule the peristaltic waves can be seen passing across the stomach, and Mayo Robson has observed in one of his cases that "the exacerbations of the tetanic state were always associated with a painful contraction of the stomach, and that when the wave of contraction had reached the pylorus, the latter, which was previously incapable of being felt, formed a distinct hard tumor. The abdominal pain then became very intense, and the tetanic cramps in other muscles came on, or, if already present, became intensified." The ulcer at the pylorus may extend into the duodenum, or be associated with separate duodenal ulcers (as recorded by Loeb, Neumann and others), or duodenal ulcer may alone be found (as recorded by Bamberger, Renvers, Dujardin-Beaumetz and others). In Blazicek's case the gastric dilatation was due to the pressure of an enlarged stone — containing gall bladder upon the duodenum. Berlizheimer assigned the dilatation in his patient to the pressure of a pancreatic cyst on the duedonum. In one case related by Muller tetany occurred in connection with an hour-glass stomach. In fewer instances the pyloric obstruction may be caused by malignant disease, as recorded by Trevelyan and others, and in fatal cases a condition of "ulcus carcinomatosum" has been found by Bouveret and Devic and Riegel. In Trevelyan's first case malignant disease of the duodenum was found. In three cases out of a total of five under my own care submitted to operation, duodenal ulcer, associated in all with gastric ulcer, was found. In one of these there was well-marked chronic pancreatitis. An examination of the recorded cases has certainly seemed to show a large proportion of instances of duodenal ulceration.

The conditions most frequently found associated with gastric tetany are pyloric stenosis, dilatation and hypertrophy of the stomach, and enduring hyperchlorhydria. The stenosis is due to the partial or complete healing of a chronic ulcer of the stomach or duodenum. Of the existence of this ulcer there is ample evidence in the history of prolonged indigestion, vomiting and other characteristic symptoms.

Treatment and prognosis. — The medical treatment of gastric tetany consists in frequent and thorough lavage, rigid dieting and the administration during the height of an attack of sedatives, bromides of potassium or ammonium, or in the severer crises of morphine hypodermically.

It has been said, and with some show of reason, that the washing out of the stomach excites the occurrence of tetany. The lavage is distinctly teasing and irritating, and if the cleansing of the stomach be inadequately done an ample quantity of putrid fluid may be left to provide a toxin for absorption — absorption which is rendered easier by the washing away of mucus from the lining of the stomach. But the lavage — and the point needs emphasis — should be very thoroughly done, and the surgeon must not desist until the fluid returns absolutely clean. In one patient of my own no less than forty quarts of fluid were used before the return water was clear, and the washing-out took sixty-five minutes. The process of gastric lavage is too often performed in a hasty and very perfunctory fashion. But carefully and patiently done it cannot be in itself the cause of gastric tetany. As Clifford Allbutt says, "Careful washing should rather cleanse and prevent evil, than be itself the cause

of tetany and convulsions." Carnegie Dickson states that in the case related by him the feeling of gastric discomfort and the tendency to vomiting were considerably allayed by the following method, which Professor Greenfield has for several years adopted with very marked benefit in many cases of gastric dilatation: After washing out the stomach with a solution of phosphate of soda, and previously, if necessary, with weak Condy's fluid or boric acid solution, a certain quantity, say ten ounces, of boiled milk containing sodium phosphate in the proportion of a drachm to the half-pint is left in the stomach diluted with hot water. Intravenous infusion of saline fluid may be adopted or copious hot water enemata may be given. The final and the appropriate treatment in all cases of gastric tetany should, however, be surgical. From what has been said as to the pathology of the condition it is clear that in almost all cases there is a grave mechanical obstacle to the onward passage of the food. It is this obstacle which causes the dilatation and the hypertrophy of the stomach. To relieve this obstruction and to do away with the stagnation of the stomach contents, surgical measures are necessary. In simple cases gastro-enterostomy will be the method of choice. In malignant cases a partial gastrectomy or gastro-enterostomy as circumstances dictate. In hour-glass stomach, gastro-gastrostomy combined with gastro-enterostomy performed in the distal pouch will, as a rule, be the suitable operation. Death occurring as the result of gastric tetany may occur in the first seizure or after a long series of attacks. Marten's case terminated fatally in the first attack, four hours after its onset. Trevelyan's patient, who had carcinoma of the duodenum, was first attacked with tetany on the morning of July 8, 1898, and died at 2 P.M. the same day. In other cases, as in Kussmaul's and in Carnegie Dickson's, there may be intervals of perfect health between severe attacks.

The records given by many writers show that gastric tetany is an extremely serious and often fatal disease. Thus in 11 cases accepted by Frankl-Hochwart as genuine, 10 died; Bouveret and Devic record 18 deaths in 23 cases; Albu, 31 deaths in 40 cases; Riegel, 16 deaths in 27. But almost without exception, such cases are of old standing. The chronic gastric ulcer, the stenosis which it causes, the dilated and hypertrophied stomach, have all been sources of troubles for months or for many years. It is only in the late stages of such cases that severe gastric tetany is seen. And such late stages are preventable. By treating all such cases surgically, and there is no other rational treatment, gastric tetany of the lethal type will soon be a forgotten disease. Even the slighter manifestations which I have mentioned, prickling, tingling or numbness of the hands, occasional and transient cramps in the muscles of the extremities, — even these are only seen in cases of long standing. The earlier adoption of surgical measures in these disabling conditions of the stomach, conditions in which there is grave mechanical impediment to the free working of the organ, will banish altogether that class of patient which furnishes us with the last desperate forms of gastric tetany.

A STUDY OF PATHOLOGICAL FERMENTATION IN THE STOMACH.[1]

BY HENRY F. HEWES, M.D., BOSTON,

Physician to Out-Patients at the Massachusetts General Hospital; Instructor in Chemistry at the Medical School of Harvard University.

PATHOLOGICAL fermentation in the body produced through the agency of bacteria and other lower organisms introduced from without is today established as one of the most fundamental and fruitful sources of the various diseased conditions to which the flesh is heir.

The process has various manifestations and occurs in various localities in the body. It is a chief causal factor of the conditions and symptoms found in the so-called infectious diseases. It occurs in abscess formation and so-called septic infection generally. It is a prominent feature in the disturbances of the alimentary tract.

Whenever and however it occurs, its manifestation and action may be both local, causing disturbance of the part where the process is located, and general, causing systemic disturbance from the absorption of the pathological products due to its existence. We thus have to look to it as an element or associate in a great variety of diseased conditions and the study of the process, both generally and specially, is most essential and practical for the understanding of medicine.

I have been for some time investigating these processes of pathological fermentation in one principal locality of their occurrences in the body, the alimentary tract. And I wish to report to you to-night the results of a study of this subject in a very interesting case of gastro-enteric disease which I saw at this hospital. The case was one of gastrectasis due to obstruction from an ulcer of the pylorus and upper duodenum, and one of its chief manifestations in its symptoms and clinical findings was an excessive pathological fermentation in the stomach.

The history of the case was as follows:

James Dwyer, aged forty-six. Foundryman.

Up to a year ago the patient was perfectly well. At this time his wife was ill with a fatal

[1] Presented at the Massachusetts Hospital Clinical Meeting April 10, 1903.

illness and he was up all night with her, besides working all day, for three months. Towards the end of this vigil he began to note distress in his stomach and eructations of gas, the trouble occurring most frequently at ten or eleven o'clock at night, five hours or so after his evening meal. As time went on this trouble increased. Finally he came to have regular spells of severe pain in the epigastrium associated with eructation, regurgitation, waterbrash and finally vomiting, occurring each night. Vomited once or twice in the night, often a quart or more at a time. Vomitus was very acid. There was never blood. The vomiting gave relief of pain until the next night. During the day had some eructation and occasional regurgitation of very acid stuff, but no special distress. There was loss of twelve pounds' weight in six months.

The patient came to me in the morning, having eaten nothing since 6 P.M. on the previous day. He had vomited once in the night.

At this time 1800 cc. of contents were expressed from the stomach. With inflation the lower border of the stomach was four inches below the umbilicus, upper limit normal. There was a suggestion of thickening of the stomach or intestinal wall in the region of the pylorus. The stomach held 2500 cc. of water without difficulty. The blood and urine were practically normal and there were no other evidences of disease about the case.

The record of the physical and chemical examination of the contents was as follows:

Quantity 1800 cc.

Upon standing, contents separated into three layers and bubbles of gas could be seen rising from lower portion.

Odor, sour — the odor of acetic acid and butyric acid in gastric contents.

Reaction acid (litmus).

Free acid present (congo red).

Free HCl absent (Gunzburg reagent).

Combined HCl present (Ewald Sjoqvist test).

Lactic acid present (Fe_2Cl_6 test in ether extract of residue from distillation).

Butyric acid present (ethyl ester in distillate).

Acetic acid present (Ethyl ester in distillate test).

Total acidity = 0.43%.

Total free organic acids = 0.14%.

Total combined acids = 0.28%.

Pepsin present.

Rennin present.

The contents gave the reaction for alcohol (iodoform test; bichromate test).

The gas evolved by the contents was found to be principally carbon dioxide. The quantity of gas evolution was measured by placing contents in one of these gas tubes at 37° C. It was found that 100 cc. of contents formed 30-40 cc. of gas in twenty-four hours.

Specimens of contents removed on several occasions after the patient had, first; complete lavage of the stomach, then regular feeding for a day upon selected food which contained traces only of organic acids or their salts, then a twelve-hour fast showed a similar character to that of which the analysis is given.

The patient was placed upon a suitable method of diet with lavage every second day. From the institution of the treatment vomiting and distress ceased. After a short period the patient was able to keep at his work and feel perfectly well by keeping upon this system of diet and using the stomach tube once a week at the most. Finally the use of the tube was entirely done away with. In six months the patient had gained twenty-five pounds and was as well as ever.

Eight months from the time of the first visit the patient was taken suddenly in the afternoon with dizziness followed by extreme weakness. An hour later there was a copious movement of the bowels, which was black and tarry in appearance (patient's statement). For three days following there were one or two similar movements. Patient was extremely restless and very weak. On the fourth day vomited some blood. The next day he came to my office with the above history.

At this time was very pale and walked unsteadily.

Pulse 110, temperature 99° F.

Blood showed hemoglobin 25%.

Red count, 1,400,000 per cmm.

White count, 15,000 per cmm.

Stained specimens showed marked anemia, with a few blasts present. A diagnosis of ulcer of the duodenum was made and the patient sent to the hospital. At ten o'clock that night he had a large hemorrhage indicated by copious discharge from the bowels of a tarry nature, containing blood, and by a drop in the hemoglobin to 10% and in the number of red corpuscles to 800,000. On the next day the patient, then unconscious, was operated upon by Dr. Harrington. A large bleeding ulcer of the duodenum with evidence of present or previous ulcer growth extending from the pylorus an inch and a half along the duodenal wall was found. Patient died six hours later. The autopsy confirmed the previous findings.[2]

The element of this case which has been the subject of this special investigation is the pathological fermentation which was associated with it.

The evidences of this fermentation, found both in the symptoms and in the results of the physical and chemical examination, were first, the excessive formation of gas demonstrated by the experimental observations described and evidenced by the symptoms of swelling of the stomach and excessive eructation.

Second, the presence in the gastric contents of certain chemical substances not found in the normal stomach, or quantities of these substances greatly in excess of those which are found in normal conditions. The most prominent and important of these substances were alcohol and these organic acids — lactic acid, butyric acid and acetic acid. The presence of these compounds

[2] See Mass. Gen. Hospital autopsy reports, 1902.

was evidenced by the results of the chemical analysis.

Third, the presence in the sediment of excessive numbers of bacteria, including sarcinæ, and of the yeast fungus.

The contents removed from the normal stomach give practically no gas formation in experimental tests such as those used to test this matter in the case in hand.

They show no test for alcohol upon removal from the stomach and give no test for lactic, butyric or acetic acid unless the food contain these substances or the salts of the acids, in which case the quantity present is never in excess of the food content.

The sediment contains very few bacteria or yeast fungi and almost never sarcinæ. Here is a tube of normal contents arranged to show gas formation, which has been kept at 37° C. for forty-eight hours. As you see, there is practically no evidence of gas formation as compared with the tube from the contents of our case, where a half tube full of gas has formed in twenty-four hours.

Having established the fact of fermentation and the definite products in this case, I proceeded to make a further investigation to determine, if possible, by experimental methods the genesis and controlling conditions of this pathological fermentation.

The first step in the investigation consisted of a biological study of the fresh contents to determine what active forms of organized ferments which might serve as causes of fermentation were present.

Gelatin plate cultures were taken from several specimens of the fresh contents removed at various times from the stomach after a twelve hours' fast.

In the first attempt numerous colonies of various appearances were obtained. A careful examination of all these colonies showed that they represented four (4) distinct types of bacteria, and four only.

These four types were:

(1) A coccus growing in small white colonies on the gelatin.

(2) A short bacillus growing in small white colonies and showing in instances in the growth in gelatin evidence of gas formation.

(3) A long bacillus growing in large creamy white colonies and liquefying the gelatin.

(4) An organism growing in white colonies and answering to the morphological characteristics of the sarcinæ ventriculi. The sarcinæ were obtained only once. This was in the culture made from the first specimen of contents obtained.

Several plate cultures taken from this same contents showed in all instances one or more of these four respective organisms and in no instance any other form of organism.

Here is a plate culture preserved by formalin representing a first dilution of an original gelatin culture from the contents, containing three of the above forms of bacteria,— the coccus, the short bacillus and the long bacillus. You can see the evidences of gas formation about some colonies, those of the short bacillus.

I have here also agar culture of each of the four types of bacteria found, isolated on the agar in pure culture: (1) the coccus; (2) the short bacillus; (3) the long bacillus; (4) the sarcinæ. Here is also a pure culture of the short bacillus in gelatin, showing the abundant gas formation about the colonies.

From these culture experiments, then, we have obtained evidence of the existence of at least four forms of organized ferment in our contents.

That the number of forms of organism obtained on gelatin growths was limited to four in all cases was a surprise, for it has been proven that the mouth in normal conditions contains a large number of organisms which are swallowed with the food, many if not all of which grow on gelatin. Also the food itself contains many bacteria, and many forms of bacteria introduced from these sources and in this manner have been isolated from the normal stomach.[3]

Miller has isolated seventeen forms of bacteria from the mouth. Abelous[4] has isolated sixteen forms of bacteria from the stomach in a set of observations. A few of these were found present in the stomach of a man killed at the height of digestion. None were pathogenic. All sixteen forms produced some fermentation of food in vitro. Most of them caused no appreciable effect of this kind in normal gastric contents. At first their action was very slow, taking several days to be appreciable and not to be compared with the energetic action of our pathological ferments in this case.

It is to be presumed that the failure of many of such forms as are found in the normal stomach contents to grow in this case and the reduction of the active bacterial products to four forms, was due to the inhibiting effect of the products of the fermentation upon bacterial growth. Also there were doubtless organisms present here which did not grow on gelatin. Thus the yeast fungus seen in such growth in the sediment does not grow on this medium. From its appearance in the sediment, however, it gave every evidence of being or having recently been in active growth in the contents.[5]

The capacity of yeast to cause fermentation of sugar is long established since the original observations of Cagniard-Latour.[6] The capacity of yeast to perform this fermentation in the human stomach is proven. Kuhn isolated and grew yeast from the stomach and produced by its action alcohol and gas in carbohydrate solutions in vitro.

Having determined the presence of these possible causes of our fermentation, the next step in the investigation was to associate them definitely in the chain of cause and effect with this fermentation by experimental demonstrations. To accomplish this fact, mixtures of food substances

[3] Straus: Ztschr. f. klin. Med., xxvii, 1895.
[4] Abelous: Soc. de Biologie, Feb. 9, 1889.
[5] Ztschr. f. klin. Med., Nos. 49 and 50, 1892.
[6] L'Institute, 1835, iii, 150.

similar in character to those present in the contents of the case were made up, sterilized and inoculated with the various forms of organism isolated. This experimental work was done with the three forms of bacteria which were present on repeated culture experiments.[7]

The food mixtures used were solutions of glucose and peptone. The test solutions, having been sterilized and found by tests to be free from alcohol and organic acid, were inoculated and placed in gas test tube at 37° C. and tested at various periods up to forty-eight hours to detect the evidences of fermentation, gas formation, or alcohol or organic acids.

As a result of these experiments it was found that each of the three forms of organism isolated possessed the capacity to produce in the food mixture some decomposition products similar in nature to those abnormal products found in the fermenting contents from which the bacteria were isolated.

The action of the several forms of organisms showed considerable variety.

All three formed gas (CO_2) and alcohol at some stage of the fermentation and all formed some kind of organic acid.

The specific action of each organism may be seen from the accompanying table. As you can see from this, when the products of each organism are combined we have the whole collection of abnormal organic products which are found in our contents.

TABLE.

1. Coccus in 100 c.c. neutral carbohydrate-proteid solution for 24 hours produced — gas 50 cc.
   Alcohol.
   Lactic acid (a trace).
   Acetic acid.
   Total acidity = 44 cc. decinormal soda in 100 c.c.
   Total free (organic) acid = 14 c.c. decinormal soda in 100 c.c.
2. Short bacillus in 100 c.c. solution for 24 hours produced — gas 40 cc.
   Alcohol.
   Butyric acid.
   Acetic acid.
   No lactic acid.
   Total acidity =30 cc. decinormal soda in 100 cc.
   Total free acid = 10 cc. decinormal soda in 100 cc.
3. Long bacillus in 100 cc. solution for 24 hours, produced — gas 20 cc.
   Alcohol.
   Lactic acid (much).
   Acetic acid.
   Total acidity = 40 cc. decinormal soda in 100 cc.
   Total free acid = 16 cc. decinormal soda in 100 cc.

Control solutions of the food mixtures showed none of these abnormal products and no gas formation under the same conditions.

We have thus in our case determined a genesis of the pathological fermentation present by the experimental method. That is, we have, to use the traditional phraseology, isolated certain definite organisms repeatedly from a contents, grown these in pure culture, and produced by their inoculation to sterilized food mixtures an infection similar in character and producing similar fermentation products to that found in our original case.

Also we have determined the special ferment action of each of the three organisms present.

Of course, it does not follow from this work that the organisms isolated are the whole cause of the fermentation in our case. Also, in this work the complete fermentation process has not been investigated. We simply determined the fermentation by the presence of certain abnormal decomposition products and reproduced the fermentation which will form these products.

This work is sufficient, however, to serve as an experimental demonstration of pathological fermentation in the body and to give us a fundamental understanding of the process, as it was produced in our case, serviceable for clinical instruction, and it was to obtain a simple scheme of demonstration of this subject for use in medical instruction that this work was undertaken.

Further investigation of the subject — consisting of the identification and study of the properties of the bacterial ferments isolated in this case; their action in varying strengths of free hydrochloric acid; their growth and products in various food substances, as pure carbohydrate or proteid solution; and the influence of various so-called disinfecting drugs upon their activity — will be reported in a late article.

I wish to express my thanks to Prof. Harold C. Ernst for assistance in this work, a part of which was done in his laboratory.

[7] Sarcinæ were obtained but once in culture. They were present in numbers in the sediment in the first specimen of contents only. The ferment action of this form of bacteria has been studied by Coyon (Contribution to the Study of the Sarcinæ Ventriculæ, Compt. rend. de la Soc. de Biol., Dec., 16, 1899). He found that sarcinæ in pure solutions of peptone formed acetic and formic acids and some butyric acid. In carbohydrate solution they formed acetic, formic and lactic acids.

INTERNAL MEDICINE, TO WHAT EXTENT REQUIRED OR ELECTIVE IN THE MEDICAL COURSE?[1]

BY S. G. BONNEY, A.M., M.D., DENVER, COL.,

Dean and Professor of Medicine, Denver and Gross College of Medicine.

In order to more clearly define the applicability of the elective system to internal medicine it is almost necessary to consider first its general relation to a medical course and to review briefly the trend of medical educative thought.

The sociologic and economic conditions of the country do not at present, as formerly, require a large number of physicians to supply from time to time the needs of the smaller communities. There is on the contrary an appeal for relief from the incubus of the insufficiently prepared practitioner, in order that more encouraging inducements may be offered to the type of the educated physician.

From a strictly business standpoint these inducements to spend years of preparatory study are now becoming not particularly attractive to those contemplating general medicine in view of the active competition incident to the overcrowding of the profession. Failure to remain

[1] Read before the American Academy of Medicine in Washington, May 12, 1903.

in medical practice is said to attend the efforts of nearly one-third of all graduates in recent years.

Despite the recent advances in medical teaching, consisting in part of more rigid requirements for admission, the lengthening of the period of study and the enlargement of the curriculum, all tending to impose legitimate restrictions upon the number of students, and notwithstanding, also, the well-known uncertainties of success in practice, there is, nevertheless, no material diminution in the number of young men willing and anxious to undertake the laborious task of systematic medical study.

This implies a certain change in the motives and aspirations of the more liberally educated medical students of to-day, some of whom are induced to begin the study of the purely scientific aspect of medicine, with its opportunities for original research and investigation, while others are attracted early to the possible attainment of special knowledge and skill in certain departments, with the hope of subsequent contribution to the science of medicine, rather than the acquirement of a large general practice.

These natural tendencies in students have been further influenced by necessary and progressive changes in the course of medical instruction.

As a result of the greatly enlarged curriculum and the enormous increase of medical knowledge, the student is brought to a realization in the beginning of his career that he will be utterly unable to acquire even a superficial knowledge of all branches, and that he may hope to attain a degree of proficiency only in a small proportional part of his profession.

The inevitable result is an appreciation of the necessity for specialization in some form. In spite of the admitted objections to the greater development of specialism, the fact remains that it is distinctly in accord with popular and professional demand. A high degree of special attainment based upon broad fundamental knowledge has ever been the chief factor in advancing the science and art of medicine. Save in the remotely settled districts, the day of the general practitioner in his ordinary acceptance is nearly at an end, and in his place are to be found men, who, if they are less courageous, less self-reliant than the time-honored country doctor, are, nevertheless, more cognizant of their limitations.

To encourage intelligent specialism, to afford an opportunity to excel in certain departments, and at the same time to guard against superficial and disproportionate work, constitutes an important province of the modern medical school.

To this end a full interpretation of the elective system has been offered, not with a view of aiding premature specialization, but more to permit an early beginning of a thorough preliminary preparation leading to subsequent advanced work either in internal medicine or other specialties.

The elective system may be defined as that method of instruction which permits the exercise, under a supposedly wise direction, of the student's choice of study according to his conception of his peculiar needs and purposes and his inherent adaptability for certain work. That a flexible curriculum is correct in principle and has been shown by experience to be a distinct advance in colleges of liberal arts and preparatory schools, no observer of pedagogic conditions will deny. This, however, in view of the greater responsibility involved in medicine, does not necessarily constitute evidence in favor of its general adoption as a system of medical education.

It may be said to possess definite advantages in certain institutions, and be capable therein of its most complete and satisfactory elaboration, according to the size, facilities and purposes of the school. Manifestly precisely similar conditions may not be in force in other colleges, and an equal observance, therefore, of the elective system rendered impractical, or if attempted to the same degree productive only of harm.

It follows that the extent of the applicability of the system to any school must vary according to the peculiar scope and working ideals of the institution. It is recognized that the purposes of some of the modern university medical schools are much more comprehensive than merely to educate doctors. The preparation and training of practical physicians, as exemplified in undergraduate instruction, forms but a single integral part of their real mission or ambition. Their energies are devoted in part to the rendering of post-graduate instruction, the pursuit of original research on the part of the professors and selected students, the investigation of new discoveries and new phases of medical learning and to the possible enlargement of the practical scope of pure science. It is in these institutions that the elective system is of the utmost advantage in offering opportunity for the attainment of the highest degree of technical learning, and is to be commended in its fullest interpretation, if practised under the restraining, governing and advisory counsel of the proper officials of the faculty. Such institutions are scarcely to be subjected, however, to the same principles of thought accorded to the medical school proper, whose sole object is to shape the early education of working doctors. Even in such institutions the elective system may be said to present certain features of advantage if applied with discrimination to the latter portion of the course, presupposing a thorough preparation in the required fundamental studies, and subject in each instance to the well-considered approval of the medical authorities. The degree to which such satisfying result may obtain must vary according to the peculiar conditions in force in each institution, thus rendering any school in this respect a law unto itself. The size of the school, the number of students, the amount of endowment and the proportionment of electives, afford no reliable measure of its real efficiency. A small school is not necessarily of low standard, provided it possesses ample laboratory and hos-

pital facilities, and embraces in its faculty men of sufficient preliminary education, of ripe experience and possessed of proper enthusiasm and high ideals. In like manner it is not simply the method or system of instruction, elective, required, didactic or clinical, that determines in full the career or usefulness of the student, as much as the manner in which the subject is interpreted and the degree of inspiration awakened by the instructor.

The practical utility of the elective system varies not only with reference to the institution where it is employed, but also according to the extent of its application to the various departments. As practiced in a few institutions it permits not only the choice of the subject, but of the instructor as well, and the manner in which instruction shall be given.

What are some of its recognized general advantages in a well-balanced and duly proportioned course of instruction?

I. The adaptability of the particular study to the peculiar requirements and mental receptivity of the student based on the known divergence in character and degree of individual capacity.

II. The consequent increased interest on the part of the student in not being compelled to devote valuable time to some irrelevant, and to him apparently unimportant branch.

III. The greater degree of technical efficiency attained by those anticipating a specialty through the additional time afforded for such preliminary preparation.

IV. The improved opportunities for observation and study afforded to those contemplating general medicine in being relieved of too rigid requirements in a few of the distinctly refined specialties.

V. The shortening of the period of time demanded in preparation for practical work, this not to imply, however, the completion of special education in a four years' course.

VI. The inspiration and incentive derived on the part of the instructor, from the fact that his students are at once earnest and enthusiastic, and that he himself is given immediate active recognition.

VII. The opportunity afforded in the larger institutions for the more intimate contact of instructor and student. This closer association and exchange of thought incident to the smaller colleges is of great utility in the imparting of knowledge.

These general advantages of the elective system, though scarcely worthy of detailed elaboration, may obtain in all instances if under the actual and not nominal supervision of a board of control.

There are objections, however, to be made and answered as to the practical employment of the system. The basis of these objections is found to exist purely through a possible laxity or carelessness on the part of the faculty in the exercise of their advisory, or, if necessary, arbitrary function.

I. The necessity exists on the part of the faculty for infinite patience and time in the deliberate consideration of each student's needs and purposes in order to ensure a proper selection of study. This is sometimes difficult of practical attainment, and demands that the work of review and counsel be apportioned to a duly constituted committee who shall be held responsible for results.

II. There is a possibility of error in the choice of method of instruction, the tendency being perhaps to neglect didactic and recitation teaching for the apparently more natural or practical instruction at the bedside. Here the text is found in the patient rather than the disease. While this constitutes the essential thought in actual practice, it is insisted that its proper judicial fulfilment could not be there attained, save by a course of preliminary instruction relative to the disease itself. The student is enabled to profit by the clinical work as illustrative of what has been previously acquired from the comprehensive and well-rounded lecture or recitation. The bedside teaching develops careful methods of examination and closeness of observation, besides emphasizing in a practical way the lessons of the didactic lecture and textbook. It should be carefully guarded, therefore, that in the student's choice of method each co-ordinate branch of instruction be given within certain fixed limits its due and justly accorded place.

III. The selection of a prospective specialty may be made at too early a period in the course of medical instruction, this involving the possibility of an unwise choice before the student has had sufficient opportunity to properly appreciate his own inclinations and special fitness.

As a matter of fact, however, the student is usually prepared to judge somewhat as to his tastes and desires relative either to scientific or practical work upon the completion of his required fundamental studies. If teaching of scientific subjects or laboratory investigation is selected as the most suitable field for future work, the decision is better made then than at the time of graduation. If a course of special practical study is avowedly instituted in the midst of his period of undergraduate instruction, it is certainly destined to result more satisfactorily if pursued under the direction of the faculty than if practiced as formerly, according to the fancies and prejudices of the student, who has always been found to entertain notions of his own concerning the line of work he is supposedly designed to follow.

IV. The likelihood is suggested that measures looking toward too early specialization may produce superficial and embryonic results. Should the training and instruction in special work preparatory for practice be permitted to end upon graduation, against which possibility there is unfortunately no distinct remedy, the objection is only too well sustained. If, however, postgraduate work is insisted upon as a *sine qua non* before entering upon special practice, it must follow that the selected grouping of studies in

undergraduate instruction has only served to render more thorough and complete the preliminary preparation for specialism.

It is evident that a properly regulated course of electives constitutes one of the most conspicuous advances in modern medical teaching. Its degree of usefulness varies according to the extent of its application and control peculiar to each department of a medical course.

How far shall this apply to internal medicine?

The relation of internal medicine to the elective system is radically different from that of all other co-ordinate branches of medical instruction, in that it occupies a position singularly unique and distinctive in its scope and requirements. Its practical working basis may be said to consist of a modified form of individual and original research supplemented by inductive clinical reasoning. It is not even an applied science in the sense of the suggested assumption of fixed definite evidence or demonstrable truth. Its sphere of action may be regarded rather as a thinking, reasoning empiricism, involving speculative deductions along the projected lines of laboratory and pathological investigation, extended to the border limits of actual experience. In the practice of internal medicine the cases are not presented in classified form, catalogued and indexed, but rather furnish in themselves the source and inspiration for needful study and detailed investigation, in order to harmonize apparent differences and properly elucidate the relations of perplexing complications.

Rational medical interpretations are directly resultant upon the closeness of the observations, the accuracy of the premises and the soundness of the logical reasoning, rather than upon the application of the known laws of pure science, or resource to a mental accumulation of authoritative data.

The field of knowledge of internal medicine may be said to comprise an enormous mass of discrete, disordered and unsettled medical information, to which are added the confusing results of original research, new discoveries and fresh observations. The correct expounder of changing medical opinion must possess, above all, the attribute of experienced clinical wisdom, not to be obtained through the possession of the highest degree of technical knowledge nor the retention of a great mass of precise facts, capable of laboratory demonstration, but rather acquired through proper methods of observation, suitable habits of thought and processes of reasoning. These are accorded in a satisfying degree only to the well-balanced and judicial mind, disciplined thoroughly through the medium of an education by no means entirely technical. The ability to select scientific facts with wisdom and discrimination, and to interpret them with accuracy, to recognize error and pretence, to form rational conceptions and to exercise intelligent conservative judgment, requires at present, no less than formerly, a degree of broad and liberal culture in its fullest sense as supplementary to a natural mental endowment.

The proposition is now advanced, Can this intensely practical and vitally important branch of medical education be justly subjected to the elastic principles of the elective system? The question may be said to apply, first, to those contemplating internal medicine, and, secondly, to those anticipating special work. For the future practitioner in internal medicine it must be apparent that the most complete and the best proportioned system of preparatory education is none too good. He has never been trained too thoroughly. It is also insisted that the teaching faculty is by far a better judge as to what should constitute a comprehensive and well-rounded course of instruction in this department. The teaching of internal medicine comprises such various subdivisions of the subject, such diversity of method and such a large staff of instructors, as to allow, under the elective system, a very wide latitude as to the relative amount of attention assigned to the several collateral branches. It is easy to conceive how a student might elect certain of these and be given credit for the required amount of time in internal medicine, and even pass brilliant examinations, yet have sadly neglected other equally important portions of the work.

To preclude this possibility the student should be compelled to devote a certain definite time to each of the various methods and means of instruction, none of which are entirely without their proportionate value. The fact that there exists a wide difference of opinion among teachers of medicine as to the best methods of imparting knowledge to senior classes affords no justification in itself for permitting students to select the manner in which to pursue the study of given subject, but rather suggests the wisdom of demanding at least a degree of familiarity with all branches of the department. A well-balanced and required system of didactic, recitational and bedside instruction, with original conference work according to the seminar method, offers to students the best that can be afforded in undergraduate work.

While the elective system offers opportunity to special students for original and advanced work in medicine, the necessity and practical advantage of this is hardly apparent. The prescribed course during the four years in this department of the modern medical school offers a sufficient degree of advanced study if properly taken advantage of to satisfy the actual demands of the most exacting student. If more than this be attempted along certain lines of undergraduate instruction in medicine, it must be at the expense of other work in the same branch, or else through the sacrifice of even a superficial attention to the so-called specialties. The educated physician in internal medicine should possess at least a general knowledge of the special branches. In view of these considerations there does not seem to exist good and sufficient reason to justify the application of the elective system in internal medicine to those contemplating general medicine.

To what extent shall the prospective specialist be permitted to exercise his prerogative under the elective system as applied to internal medicine before graduation?

It may, perhaps, be the opinion of some medical educators that a certain given course for such students be offered as a minimum requirement, and that by this means more time be afforded for work in their chosen field or for original research. To this, however, objection is here made on the following grounds:

I. That expert practical knowledge in any specialty presupposes and demands a good working familiarity with the theory and practice of medicine, and this is not to be learned any too thoroughly in a completed system of undergraduate work.

II. That the finished work in any specialty should never be attempted in a medical school regardless of its scope or facilities, the only field for the attainment of a sufficient degree of special knowledge to justify practice being found in postgraduate work reinforced by clinical experience.

III. That the demand for original research among undergraduates is more fancied than real, the actual purpose of the student at this time being to absorb much, rather than to attempt to contribute a little.

IV. That in view of the uniformly earlier attainment of social, professional and financial success of the specialist, and greater ease of living, the law of compensation justly requires a much longer period of earnest studious preparation.

V. That the present overcrowding of the profession morally necessitates the imposition of rigid restrictions to graduation as well as to admission and the possession of the highest possible degree of proficiency in order to compete successfully with those unhandicapped by knowledge or conscience.

For these reasons there does not appear in the interests of the would-be specialists any especial necessity for the application of the elective system to this department.

It is hoped that these mere suggestions may sustain the thought that a consistent regard for the highest ultimate welfare of all students and practitioners of medicine requires that the elective system, although of great recognized value as applied to a portion of the course of instruction, yet should bear no considerable relation to the study of internal medicine in American medical colleges.

OBSERVATIONS ON THE IODINE REACTION IN CHILDREN.

BY CHARLES HUNTER DUNN, M.D., BOSTON.

THESE observations were made chiefly with the view to adding to the data already accumulated, on which the diagnostic value of the iodine reaction is based, and also with a view to determining whether the reaction in the diseases in children corresponds with that of similar conditions in the adult. For this purpose a test was made of the iodine reaction in the blood of every child immediately upon admission into the Children's Hospital during a period of three months, and also in all cases where any fresh disease developed during the child's stay in the hospital.

The technique employed was described by Drs. Richard C. Cabot and Edwin E. Locke in an article in the *Journal of Medical Research*, 1902, Vol. vii, No. 1, and further described by Dr. Locke in the Boston MEDICAL AND SURGICAL JOURNAL of Sept. 11, 1902.

In addition to merely noting the presence or absence of the reaction in each case, an attempt was made to estimate the per cent of leucocytes showing the reaction. The figures give percentages of the whole number of white corpuscles noted, not of the polymorphonuclear neutrophiles alone. In estimating these percentages, from one hundred to four hundred leucocytes, according to the presence and amount of leuco cytosis, were counted, and of these, all leucocytes showing a distinct reaction, no matter how slight, were counted in.

The reactions were further classified according to the intensities of the reaction in each individual leucocyte. In cases in which only a brownish discoloration was present the reaction was classified as slight (Sl.). In cases in which, in addition to such discoloration, distinct but small brown granules were visible in any of the corpuscles, the reaction was classified as average (Av.). In cases in which many large brownish granules were observed in any of the cells the reaction was classified as marked (M.), and where any cells were observed in which the large granules were so numerous as to coalesce in brown masses giving a deep brown color to the protoplasm, the reaction was classified as very marked (V.M.).

In addition to the single observation made on each case admitted to the hospital, in certain diseases, notably pneumonia, typhoid fever and cerebro-spinal meningitis, further observations were made during the course of the disease, with a view to determining the frequency and intensity of the reaction in the various stages and the approximate time of its disappearance. Also, for purposes of comparison, a count of the white corpuscles was always made at the same time that the blood was taken for reaction.

LOBAR PNEUMONIA.

Case.	*Age.*	*Stage of Disease.*	*Reaction.*	*Intensity.*	*% Cells Affected.*	*White Count.*
1	4 years	7th day	+	V. M.	80%	21,400

20	7 years	4th day	+	Av.	56%	18,000
21	2 years	4th day	+	Av.	36%	29,300
22	7 years	3d day	+	Av.	48%	19,100

The results in the twenty-two cases tabulated show the presence of the iodine reaction in all. As to intensity, the reaction was average in eight cases and marked in fourteen. The percent of leucocytes affected was almost uniformly high, the average being 70%. We may conclude from these results that in the active stage of lobar pneumonia in children a positive iodine reaction is the rule, such reaction being often marked, and always at least average in intensity, and that the percentage of leucocytes affected is high, being more than 50% in most of the cases.

The following table shows the results of further observations upon some of these same cases taken at various times after the crisis. In those cases where no distinct crisis occurred, the day the temperature reached and remained at the normal point was considered as equivalent to the day of the crisis.

Case.	*Time after Crisis.*	*Reaction.*	*Intensity.*	*% Cells Affected.*	*White Count.*	*Remarks.*
1	4 hours	+	Av.	60%	12,300	
1	4 days	0				
2	10 days	0				
3	3 days	+	Sl.	6%	7,400	
3	4 days	0				
4	5 days	0				
5	10 days	+	Av.	54%	18,300	Consolidation unresolved. Slight fever.
6	10 days	+	Av.	40%	13,400	Consolidation unresolved.
7	1 day	+	Sl.	8%	24,000	
7	3 days	+	M.	84%	28,700	Rise of temperature. Empyema.
8	9 hours	+	Av.	30%	12,100	
8	3 days	+	Sl.	6%		
8	5 days	0				
9	5 days	0				
10	5 days	0				
11	10 days	+	M.	42%		Consolidation unresolved.
11	15 days	+	M.	88%		Consolidation unresolved.
14	4 days	0				
15	3 days	+	Sl.	12%	14,400	
15	5 days	0				
19	2 days	+	Sl.	28%		Consolidation unresolved.
19	6 days	+	Av.	34%		Consolidation unresolved. Fever again for two days.
19	8 days	+	Av.	48%		Consolidation unresolved.
19	10 days	0				Four days after resolution.
20	1 day	+	Sl.	22%	11,800	
20	3 days	0				
21	12 hours	0				
22	2 days	0				

The results of these observations show that in those cases of lobar pneumonia in which quick resolution occurs the reaction becomes rapidly less marked both in intensity and in per cent of cells affected immediately after the crisis, and quickly disappears. It had disappeared in all cases by the fifth day after the crisis, and in one case (No. 21) it had disappeared in twelve hours; hence we may conclude that it may disappear at any time between the crisis and the fifth day. In cases where the consolidation remains unresolved, even with a normal temperature, as in Cases 5, 6, 11 and 19, the reaction may persist for at least ten or fifteen days. Case No. 7 is interesting as showing the behavior of the reaction when empyema develops after the crisis. In this case the reaction which before the crisis was marked, 74%, white count 60,000, became one day after the crisis slight, 8%, white count 24,000. On the third day after, the temperature rose again and before the signs in the chest were sufficiently well marked to warrant a diagnosis, the reaction had become marked, 84%. The increase in the intensity of the reaction was much more marked than the increase in the leucocyte count, which only rose from 24,000 to 28,700.

BRONCHO-PNEUMONIA.

No.	*Age.*	*Stage of Disease.*	*Reaction.*	*Intensity.*	*% Cells Affected.*	*White Count.*	*Remarks.*
1	2 years	?	+	M.	74%	12,100	
2	2 years	?	+	M.	74%	12,100	
3	5½ months	?	+	Av.	74%	32,800	Autopsy, tb. broncho-pneumonia with fresh pneumococcus infection.
4	14 months	?	+	Av.	66%	39,000	
5	1 year	3d day	+	Av.	58%	23,800	
6	6 years	7th day	+	Av.	46%	62,100	Complicating pertussis.
7	2 years	?	+	Av.	40%	31,400	Autopsy.
8	2 years	31st day	+	Sl.	30%	15,200	Slight fever.

The results of these observations are very similar to those obtained in lobar pneumonia, the reaction being present in all cases. The stage of the disease could not be absolutely determined, but all but the eighth case were in the active stage.

INFLUENZA PNEUMONIA.

No.	*Age.*	*Stage of Disease.*	*Reaction.*	*Intensity.*	*% Cells Affected.*	*Remarks.*
1	7 years	3d day	++++	M.	66%	Complicating (pertussis).
2	11 years	3d day		Av.	70%	
3	9 years	11th day		Av.	60%	Complicating (pertussis).
4	5 years	7th day		Av.	26%	

The reaction was present with at least average intensity in all cases, and a high per cent of corpuscles was affected in a majority of the cases observed.

Further observations showed that in Cases 2 and 3 the reaction disappeared on the fourth and third days respectively, after the temperature reached the normal. In Case 1 the disease ran a

very prolonged course, the reaction being average, 30%, white count 12,400 on the twenty-first day. The patient was discharged on the one hundred and fourth day with some fever and several areas of consolidation in the chest. The reaction on the day of discharge was slight, 8%, white count 9,100. Case 4 also ran a long course. The reaction was average, 30%, white count 19,200 on the thirty-first day.

No.	Age.	Stage of Disease.	Reaction.	Intensity.	% Cells Affected.	White Count.	Remarks.
1	2½ years	3d day	+	V. M.	68%	13,300	Severe case.
2	10 months	18th day	+	M.	72%	21,700	Autopsy.
3	3 years	26th day	+	Av.	52%	30,000	Severe case.
4	4 months	3d day	+	Av.	24%	43,300	Mild case.
5	13 months	90th day	+	Sl.	30%	29,600	Chronic relapsing case.

TYPHOID FEVER.

Of ten cases the reaction was positive in nine at some stage of the disease. In one case (No. 8) it was absent on the third day but present on the eighth day, but in all other cases it was present at the first examination, the stage of the disease varying from the fourth to the twelfth day. In one case the reaction was absent on the first examination and remained so throughout the disease. In the uncomplicated cases the intensity was slight or average, and the per cent of cells affected in all but one case (Case No. 6) was under 50%. In the two cases with complications, the intensity was marked and the per cent of cells affected high.

No.	Age.	Stage of Disease.	Reaction.	Intensity.	% Cells Affected.	White Count.	Remarks.
1	9 years	1st week	+	M.	74%	19,200	Comp. with septic pharyngitis.
2	3½ years	5th day	+	M.	62%	9,500	Comp. with Otitis media.
3	3½ years	12th day	+	Av.	40%		No complication.
4	10 years	4th day	+	Av.	40%	4,800	" "
5	10 years	1st week	+	Av.	18%	5,200	" "
6	10 years	1st week	+	Sl.	70%	8,400	Widal-O. No complication.
7	5 years	8th day	+	Sl.	50%	7,000	No complication.
8	5 years	8th day	+	Sl.	32%	10,200	" "
9	6 years	5th day	+	Sl.	8%	5,800	" "
10	7 years	7th day	0			9,000	" "

Further examination on some of these cases made with a view to determine the persistence of the reaction after the temperature reached the normal, were as follows:

No.	Temperature Normal.	Reaction.	Intensity.	% Cells Affected.	Remarks.
3	8 days	+	Av.	18%	Chronic discharging ear.
3	13 days	+	M.	14%	Chronic discharging ear.
3	18 days	+	Sl.	28%	Chronic discharging ear.
3	28 days	0			
4	8 days	0			
6	8 days	0			
7	11 days	0			
8	7 days	+	Sl.	18%	
8	16 days	+	Sl.	28%	
9	10 days	0			

In four uncomplicated cases the reaction disappeared between the eighth and the eleventh day. In one uncomplicated case (No. 8) the reaction persisted until the patient was discharged, on the sixteenth day. In one case complicated with chronic discharging ear the reaction persisted until the twenty-eighth day.

Conclusions. — In typhoid fever in children the iodine reaction is usually present, but may be absent. It is of less intensity and shows a smaller per cent of cells affected than in the pneumonias, but it persists, as a rule, for a much longer time, and may persist for more than two weeks after the temperature reaches the normal.

CEREBRO-SPINAL MENINGITIS.

In all of the following cases the Diplococcus intracellularis was at some time found in the cerebro-spinal fluid:

These observations, though limited in number, suggest that the reaction is always present during the active stage of this disease, and that the intensity and per cent of cells affected show a correspondence with the severity of the symptoms. Case 2 was fatal, Cases 4 and 5 made a complete recovery, Cases 1 and 3 became chronic, and both at the present writing are still totally unconscious with muscular contractions, Case 3 being on the two hundred and fiftieth day and Case 1 on the one hundred and fiftieth day since the onset of the symptoms. Further observations on these cases were as follows:

No.	Stage of Disease.	Reaction.	Intensity.	% Cells Affected.	White Count.	Remarks.
1	19th day	+	Av.	30%	10,400	Still fever.
1	35th day	0			11,200	Temperature normal.
3	36th day	0			24,600	Still moderate fever.
3	113th day	0			18,000	Temperature normal.
4	28th day	+	Sl.	10%	18,400	Temperature normal.
4	35th day	+	Av.	20%	37,200	During relapse of fever.
4	50th day	0			18,000	Temperature normal.
5	120th day	+		86%	44,700	During severe relapse.
5	150thday	0			21,900	Temperature normal.

It would seem that the reaction disappears in cases where the active process, as evidenced by fever, subsides, even in the chronic cases where the child remains unconscious, but that the reaction persists in those cases where there are relapses.

ACUTE MILIARY TUBERCULOSIS.

Of the following cases, in Nos. 2, 5, 7 and 8 the diagnosis was confirmed at autopsy; they had all been diagnosed clinically as tubercular meningitis.

In Case 3 glands excised post mortem were found to be tuberculous.

In Cases 4 and 6 the cerebro-spinal fluid obtained by lumbar puncture was characteristic of tubercular meningitis, but the clinical type of the disease was pulmonary with severe dyspnea and cyanosis.

In Case 7 the disease developed on a chronic pulmonary tuberculosis, tubercle bacilli having been found in the sputum.

No.	Age.	Stage of Disease.	Reaction.	Intensity.	% Cell Affecteds.	White Count.	Remarks.
1	11 years	5th day	+	Av.	34%	5,600	
2	7 months	5th day	+	Sl.	52%	18,000	Two weeks before death.
3	6 years	?	+	Sl.	50%	25,600	
4	7 months	?	+	Sl.	22%	27,500	Four days before death.
5	11 years	?	+	Sl.	12%	16,000	Exam. made twenty-four hours before death.
6	2 years	?	+	Sl.	4%	18,900	Three days before death.
7	4 years	7th day	0			16,300	Three days before death.
8	2½ years	?	0			11,300	Twenty-four hrs. before death.

From these observations it appears that the reaction may be either present or absent. When present the intensity is usually slight, and the per cent of cells affected comparatively low.

ANEMIA.

These cases of anemia were all of the secondary type. In Cases 2 and 3 second observations were made.

No.	Age.	Hgb.	White Count.	Red Count.	Reaction.	Intensity.	Cells Affected.
1	10 months	30%	27,100	2,000,000		Av.	60%
2	3 years	30%	17,800	2,160,000		Av.	34%
2		20%	12,900	1,516,000		Av.	22%
3	2 years	55%	16,000	2,320,000		Sl.	30%
3		65%	14,800	5,008,000	0		
4	2 years	35%	6,000	3,440,000	0		
5	2 years	40%	10,700	4,300,000	0		
6	6 months	40%	6,300	3,500,000	0		

In general from this limited number of cases it would seem that the iodine reaction is present in the more severe anemias, absent in the milder ones, and when present a low per cent of cells is affected. Case 3 is interesting, showing the disappearance of the reaction coincident with improvement in the condition of the blood.

INFLUENZA.

I have included under this heading seven cases, all of which were obviously acute infections, but in none of them was the precise nature and localization of the infection determined. They all presented clinical pictures greatly resembling the ordinary grippe attacks, and they occurred at a time of year when cases of influenza pneumonia were common. In no one of them was a satisfactory specimen of sputum obtained. In all of these cases the iodine reaction was positive and of average intensity. The percentage of cells affected varied between 30% and 66%. Leucocytosis was absent in five cases, present in two.

NEPHRITIS.

The first five cases were acute, the last two of the chronic glomerular type.

No.	Age.	Stage of Disease.	Reaction.	Intensity.	% Cells Affected.	White Count.	Remarks.
1	4 years	?	+	M.	68%	27,600	Complicated with acute follic. tonsilitis.
2	4 years	?	+	Av.	68%	16,600	Complicated with eczema.
3	3 years	10th day	+	Av.	54%	12,700	Severe case.
4	6 years	10th day	0			14,000	Mild case.
5	3½ years	?	0			17,300	Marked edema but no uremic symptoms.
6	7 years	?	0			19,600	Edema. No uremic symptoms.
7	6 years	?	0			17,000	Edema. No uremic symptoms.

From this small number of cases the reaction would seem to be positive in the severe acute cases, absent in the mild or chronic cases.

PLEURISY AND EMPYEMA.

No.	Age.	Stage of Disease.	Reaction.	Intensity.	% Cells Affected.	White Count.	Remarks.
A. WITH SEROUS EFFUSION.							
1	5 years		0			11,300	Fifth day traumatic etiology
2	3 years		0			13,000	Duration unknown. Tb. reaction.
3	9 years		0			13,000	Tb. reaction.
B. EMPYEMA.							
4	5 years		+	M.	88%	29,600	Pneumococcus infection.
5	3 years		+	M.	76%	31,000	Streptococcus infection.
6	2 years		+	M.	64%	20,700	Pneumococcus infection.
7	3 years	+	+	Av.	26%	16,000	Pus, sterile, tb. reaction.

The results in this small number of cases agree with those of Cabot and Locke, based on a larger number of cases. Case 7 is interesting as showing the probable relation between the character of the infection and the intensity of the reaction, and the per cent of cells affected.

FUNCTIONAL INDIGESTION.

Observations were made on seventeen cases of gastric and intestinal indigestion. These included twelve cases in early infancy, so-called feeding cases, and five cases in middle childhood. Of the latter, one was a severe case of gastroduodenitis, with severe jaundice. The iodine reaction was negative in all cases, nor did any of the cases show a leucocytosis.

CHRONIC VALVULAR CARDIAC DISEASE.

Six cases were examined, in all of which compensation was disturbed, in one of which it was wholly broken. The reaction was negative in five cases, slight, 8%, in the sixth case, this being the case of badly broken compensation.

OTHER DISEASES.

The following table (see next page) includes all cases in which only one or only a few observations could be made.

The number of cases in the above table is too few to warrant the drawing of any general conclusions. So far as they go the results agree with those of Cabot and Locke in similar cases.

The two cases of abscess were especially interesting in that the clinical diagnoses were the reverse of what was found to be the case on an examination of the pus. Further observations are needed to determine if a so-called cold abscess can be distinguished from a septic abscess by means of the iodine reaction. The three cases of pericarditis are interesting from the fact that the variation of the reaction seems to agree with

the nature of the cause, the pneumococcus infection giving a very marked reaction with a high per cent of cells affected, and the rheumatic pericarditis giving a negative reaction, the probable tubercular pericarditis being midway between.

The results of the above observations as far as they go are in general confirmatory of the

(2) The reaction is usually present but may be absent in cases of typhoid fever, and miliary tuberculosis.

(3) The reaction may be absent or present in anemia.

(4) The reaction is usually absent but may be present in nephritis, cardiac valvular disease and tuberculosis.

theory that the iodine reaction is a measure of the degree of toxemia. The observations on cerebro-spinal meningitis, on acute nephritis and on anemia are especially interesting in connection with this point. The single observation in the case of diphtheria gave the most marked reaction in intensity of any I have seen. I have not seen any other observation on this disease. The result is what one would expect in a disease characterized by so very profound an intoxication.

SUMMARY.

A general summary of the results, though necessarily imperfect from the comparatively small number of cases observed, may yet be of some use for comparison with future observations. It would be as follows:

(1) The reaction is always present, usually of average and often of marked intensity, a high percentage of cells being affected in the following conditions: Lobar pneumonia, broncho-pneumonia, cerebrospinal meningitis, influenza (see above), empyema, suppuration (non-tubercular), and was found present in single cases of appendicitis, diphtheria and starvation.

(5) The reaction is absent in pleurisy with effusion, functional indigestion, rachitis, articular rheumatism, congenital cardiac disease, chorea, infantile atrophy and was found absent in single cases of bronchitis, eczema, purpura, urticaria and scorbutus.

Clinical Department.

MIRROR WRITING.

BY CHARLES D. JONES, M.D., BOSTON,

Ophthalmic Clinical Assistant, Massachusetts Charitable Eye and Ear Infirmary; Consulting Oculist, Malden Hospital.

ACCOMPANYING this paper is an admirable specimen of that curious anomaly known as mirror writing. The author was a boy about seven or eight years old who had been referred to me because of his very peculiar handwriting. The eyes were normal and the boy's teacher was assured that the condition would gradually be outgrown. Some months later the boy had accustomed himself to write correctly most of the time; but his teacher, who has kept an intelligent eye upon him, stated that when he became tired or even in some cases confused from

merely changing his seat in school, he occasionally reverted to his old system. The boy is bright and the handwriting, when reversed, will be acknowledged excellent for one of his age. He writes usually with the right hand, sometimes with the left.

In considering the causes of this condition, the various explanations seem altogether inadequate. It is apparently more common in persons having some manifest mental trouble, but also occurs in those of normal mental capacity. In most cases the writing is done by the left hand, and this fact gives a clue to the only explanation offered which is at all rational. Mills, in the Encyclopedia Medica, argues on the supposition that it is left-handed, "that the movements which produce mirror writing . . . are primarily guided from the left cerebral cortex," through some preponderating influence which the left cells have over the right, the result being that the left hand makes movements symmetrical with those made by the right; and mirror writing results because the same muscles (on the two sides) are called into action simultaneously. The author lays some stress in elucidating this theory upon a particularly close association of the two hemispheres of the brain through the corpus callosum. This is a point for the neurologist to settle; it seems to me to afford little light. Even more barren of results are theories which assume that an "image" is formed on the "mind." One writer categorically states that "visual sense alone would give us a world upside down." [1] Physicians as a body have always appreciated less clearly than metaphysicians that the mere fact that the retinal image is inverted, as are all real images, has *per se* no bearing whatever on the final perception of the object. The writers just quoted render the problem even more complex when speaking in this manner: "It may be asked is the image or impression or change in the brain tissue from which the image is formed on the mind reversed like the negative of a photograph; or if a double vision be formed in the visual center, one on the right hemisphere and the other on the left, do the images lie to each other in opposite directions?" After reading such statements and conjectures, it is well to recall to mind plain physiological facts; to remember that the sensation of light is not dependent upon the existence of a retinal image. The following is good: "Some have supposed that this picture [the retinal image] acting upon the sensitive nerve is reproduced on the gray matter of the brain. But there is difficulty in assigning to the sensory nerve a power of producing such an effect as copying a pictorial representation of an object, and it is at variance with the recognized functions of the gray matter to suppose that it is a sensitive surface capable of receiving pictorial impressions." [2] Another author writing upon this question of mirror writing gives a long account of a child who persistently saw things reversed, not only laterally, but even upside down; such is not the experience of persons previously blind who have been suddenly cured, and every care should be used to prevent error before accepting these results.

In the case here reported the boy copied objects, letters and words correctly, writing in the ordinary manner, but wrote mirror writing from dictation.

Mirror writing is said to be not uncommon in England, in one group of 451 the percentage of mirror writers being 5.1. I am convinced it is much less frequent in this country. In several cases which I have been assured were mirror writers, the specimens have proved to be merely those of poor penmanship, due to ignorance and carelessness, and the writing quickly became normal under suitable instruction.

Medical Progress.

PROGRESS IN ORTHOPEDIC SURGERY.

BY ROBERT SOUTTER, M.D., BOSTON.

HIP DISEASE.

In the last two years there has been considerable work done on hip disease. Most of the literature contains much that is familiar; many noteworthy articles I shall not mention. Some revived old methods, new features in old methods and new ideas on the disease itself.

Koenig,[1] in his extensive work on bones and joints, devotes considerable space to hip disease. Perhaps the most interesting part of his article is the comparison of tuberculosis of the hip and infectious coxitis and the classification of the latter into three groups. His work is well worth reading in detail. There are 568 cases of tuberculosis of the hip, 110 cases of acute infectious coxitis, 30 gonorrheal, 22 arthritis deformans, 20 miscellaneous. In all, the hip observations number 758.

The anatomy of the hip, the development of the bones, the pathology of tuberculosis are treated in detail. In tracing the location of tuberculosis:

(1) Examples of pressure changes on the head of the femur without disease at that point.
(2) Disease of upper part of head and cartilage.
(3) Erosion of the upper head and cartilage called "superficial caries."
(4) Cartilage about the head destroyed completely.
(5) Destruction of the head and cartilage complete.
(6) Disease of the outer part of the head of femur.
(7) Inner part of the head diseased.
(8) Wedge of tuberculosis in the head.

[1] Huft und Kniegelenk, November, 1902

(9) Disease of the epiphysis extending into the neck.
(10) Sequestra formation in the head and neck.
(11) Caries sicca early; caries sicca advanced.
(12) Disease of the socket.
(13) Perforation of the socket.
(14) Spontaneous luxation with focus in pelvis.
(15) Necrosis of epiphysis and cartilage.
(16) Necrosis of the center of the bone.
(17) Focus in the neck only.

In 381 resections he noted the position of the primary tubercular focus. In brief, $\frac{1}{3}$ involves the head; $\frac{1}{7}$ the socket; $\frac{1}{13}$ the neck; $\frac{1}{38}$ the pelvis above the joint; the shaft and trochanter were each the primary focus five times in 381. As to the origin, it was positively primary in 185 cases.

Statistics, 381 resections: 146 involving the head; 187 involving the socket; 28 involving the neck; 5 involving the shaft; 5 involving the trochanter; 10 involving the pelvis above the joint. (p. 29).

Primary disease, 185: doubtful, 94; of the head: primary, 44; secondary, 48; uncertain, 34; neck disease, 28; trochanter, 5.

Socket: primary, 98; secondary, 49; uncertain (as to 1 or 2), 40.

Pelvis: primary, 8; secondary, 2.

Pelvic origin therefore occurred 197 times, femoral, 184.

In tubercular hip disease rotation disappears completely earliest, flexion last, but the disease may be present without loss of motion. It was observed that slight flexion, slight abduction and outward rotation was the position of early tubercular disease, though position only is no guide. Adduction position comes on later and with it inward rotation. Adduction is also the rule in acute cases, but primary adduction in tuberculosis is rare. The primary abduction will not be evident from statistics, for the majority of cases come under observation too late; moreover, in statistics the number of adduction cases is augmented by luxations and later the pathological conditions. These facts are borne out by the following:

Statistics of usual cases: abduction cases, 267; adduction cases, 232; in 68 acute cases 44 were in the position of adduction. Koenig considers disease of the ligamentum teres, granulations on it and in the socket the cause of adduction and of luxations and dislocation.

In 568 cases nearly two-thirds had abscess. Swelling of the joint may occur without abscess, but with abscess the joint is always involved. Origin of abscess is always in the joint.

As to the result of treatment of all cases it is noteworthy that Koenig reports 568 tubercular coxitis cases of which a little less than two-thirds had abscesses. But in 294 conservatively treated cases there were 49 abscesses; one in six. In 118 resections with disease of the socket one-fourth had pelvic abscesses. In another list of 156 resections only 12 did not have disease of the socket.

The temperature curve of tubercular coxitis is characteristic: tubercular curve with slight rise in the afternoon, with low temperature in the morning.

Koenig believes the x-ray very valuable often, but not so valuable in adult hip joints nor in deep-seated disease of the pelvis or socket, whereas in superficial parts and the edge of the socket sequestræ and disease may be made out.

Treatment. — Slight cases: bed with or without extension; later, up with crutches. More severe cases: extension with plaster of Paris fixation. Resection and operation used to be too frequent, but now that the treatment is well understood it is apt to be used too infrequently. Koenig operates in the following conditions:

(1) For abscess.
(2) Where there is severe joint disturbance.
(3) When there is severe shortening due to dislocation.
(4) When x-ray shows a focus distinctly.
(5) Often for fistulæ.
(6) When treatment does not check pyogenic symptoms.
(7) If there is deformity or fistulæ with difficulty in locomotion.

In these cases he rarely tries extension first, but operates, unless pus is very slight.

(8) Resection without abscess is justifiable if after a reasonable period of good treatment pain and swelling and disease does not improve.
(9) Resection is advised especially in adult cases and in the aged.
(10) For ankylosis with outward rotation.

Reposition is not a success. The age of occurrence and the duration are interesting, also the sex, two-thirds being male. Right and left are equally affected.

In 568 cases only 7 with double hip disease, nearly four-fifths were under 15 years of age and one-half 10 years and under.

The following statistics of are interest: 1 to 5 years of age, 152 cases; 6 to 10, 149; 11 to 15, 102; 16 to 20, 60; 21 to 25, 18; 26 to 30, 10; 31 to 40, 15; 41 to 60, 7.

Duration. — Two hundred and fifty-nine, or slightly less than one-half, last one year; 130, or slightly less than one-fourth, last two years; one-fourth slightly less than 3 years; $\frac{1}{13}$ last 4 and 5 years; the longest duration was one of 32 years; — four-fifths of the cases last from 1 to 5 years.

In double tuberculosis of bone in 24 cases, the following facts were observed: Hip and foot affected, 7 times; hip and hand, 3 times; hip and ankle, 10 times; hip and rib, twice; hip and sacrum, once; hip and sternum once.

Of hip tuberculosis and joint tuberculosis: knee, 7 times; foot, twice; elbow, twice, 11 of joint. There were then 24 cases of other bone tuberculosis and 11 cases of joint tuberculosis with hip tuberculosis.

Statistics on the frequency of each abnormal position in deformity, such as abduction with or without shortening; adduction with or without

shortening; shortening with or without abduction or adduction; real or relative shortening, etc., show:

(1) Without abduction and adduction, 27.

(2) Abduction 267, alone 184, with shortening 83.

(3) Adduction 232, alone 68, with absolute shortening 164.

(4) Real shortening alone 24, 164 adduction shortening; 83 abduction, 24 without abduction or adduction.

Another table shows atrophy of resected and non-resected cases, and of resected cases after resection.

Now tubercular hip cases are grouped under acute infectious coxitis, gonorrheal and rheumatoid. The grouping of infectious coxitis is interesting. There are 110 cases. The symptoms differ from tuberculosis of hip in that the onset is sudden and with fever. These vary from mild symptoms to those of severe acute osteomyelitis. The classification is based on pathological rather than the clinical condition into three groups:

I. Synovial coxitis.

II. Ostate coxitis.

III. Acute osteomyelitis of bone about joint.

Group I. — In the synovial form the majority are trivial and limited to the synovial membrane. In acute purulent joints the prognosis is more favorable for children than for adults, both as to the disease and the return of joint function.

Group II. — Ostate coxitis resembles tuberculosis as to the region of bone affected. It is a disease of the joint and of the bones making up the joint. Of 73 excisions in acute coxitis 50 had bad disease of the bone; 15 of these the head and glenoid cavity were diseased; in 14 the glenoid cavity ; in 13 the head alone; in 20 the epiphysis was involved; in 11 the trochanter, with either the socket or shaft.

The difference in the number of cases resected in tuberculosis and infectious coxitis makes it difficult to draw any reliable comparative statistics. Those with involvement of epiphysis of head are not readily classed here. There were three cases of disease of the head and epiphysis without involvement of the cartilage. The symptoms in acute coxitis come on suddenly, with hip pain, immediate and rapid increase of fever and delirium. With the sudden onset there may be chills and typhoid condition. In about two weeks fever disappears, and the disease takes the chronic form, leaving the patient generally run down.

In tuberculosis, abduction and rotation outward was more common. In acute infectious coxitis, adduction and rotation inward is the more common. There were in 68 cases 44 adduction position, 24 abduction position. Rotation outward is usually characteristic of disease of the epiphysis.

Age of occurrence. — One hundred cases: 86 were under 25; one third between 10 and 15; one half under 15.

Statistics. — Ages 1 to 10, 23; 10 to 15, 30; 15 to 25, 33; after 25, 16; under 25, 86.

Group III. — Osteomyelitis of the bones *about* the joint. There are two types:

(*a*) Pelvic ostitis. If operated on early it may not involve the joint.

(*b*) Femoral ostitis. Disease of trochanter or neck. Many of these die, especially when the joint is involved early.

Of the acute infectious cases 80 were operated on and 23 had simple incision for abscess or correction of deformity without incision.

In 72 resected cases 66 recovered; 6 deaths. The incision used was Lagenbeck's long posterior. Cases heal in 6 to 8 weeks. In 72 cases only two fistulæ after 8 weeks.

Broca [2] treates the same subject as Koenig minutely, but uses another classification for non-tubercular coxitis, his basis being clinical.

If there are other joints, or if onset is sudden with fever, he would eliminate tuberculosis, especially without the presence of atrophy or without glandular enlargement or if the recovery is very rapid. He makes no synovial class and the others of Koenig's, but divides the cases clinically into suppurating and non-suppurating, operative and non-operative.

THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

SEVENTEENTH ANNUAL MEETING, HELD MAY 12-14, 1903, WASHINGTON, D. C.

(Continued from No. 18, p. 493.)

(SECOND DAY — *Continued.*)

SOME SUGGESTIONS IN THE MANAGEMENT OF PROSTATICS ABOUT TO ENTER CATHETER LIFE.

DR. GEORGE K. SWINBURNE of New York read this paper. He believed that many cases of prostatic hypertrophy were introduced to catheter life, and allowed to use the catheter themselves, who for a longer or shorter period, by judicious management, could be saved from the frequent self-catheterization with its attendant dangers. The cases varied markedly in the rapidity with which the amount of residual urine increased according to the situation of the obstruction, but he said there was one element often overlooked, the superinduced congestion, or rather edema of the surrounding tissue, which increased the obstruction and consequently the amount of residual urine; when this obstruction and consequent congestion had been reduced then the amount of residual urine fell back to an amount due to the mechanical obstruction itself. Many of these patients could be brought back to the condition they were in before the onset of any acute symptoms, and kept there for a varying period of time; they would have nocturnal polyuria and a small amount of resid-

[2] Rev. Orthop. iii, 4, Paris, 1902.

ual urine, but the urine will be sweet and clean and the bladder remain uninfected; then careful dieting, abstemious living, the proper amount of exercise and the local treatment, etc., will cause a lessening of the physician's visits until they would not exceed twice or thrice a month. In those cases in which are found a considerable amount of residual urine, when it would seem dangerous to remove all the urine at a time, it seemed to him a good plan to replace the amount of residual urine with about the same amount of argyrol solution, 1–1,000, gradually diminishing the entire amount, and thus to prevent infection, and to reduce infection by the injection of ½ oz. of a 10% solution argyrol. He claimed that this new salt of silver was non-irritating and had a marked effect in reducing the pain and inflammation; in his hands it had superseded the use of nitrate of silver solutions used for the same purpose. The object of his paper was rather to bring out an expression of opinion as to whether or not it was not often better to carry a patient over as long a period of time as possible before they themselves were allowed to resort to self-catheterization, but also to call attention to the beneficial results that could be had by the use of argyrol as a local urinary antiseptic.

Dr. H. M. Cristian of Philadelphia believed we were drifting back to the conservative treatment in cases of prostatic hypertrophy. The life and happiness of the man now rested in his having a sterile urine; his trouble begins with bladder infection. In the conservative treatment he believed 85% of these lives could be made comfortable and prolonged by proper catheterization. The personal equation should be emphasized in these cases. The drug mentioned by Dr. Swinburne he had used to prevent attacks of cystitis with great benefit.

Dr. Francis S. Watson of Boston liked argyrol very much, and had also received the most brilliant results from the use of a 1% solution of methylene blue.

Dr. E. L. Keyes, Jr., of New York, reported an instance in which the use of argyrol made the patient worse, the drug acting as a strong irritant.

Dr. George K. Swinburne of New York had never noted any signs of irritation from the use of this drug after an experience with it of one and a quarter years.

CANCER OF THE PROSTATE.

Dr. Robert H. Greene of New York presented this communication, and said that he had great difficulty in finding any literature which bore upon this subject. Frequent symptoms were pain, referred to the perineum, to the rectum and to branches of the sciatic nerve; the amount of residual urine had little relation to cancer cases. The average age of all cases was sixty-eight years. The size and feel of the growth as found by rectal touch was of no special diagnostic value. There followed secondary lymphatic infection. Autopsies were made on seventy-one men; in 88% the glands were found to be involved and in about 35% the inguinal glands were infected; in about 3% the axillary glands were involved.

He reported a case of this nature. The patient was sixty years old and had had gonorrhea forty years previous. At Christmas time, 1901, he had retention of urine, and was relieved by catheter. From then on he noticed pain in the right perineal region. There was but little residual urine. Urinary examination was negative. There was no tenderness over the prostate. The bladder was irrigated with nitrate of silver solution and he was given tonics, and all was done that was possible towards improving his general health. The pain continued. He insisted upon an operation. The diagnosis at that time was an abscess of the right lobe of the prostate, or else a small stone encysted in the prostate. The patient was operated upon last June, and the prostate was removed. He claimed that the operation injured his sexual functions. The pathologist reported the right lobe of the prostate to be cancerous. Dr. Guiteras presented some photographs of the case.

Dr. H. M. Cristian of Philadelphia reported a case of cancer of the prostate in which sciatica was a very prominent symptom.

Dr. Eugene Fuller of New York said that cancer of the prostate was apt to involve the bladder wall early, and when it extended beyond we were apt to get sciatica or pains running down the thigh. He said he was rather skeptical regarding the many diagnoses of cancer of the prostate received from pathologists. He thought they erred many times.

Dr. Robert H. Greene of New York said that when we considered the number of times we meet with prostatic hypertrophies and the chronic infiltrations there, we should cease to be surprised at the frequency of cases of cancer of the prostate.

A MEDICO-LEGAL STUDY IN A CASE OF ALLEGED SYPHILIS.

Dr. Abner Post of Boston reported this case to the Association, and asked that your reporter refrain from reporting it on account of possible medico-legal complications that might ensue.

Third Day — May 14, 1903.

DEMONSTRATION OF THE AUTHOR'S COMPOSITE CYSTOSCOPE.

Dr. F. Tilden Brown of New York made this demonstration. With his instrument he was able to irrigate the bladder, make a cystoscopic examination and catheterize each ureter. It was important that the patient occupy the dorsal position upon a table, the lower end of which was elevated.

THE USE OF THE CYSTOSCOPE IN THE STUDY OF PROSTATIC HYPERTROPHY.

Dr. Hugh H. Young of Baltimore presented this communication. He said that the use of this instrument in the study of prostatic hyper-

trophies had been doubted by many, many declaring it valueless. With the cystoscope he had had manufactured one was enabled to study the prostate from every side. The ordinary cystoscope had a right-angled prism. The instrument he had devised enabled one to look backwards. In order to get a view of the entire prostatic orifice it required six different pictures, each picture representing one-sixth of the circle, or 60°. Instead of a compound prism he used a four-sided prism, which enabled him to look backward and view the prostatic lobes. The object of his paper was not to demonstrate his instrument, but to show how it was possible to make an ordinary cystoscopic examination tell us the condition of the prostate in ordinary cases of prostatic hypertrophy. He exhibited a series of charts showing the pictures given by the six different turns of the cystoscope, and demonstrated how one could tell the kind of enlargement from a study of these pictures. He had a series of pictures taken of 120 cases which were of great value to him in his work in this connection. On account of imperfections in the instrument due to poor instrument makers in this country, his results had not been entirely satisfactory.

DR. W. K. OTIS of New York said that one of the principal objects in a cystoscope was to have sufficient room for light, and therefore his instruments were larger than usually used, about 30 F. He believed that a careful and methodical examination of the prostate still required more practical experience in order that an idea might be formed of the conditions presented.

REPORT OF A CASE OF FILARIASIS.

DR. F. TILDEN BROWN of New York reported this case. He said that a mistake in clinical diagnosis had been made in this case, but he was fortunate enough, in the microscopical examination which followed the operation, to find numerous embryos in different developmental stages of what he took to be filaria Bancrofti. The patient's blood failed to show the embryo, and he thought this might in part be explained by the supposition that the orchidectomy had removed all the female worms, if in fact more than one had originally been present. The patient was a German, thirty-four years old, in the United States Marine Hospital Service, and he had been stationed at Porto Rico for the past two years, and had had no fever or illness of any kind. During the past two months he noticed an enlargement and slight tenderness of the left testis. The possibility of its being a barrier to re-enlistment led him to enter Bellevue Hospital, New York City, for operation. Examination showed a moderate enlargement of the left testis, and it was difficult to determine whether the slight but tense effusion in the tunica vaginalis was responsible for the increase in size or not. A small nodule, the size of a marble, slightly tender, was felt where the midbody of the epididymis was apposed to the testis. Which of the two organs it involved could not be determined. The spermatic cord was found to be larger than its fellow. The vas was thicker, but not beaded. He had had no gonorrhea for ten years, and never a swollen testicle from this cause or from traumatism. A diagnosis was made of tuberculous epididymitis, and the patient requested that the testis be removed. At the operation fully an ounce of straw-colored fluid was found occupying the tunica vaginalis. This sac, together with the testicle, the lower one-third of the cord and a considerable more of the vas was removed. Palpation of the specimen now showed a small nodule occupying not the epididymis, but the rete testis just underlying it. In cutting into the lesion a compact fibrous periphery was noted, and in its center a yellowish-white semi-fluid material, somewhat resembling tuberculous débris. A small amount of the adherent material was placed upon a slide and, when examined microscopically for tubercle bacilli, small wormlike forms were seen. Another slide treated with eosin glycerin showed a number of field clusters of lumbricoids having the characteristics of the filaria sanguinous hominis. The larvæ were granular and surrounded by a loose fitting hyaline membrane. Immature forms were of oval shape, and the intermediate forms showed the embryos coiled and doubled in a larger oval sac. Dr. Brown concluded that when cutting into the nodule he may have opened a dilated lymph vessel or space, the abiding place for the adult female filaria; the knife had probably severed this worm in several places, and in scraping it the uterine canals had been compressed and more or less emptied of their contents, and this might account for the great number of embryos found in the different developmental stages.

REMARKS ON SURGICAL TREATMENT OF CHRONIC BRIGHT'S DISEASE BY RENAL DECAPSULATION.

DR. RAMON GUITERAS read this paper. He said that through the efforts of Dr. George Edebohls an operation for the treatment of chronic Bright's disease had been launched, and has caused general interest among surgeons both in America and Europe.

This operation consisted either in partially decapsulating one or both kidneys, and fastening the denuded surfaces to the posterior abdominal wall, or of fully decapsulating these organs and replacing them in their fatty capsule. The former of these procedures had been in a great measure superseded by the latter, although in his mind there was still a question as to which was the better. At a meeting of the American Genito-Urinary Association, held in Atlantic City last year, he had presented a paper entitled, "The Operative Treatment of Chronic Bright's Disease," in which he had reviewed the literature of total decapsulation, and had reported two cases of his own, one of total decapsulation, the other of partial stripping of the capsule, together

with fixation of the organ to the abdominal wall. He had begun work last year as a skeptic, and had refused to operate upon many cases referred to his hospital wards, which he would now consider deserving of operative interference. His experience and the growing favor with which this operation was regarded by many of the leading surgeons led him to send a circular letter to the leading surgeons in order to ascertain their experience in this line of renal work. From the answers that he received from about one hundred and fifty of these letters, the surgeons were about equally divided *pro* and *con* on the operation. The theory as to the benefit to be derived from this operation was that the circulation of the kidney was increased by forming an anastomosis with the tissues of the abdominal wall or the fatty capsule, and thus functional activity was materially aided. Some went so far as to argue that the kidney after this operation could be compared with the lungs, as in these latter organs the bronchial arteries and the pulmonary anastomose and some of the return venous blood from the bronchial vein emptied into the pulmonary veins. Whether or not a corresponding result was obtained in the kidney would be considered later in concluding. The conditions which were considered favorable for the operation were movable kidney with casts and albumen, movable kidney associated with nephritis, chronic interstitial nephritis and diffuse nephritis. Over one hundred of these cases had been reported, 16% of which had been spoken of as cured, 40% as improved, 11% unimproved and 33% died. The cases which were most unfavorable for this procedure were those of chronic diffuse nephritis, of which there was a mortality of 75%. Many of these patients were operated upon *in extremis*, when they were suffering from general anasarca. Nearly all of them had been suffering from uremic symptoms, while 75% of them were edematous. Many cases of albuminuria and cylindruria were not properly speaking Bright's disease, although if the causes that produced them were kept up long enough chronic nephritis might occur. Movable kidney was often associated with this condition, as there was a congestion present due to the tension on the renal vessels. This might be absolutely cured by nephrolexy. In order to have a true nephritis we must have an inflammation or degeneration of the blood vessels, interstitial tissue, the glomeruli or the linings of the tubules of the kidney. Such changes always occurred in both kidneys, although they might vary in degree in different organs. This was a generally acknowledged fact by pathologists, and had been proved by Kümmel and Strauss in their investigations by means of urethral catheterization. He had looked over the records of five hundred autopsies ascribing deaths to chronic Bright's disease, and in not one instance could it be said that the nephritis was unilateral, and in only one had the reports indicated that one organ was more involved than the other.

(To be continued.)

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

SECOND SEMI-ANNUAL MEETING, HELD IN NEW YORK CITY OCTOBER 13 AND 14, 1903.

FIRST DAY, TUESDAY, OCT. 13.

THE meeting was held in the New York Academy of Medicine, under the presidency of DR. A. T. BRISTOW of Brooklyn.

HEPATIC DRAINAGE.

DR. J. B. DEAVER of Philadelphia, Pa., read this paper. He said that it was important to remember that the infection rather than the calculi was concerned in causing most of the mischief. These cases were not unlike those of appendicitis, at least in their relation to the surgeon. In addition to medical treatment, it was absolutely necessary to remove the obstruction and establish hepatic drainage. He had never regretted having done a cholecystostomy, though sometimes he had wished he had not done a cholecystectomy. If there were any suspicion of liver infection, free drainage of bile must always be secured. Dr. Deaver drew the following conclusions: (1) Suppurative cholangeitis should be operated on before infection had damaged the hepatic cells and before the retained bile had reacted injuriously on the system. (2) Cholecystotomy was the operation of election when the lesion was acute and the gall bladder had been functionating hitherto. (3) When there was calculous cholecystitis, with obstruction of the cystic duct, hepatic drainage was demanded, and this was especially true if infection were present or suspected. (4) Whenever there was any doubt, the surgeon should drain. (5) Abscess of the liver would be prevented and pancreatitis relieved by a prompt resort to such drainage.

DR. A. VAN DER VEER of Albany agreed with the author's views as to drainage. He had had good results from posterior drainage down though the peritoneal pouch.

DR. GEORGE R. FOWLER of Brooklyn cautioned against being too radical in the effort to secure direct drainage from the hepatic duct, because in the great majority of cases a successful issue would follow merely draining the gall bladder itself. From the mechanical standpoint, posterior drainage was excellent, but its practical execution was often most difficult.

THE TREATMENT OF CERTAIN CLASSES OF THE UNDERFED.

DR. W. S. ELY of Rochester considered in this paper a class of persons who could be persuaded with difficulty to take sufficient nourishment. Such persons should be placed in a hospital under proper discipline, and then should be treated by rest and a diet of milk and raw eggs. At the commencement the patient might be given 4 to 8 oz of chocolate with two raw eggs alternately every two hours, and the effort should be to give in the twenty-four hours one quart of

chocolate, one quart of milk and six raw eggs. He had never yet seen among this class of persons a single individual who could not take milk with benefit. It must be expected that the tongue will be more or less coated, and no gain should be looked for the first week. The tendency to constipation should be counteracted by giving from six to twenty tablets of rhubarb daily. Under this treatment it was not uncommon to see the patient gain from one to three pounds a week for ten or twelve weeks, and this increase in flesh would be accompanied by improvement in digestion and in the general appearance. It was well to remember that if the physician had not the courage of his convictions, he should not undertake to carry out such a course of treatment, for, it would, in all probability, end in disappointment.

DR. EDWARD B. ANGELL of Rochester said that while he had formerly made use of this method of treatment he had latterly been more in favor of so arranging the regimen that the patient would have enough exercise to secure the much-needed oxygenation of the blood. He had been studying the blood pressure, and had learned that, contrary to the statements in the books, these cases were apt to show a marked reduction in the blood pressure.

FACULTIES OF THE MIND, NOT UNDERSTOOD AND NOT USED, WITH SPECIAL REFERENCE TO THE CURABILITY OF EPILEPSY.

DR. M. A. VEEDER of Lyons presented an interesting, but theoretical, consideration of the subject.

VACCINATION AND THE LAW.

DR. NELSON G. RICHMOND of Fredonia read this paper. He said that a good deal of difficulty had arisen in interpreting the law regarding the vaccination of school children in cases in which repeated vaccination had proved unsuccessful. In this connection it was well to remember that the number of so-called immunes was becoming steadily less, and that not infrequently a vaccination would not "take" until several attempts had been made. A letter was read from Dr. John Thompson of Edinburgh, in which the opinion was expressed that the famous "conscience clause" in the English law had really accomplished the purpose for which it was intended, *i. e.*, a weakening of the opposition to vaccination.

DR. A. JACOBI of New York insisted that he had the right, as a citizen, to demand that the state should protect him by compelling his neighbors to be vaccinated.

OTITIC SEROUS MENINGITIS; LUMBAR PUNCTURE; RECOVERY.

DR. FRANCIS HUBER of New York read this paper. Lumbar puncture was done on two successive days, and improvement quickly ensued. By the end of three weeks the child was practically well. No tubercle bacilli were found in the cerebrospinal fluid.

DR. A. JACOBI thought this case was probably one of serous meningitis, and that there was no connection between this and the mastoid disease.

SYMPOSIUM ON THE ROENTGEN RAY — THERAPEUTIC USE.

DR. A. D. BEVAN of Chicago took this for the topic of the opening paper of this symposium. He directed attention to a novel and very interesting observation, *viz.*, that the internal use of iodide in conjunction with x-ray had proved potent for good in blastomycetic dermatitis. With regard to the use of the Roentgen ray in tuberculosis outside of tuberculosis, he could only say that this form of therapy was promising. The x-ray seemed to possess a selective action on the epithelial cells of epithelioma, and if the latter were situated within one centimeter of the surface, the mass would melt down and become absorbed under the influence of the Roentgen ray. The method was particularly applicable to growths about the lip and eyelid where removal by the knife would cause deformity, but in all other forms of carcinoma, particularly if rapidly growing, deeply situated or of considerable extent, the growth should be removed by the knife, and then a course of about twenty x-ray exposures given. The speaker suggested that perhaps by some modification of the treatment, such as the use of iodine or arsenic, it might be possible to so lower the vitality of the cancer cells as to bring them within the sphere action of the Roentgen ray, even though the cancerous growth were quite deeply situated.

DIAGNOSTIC VALUE OF THE ROENTGEN RAY.

DR. C. L. LEONARD of Philadelphia, Pa., read this paper. In it he paid particular attention to the use of the Roentgen ray in the diagnosis of calculus of the kidney and ureter. He said that out of 300 observations of this kind, the presence of calculi had been demonstrated in 28%; that in 50% of the latter the calculi were in the ureter, and that in 19 of the ureteral cases the calculi were passed spontaneously in accordance with the advice to postpone operation because of the result of the x-ray examination. Dr. Leonard pointed out that the variations in the vacuum of the tube, which occur in most x-ray tubes, led to penetration of the calculi and a disappointing result. He personally made use of a self-regulating tube which would maintain the vacuum at the same point throughout the entire exposure.

FURTHER OBSERVATIONS UPON THE TREATMENT OF SARCOMA WITH THE ROENTGEN RAY.

DR. W. B. COLEY of New York was the author of this paper. He stated that in the past year and a half there had come under his observation at the General Memorial Hospital 103 cases of malignant growths in which the Roentgen ray had been used. There were 30 recurrent carcinomata of the breast, 42 inoperable sarcomata and 25 superficial cancers. In only one of the 30 recurrent cancers of the breast had a deeply

seated growth disappeared under the Roentgen ray. Theoretically, the use of the x-ray to prevent recurrence was most promising, yet his own experience had not realized these expectations. The use of the Roentgen ray before surgical operation was dangerous, not only because it deceived the patient and encouraged delay in submitting to operation, but because after such treatment the operating surgeon could not determine the true limits of the growth. In Pusey's recent book the statement was made that 77% of cases were apparently cured by x-ray treatment, but the statement was misleading, because only 7 of the patients had gone over eight months, and only one beyond fifteen months since the treatment.

Dr. George G. Hopkins of Brooklyn thought his experience warranted him in stating that the x-ray was capable of curing the majority of cases of carcinoma of the breast.

Dr. W. E. Ford of Utica said that his observation of the effects of x-ray treatment in hospital led him to believe that the most it could do was to arrest for a time the growth of cancer of the breast, and that it absolutely failed in uterine cancer.

Dr. A. Van der Veer of Albany emphasized the value of the x-ray treatment as a means of affording relief to these sufferers.

Dr. Bevan thought it was possible to make a diagnosis of renal calculus in 90% of the cases by a proper use of the Roentgen ray. Better definition would be secured if the x-ray exposure were made through an aperture in a sheet lead shield, thus excluding extraneous rays. Similarly, the skiagraph should be examined in a darkened room, the light only entering through the plate, and the observer standing at a distance of about twenty feet and using a good opera glass.

Dr. Leonard said that he took care, when adjusting his apparatus, to see that the shadow of a possible calculus would not be superimposed on that of the bones of the pelvis.

Dr. Coley thought that statements like that made by Dr. Hopkins should not be allowed to go unchallenged, for, so far, there was not one well-authenticated case on record in which the x-ray alone had effected a cure of malignant disease of the breast.

RADIUM IN MEDICINE.

Dr. Samuel G. Tracy of New York presented in this paper a brief sketch of the physical, chemical and physiological properties of radium.

THE LEGAL STATUS OF THE ROENTGEN RAY.

Hon. William W. Goodrich, Presiding Justice Appellate Division, Supreme Court and Judicial District, delivered an address on this topic. He said that the first time x-ray photographs had been admitted as legal evidence was in Colorado in 1896, but that they had since been admitted in several states. In Kings County a complete x-ray apparatus had been exhibited in court. The competency of such evidence depended upon the science, skill, experience and intelligence of the party making the x-ray photograph and testifying.

SPECIAL MEETING OF THE STATE SOCIETY.

A special meeting of the State Medical Society was called for the evening of Oct. 13, to consider what should be done towards bringing about the unification of the profession of this state. A large and representative audience was present. After reviewing the situation, the president, Dr. A. T. Bristow, said that the State Association had recently appointed a committee of conference with full power, and had requested the State Society to give its committee similar power.

Dr. D. B. St. John Roosa of New York then moved the adoption of the following resolution:

"*Whereas*, The New York State Medical Association, at a recent special meeting, duly assembled, has, by unanimous vote, appointed a committee with full power to meet with the similar committee of the Medical Society of the State of New York to arrange for the unification of the two organizations under the corporate name of The Medical Society of the State of New York; Therefore be it

"*Resolved*, That the committee of conference of the Medical Society of the State of New York, already appointed, be given power equal to, and commensurate with, the powers recently granted the committee created by the New York State Medical Association for the purpose of unifying the two State Medical Societies into The Medical Society of the State of New York."

The motion was seconded by Dr. Willis G. MacDonald of Albany and the resolution was unanimously adopted amid great enthusiasm.

Second Day — Wednesday, Oct. 14.

THE NEW YORK STATE HOSPITAL FOR INCIPIENT TUBERCULOSIS.

Dr. Willis G. MacDonald of Albany described the hospital and exhibited plans of the same. The construction was quite novel, but retained all the advantages of the cottage plan, while providing, by a system of isolated apartments, the necessary protection from the rigors of the Adirondack climate. As regards the amount of sunshine, the speaker said that it had been determined by actual survey that, on the shortest day of the year, the sun would reach the porch at 8.45 A.M. and would not leave that porch entirely until 4.45 P.M. The base line of the hospital was 1,639 feet above the sea level. Patients would be placed in single rooms until sufficiently improved to make it proper for them to be placed in the small dormitories. When they were thoroughly convalescent they would be placed in a camp where, for about nine months of the year, they would live in tents or open barracks. While there was abundant sleeping space for 108 patients in the hospital, it was estimated that by the method of distribution outlined above, from 160 to 180 patients could be accom-

modated, the necessary room in the very cold months being secured, if need be, by temporarily refusing to admit new patients. The hospital, although larger than the Adirondack Sanitarium, and well constructed, would cost only $212,000, or less than half that of the sanitarium.

(To be continued.)

Recent Literature.

Portfolio of Dermochromes. By PROFESSOR JACOBI of Freiburg im Breisgau. English adaptation of text by J. J. PRINGLE, M.B., F.R.C.P., Physician to the Department for Diseases of the Skin, Middlesex Hospital, London. London and New York: Rebman, Limited. 1903.

Two of the four proposed parts of this atlas of the more common skin diseases have been published and lie before us. The avowed object of the work is not to depict the rarer forms of cutaneous disease, as is the aim of many atlases, but "to furnish to medical men, teachers and students a handy and comprehensive series of illustrations of the skin diseases most frequently met with in practice." The process employed is known as Citochromy, invented by Dr. Albert of Munich. Most of the illustrations are pictorial reproductions, by means of the process above mentioned, of models in the Breslau clinic, lent by Professor Neisser. They are, for the most part, very faithful counterparts of the diseases they represent, and the color scheme is lifelike. A few, *verruca necrogenica*, for example, are slightly disappointing. On the whole, the two parts already published are to be greatly commended. The announcement refers to the moderate subscription price, which it is thought will bring the work within the reach of all general practitioners and students.

A Chart of the Three Great Systems. Arterial, Venous and Nervous, together, in a Full, Living Human Figure. Lithographed in Five Colors.

As implied in the title, this chart, some two feet in width by three feet in length, is intended to represent graphically the course of the arteries, veins and nerves, together with a certain number of the internal organs. Bordering the human figure, upon which these anatomical structures are represented, is a brief descriptive text. Such a chart has a certain value in representing topographically the relations of these important elements of the body. It is, however, open to criticism from the fact that rather too great a complexity of detail has been introduced in representing particularly arteries and veins. The chart is to be recommended as a ready means of refreshing one's memory on certain anatomical points, but we can hardly agree with the prospectus, which suggests that it is suitable for use as a picture in the office or waiting room of a physician.

THE BOSTON

Medical and Surgical Journal

THURSDAY, NOVEMBER 5, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published a Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE THERAPEUTIC POSSIBILITIES OF RADIUM.

ALTHOUGH it is as yet too soon to say with certainty what the future possibilities of radium and allied substances are to be in therapeutics, it is evident, from the extraordinary properties of these substances and the experiments which have already been made, that we may look in the near future for positive practical results. Since the discovery of radium and polonium in 1898 by Professor and Madame Curie, naturally a great amount of work has been done in determining the properties of these hitherto unknown substances. The enormous expense of radium, owing to the highly adulterated state in which it is found, and the consequent difficulty of obtaining a pure product, has prevented as yet experiments on a large scale. There can, however, be no question that the resources of scientific laboratories will be brought to bear in such a way that the substance may be produced in sufficient quantities to render general experimentation possible.

Up to this time it appears that radium has certain qualities hitherto unknown to chemical physics. For example, it gives out heat constantly, and is the source of a high degree of energy. It is capable of rendering active, substances with which it is brought into contact; it has marked physiological effects; it is fatal to life under certain conditions; and finally it is apparently curative of certain pathological conditions. An idea of the energy of radium may be had from the statement made by Professor Curie that it maintains its temperature at 1.5° C. above its surroundings, which is equivalent to saying that the heat evolved from pure radium is sufficient to melt more than its own weight of

ice every hour. The facts that this evolution of heat is constant, and that radium loses none of its activity in consequence of its emanation, are the matters of interest confronting the scientific world. The character of the rays given off from the substance is as yet somewhat undetermined, but at least three varieties have so far been distinguished. In consideration of the extraordinary properties to which we have alluded, it is not a source of wonder that animal life is positively affected by the presence of the substance. Animals exposed to the salt contained in a closed tube succumb to its effects in varying periods, depending upon the time of exposure, after undergoing certain cutaneous and nervous changes. Apparently, also, the salt is capable of checking the normal development of the lower forms of animal life, as, for example, preventing the transition from the larval to the adult form in certain worms.

All this suggests at once the possible danger in the therapeutic use of the substance, and also its utility when properly controlled. Naturally experiments up to this time in treatment of diseased conditions have been few, owing to the very great difficulty of obtaining the substance. In the *British Medical Journal* for July 25, Mr. John Macintyre writes briefly in continuation of a previous article on work which he has done. He found that lupus and rodent ulcer were very favorably affected by exposure to the rays. Mr. Frederick Soddy also suggests the possibility of applying the rays of radium and thorium to the treatment of consumption. The theory being that inhalation of radium solution gives rise to the formation of a film of radio-active matter which persists for a certain definite time, it is conceived possible that radium would continue to exert its activity in the air cells of the patient's lung after the emanations themselves had been exhaled.

All this is to a certain extent theoretical as yet, but, in view of the extraordinary impetus which has been given to the therapeutic action of various little understood rays and emanations by the introduction of the x-ray, we have no right to assume any other attitude than one of expectant anticipation. It is perfectly clear that radium and the various substances which apparently are related to it have a definite physiological action on animal tissues. Tnis being the case, it remains, as in other therapeutic matters, to determine sharply between the limits of danger and benefit. That this will be done experimentally in the near future, there can be no reason to doubt, and we are certainly not too optimistic when we express the belief that new and serviceable therapeutic agents, through such investigations, will be found for a goodly number of human ills.

BEHRING ON TUBERCULOSIS.

We have referred in our columns to the experiments which Behring has recently carried on in the immunization of calves to tuberculosis. At the annual meeting of German Scientists and Physicians held at Cassel in September last, Behring amplified his views to a considerable extent. He again reported unqualified success in the vaccination, as he terms it, of young calves against tuberculosis by the injection of attenuated cultures of living human tubercle bacilli into their veins. His methods have been adopted on many large estates in Germany and Austria, and the demand for material has outgrown his capacity to furnish it, so that henceforth it will be put on sale. This method of immunization has recently been confirmed in Koch's Institute. Behring is confident that the extermination of tuberculosis in cattle is simply a matter of time.

The universality of tuberculosis received much emphasis from the speaker. He quoted Naegeli's observations in Zurich. Naegeli was able to demonstrate tuberculosis at the autopsy table in all bodies above the age of thirty. This is in striking harmony with Franz, who proved the presence of the disease in sixty per cent of the cases which he tested with three milligrams tuberculin and in ninety-six per cent of the cases tested with ten milligrams. In thickly settled communities practically the whole adult population is tuberculous. But tuberculous infection does not mean consumption. The case is analogous to diphtheria before the antitoxin days — the mild cases lived, the severe died.

Infection takes place in infancy. The gastro-intestinal tract of infants, as of young animals, lacks protective qualities and allows the passage of tubercle bacilli. Those entering the body are stored away till a favorable opportunity for further development offers, which is afforded by lowered vitality and unhygienic modes of life. Convalescence from the acute exanthemata and injuries to the mucous membrane afford chances for later infection. In Behring's opinion infection by inhalation is unimportant. Behring hopes eventually to take advantage of the easy permeability of the infantile digestive tract by

immunizing infants with the milk of highly immunized cattle. As yet he has done no work in this direction.

Behring takes issue with Koch by asserting that the human and bovine forms of tubercle bacilli are simply different grades of the same species. He therefore further believes that the greatest care should be exercised in securing milk which is uncontaminated with tubercle bacilli. He points out how easily it may become infected. The prevention of the spread of tuberculosis, according to Behring, depends on the precautions taken to get pure milk and the annihilation of bovine tuberculosis. These two measures attained, sanitaria will become superfluous.

THE AMERICAN SOCIETY OF CLINICAL SURGERY.

THE American Society of Clinical Surgery will hold its first meeting in Baltimore and Philadelphia on Nov. 13 and 14.

The methods proposed by this new organization should prove interesting and instructive. Among medical societies they are original, so far as we are aware. For many years it has been growing increasingly evident that the old-time didactic lectures were inefficient in themselves properly to train students for practice. Supplementary clinical exercises and practical, personal instruction have come in large measure to supplement the old-time lectures.

With that thought as their guide a number of surgeons throughout the country have formed this new society for mutual improvement in surgical practice and teaching. As the letter of announcement states, these objects shall be sought by affording members opportunities of demonstrating actively and personally advances in surgery and of showing the results of recent work, clinical, pathological and of any other nature susceptible of demonstration; the meetings shall be broadly clinical, and few if any formal communications shall be allowed.

For some years back we have been wont to see active surgeons making annual pilgrimages about the country, visiting the clinics in various centers and keeping in touch with the best work of the broader community. So the new society will become for such men a labor-saving device. They will travel about in the companionship of their fellows, and in the towns visited the best work only will be shown for their inspection: operative procedures; new technique, laboratory methods, — anything of that nature which lends itself to demonstration. It should all be interesting and practical, and stand beyond peradventure for work actually accomplished.

It is proposed to hold two meetings yearly, in November and March, each meeting to last from two to four days; and the meetings are to be migratory, the members passing from one neighboring town to another on successive days.

The experiment is a novel one, and its progress will be watched with interest.

MEDICAL NOTES.

AMERICAN PUBLIC HEALTH ASSOCIATION. — The next annual meeting of the American Public Health Association will be held in Havana.

THE COST OF TYPHOID FEVER DURING A CAMPAIGN. — It is estimated that the cost to the British Government of typhoid fever during the South African campaign was not less than £4,000,000. This calculation is on a basis of 31,018 cases and each case as occurring in the cheapest trained infantry soldier. Of this total, 6,172 died ; 15,120 were invalided home ; 9,726 convalesced in South Africa.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Nov. 4, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 63, scarlatina 20, typhoid fever 21, measles 80, smallpox 0.

ACCIDENTAL POISONING AT THE TEWKSBURY HOSPITAL. — During the night of Oct. 27 eleven inmates of the State Hospital at Tewksbury accidentally took belladonna in dangerous amount. Careful investigation is being made of the accident, and Dr. Nichols, superintendent of the hospital, has made the statement that the patients received prompt medical aid and that no fatalities have resulted. The patients will undoubtedly recover. Dr. Nichols very wisely declines to make statements in the matter, pending a proper investigation.

LOSS OF LIFE IN GLOUCESTER FISHING FLEET. — It is reported that 75 lives and 6 vessels have been lost in the Gloucester fishing fleet during the last year, with a total financial loss of $82,500, partially insured. Of the 75 men lost 20 left widows with an aggregate of 49 children. It is furthermore stated that during the past twenty-five years upwards of 2,300 lives have been lost, and that since 1830 over 5,000.

Officers of the Massachusetts Charitable Eye and Ear Infirmary. — At the annual meeting of the Massachusetts Charitable Eye and Ear Infirmary, held Oct. 27, the following officers were elected: President, Dr. George B. Shattuck; secretary, Robert Homans; treasurer, Augustus Hemenway; executive committee, George P. Gardner, Charles Lowell, William H. Seabury; finance committee, Charles P. Curtis, Charles Lowell and Francis L. Higginson.

A Unique Bequest. — It is reported that the Northampton Insane Asylum has recently acquired a fund of $500, left in the will of a former inmate, the income of which is to be used to buy tobacco for inmates. The hospital is said to have accepted the conditions of the bequest.

NEW YORK.

Shoe Leather Cure for Consumption. — A good illustration of the efficacy of the "shoe-leather cure" for consumption, which may be commended to other patients in suitable instances, is afforded in the case of a gentleman pronounced to have pulmonary tuberculosis who recently arrived in New York after walking all the way from San Francisco. During his tramp of three thousand miles, which occupied a little more than two years, he wore out sixty-one pairs of shoes. The result appears, however, to have been eminently satisfactory, as it is stated that he is now "a well man, with increased weight, good digestion, firm muscles and clear brain."

The Ms. of "Ten Thousand a Year." — By the will of the Rev. Edward Walpole Warren, late rector of St. James' Protestant Episcopal Church, New York, which has just been filed for probate, the original manuscript of the famous novel, "Ten Thousand a Year," by his father, Samuel Warren of London, is left to his son, A. Kennedy Warren, as an heirloom. Under the terms of the bequest the latter is forbidden to sell the manuscript without the consent of the other children, and then only in case of necessity. If that necessity arises, the British Museum is to have the first opportunity of purchase.

Damages for Railroad Injuries. — In the suit of Catharine Reddy of Yonkers on the Hudson, against the New York Central Railroad for $100,000 damages, which has been on trial before Judge Gaynor of the Supreme Court at White Plains, Westchester County, the jury on Oct. 26 brought in a verdict of $50,000 for the plaintiff. This is said to be the largest verdict ever rendered in the State of New York to a woman for railroad injuries. Mrs. Reddy was badly injured in a wreck on the New York Central at Fancher, a town near Niagara Falls, and had to be carried into court on a chair.

The Pure Food Law. — With a view to expediting the examination of goods under the pure food law, it has been determined by Dr. Wiley, after a conference with the Treasury Department officials, to detail two experts for this work in New York. One of these is to select samples of goods liable to adulteration, and the other will make the necessary tests in the laboratory connected with the New York Custom House.

Obituary.

IN MEMORIAM — M. F. PILGRIM, M.D.

At a meeting of the Faculty of the New York School of Physical Therapeutics, the following resolutions were unanimously adopted:

Whereas, Death has removed from us our esteemed associate and confrère, Dr. Maurice Fiescher Pilgrim, whose faithful service as a teacher in the school, marked by keenness of thought, earnestness of conviction, honesty of purpose, loyalty and kindness of personality endeared him to all his fellow workers.

Be it resolved, That we, members of the Faculty of the New York School of Physical Therapeutics, extend to his bereaved family and friends sympathy and condolence, and, in token of this esteem, the secretary be instructed to forward a copy of these resolutions to his family, and to forward them for publication in *The Journal of Advanced Therapeutics, New York Medical News, American Medicine, Journal of the American Medical Association, New York Medical Journal* and *Boston Medical and Surgical Journal*.

Hermann Grad, M.D.,
Secretary.

Miscellany.

DYSENTERY AND ITS RELATIONSHIP TO TYPHOID FEVER.

In August, 1900, the British Secretary of State for War appointed a commission to go to South Africa and investigate the nature, pathology, causation and prevention of dysentery and its relationship to enteric fever. The investigation was divided into two parts: (*a*) laboratory work; (*b*) inspection of camps, water supply, etc.

The following are the conclusions under Division One (*a*) of the investigation:

(1) Dysentery in South Africa is not caused by amebæ, as there is some reason to believe is the case with the dysentery of certain other countries.

(2) That the organs in dysentery are abso-

lutely sterile. It is a local disease attacking the mucous and sub-mucous coats of the large intestine, and unlike enteric fever, the causal agent, if any, confines itself to the intestines.

(3) That in the large intestines no particular species of micro-organism stands out prominently as in the case of cholera, so that it is impossible in the present stage of the investigation to say that any special bacterium plays a prominent part in the causation of dysentery.

(4) That there is not sufficient evidence in this work to bring forward the theory that some of the normal inhabitants of the intestines belonging to the coli group take on a pathogenic power.

(5) That there is no connection between dysentery and enteric fever. Eberth's bacillus is not found in the organs or intestines of dysentery.

(6) That there is a certain amount of evidence to show that so-called cases of dysentery following enteric fever are relapses of enteric, where the disease has attacked the large intestine.

Under the Second Division (*b*) of the investigation we find the following summary of views as to the probable causes of the prevalence of enteric fever and dysentery in the army of South Africa:

(1) That in the absence of a fuller knowledge of the nature of dysentery, it is sufficient to regard both this disease and enteric fever as being essentially filth diseases, and both due to bacillary organisms intimately associated with and given off by the excretory products of men and animals. Further, that as far as their general etiology is concerned, both diseases may be considered to have a common origin.

(2) That the prevalence of enteric fever and dysentery among the troops in South Africa cannot be explained as being due in all cases to any one specific insanitary condition, but that various conditions contributed to the incidence and dissemination of these diseases in different places.

(3) That in some places these diseases were carried by the use of foul water (notably water from public supplies) which had been polluted, not only by the excreta of men and animals, but also by the decomposing bodies of animals.

(4) That in many places where enteric fever and dysentery were specially prevalent, the condition of the water supplies was insufficient to explain the occurrence of these diseases, but that in those cases it could be accounted for by the influence of close aggregation of men and animals in small encampments, fouling of the soil, the occurrence of personal infection, the effects of the swarms of flies which covered food, the men themselves, their clothing, and haunted the latrines and other places for disposal of refuse.

(5) That the influence of impure water, aggregation in crowded camps, fouling of soil, the prevalence of flies as carriers of specific filth, was accentuated by the preponderance of young men in the ranks and by the exhausting nature of the military work which these young soldiers had to perform.

(6) That notwithstanding the greatest care and precautions for the safeguarding of the generally accepted sources of these diseases, it is practically impossible to completely prevent their occurrence in an army hastily mobilized, operating in a country in which water is scarce, and whose ranks are largely filled with young men at an age notoriously liable to be affected by diseases of this nature.

(7) That in spite of the many difficulties favoring the incidence of enteric fever and dysentery in an army of young soldiers in the field, much can be done to lessen both the incidence and mortality from these affections by suitable and adequate sanitary measures.

Correspondence.

CONCERNING "EXTREMISM."

PHILADELPHIA, Oct. 31, 1903.

MR. EDITOR: In a previous number I had asked you for specific illustrations of what you were pleased to call my "extremism" and "overworked theory." Concerning the courtesy and impolicy of editorial criticism of a contributor's views, that is of course *de gustibus*, and of course, mere general charges, glittering generalities, as regards extremism are reducible to, "You think one way, I another." Referring to definite examples of my "overworked theory" you give:

(1) An implied denial of my accuracy in saying that I have cured thousands of patients of sick headache — on the average $\frac{99}{100}$ of such patients. You cite "the experience of others with migraine." That is not the question at issue. If I have erred in observation and logic, unintentionally, as regards my own cases, it does not prove me wrong to cite vaguely the experience of others. If I have been untrue it would prove me unscientific. My case records, and any number of patients you please, may be inspected. That is the only way to prove me unintentionally wrong. I do not understand you charge me with willful misstatement.

(2) As to refraction by the Germans. Every American oculist who is not doing the same kind of work as they, knows well that what I have stated is absolutely true. This has long ago been thrashed out. The proofs are beyond all question that on the Continent there is no knowledge, desire or ability to do the kind of refraction work that we are doing in this country. All the conditions of success are utterly ignored. I will cite but a few facts:

(*a*) I have had many patients who had consulted the greatest oculists of Europe. Their prescriptions and their glasses were ludicrously wrong — the evidences of mere blunderings and guess-work.

(*b*) In an exhaustive monograph by Möbius on the ill-health of Nietzsche, fresh from the press, there is the evidence that the author and his colleagues know nothing about the existence of astigmatism or of its power to produce even the simplest reflex of headache.

(*c*) The latest edition of the best German work on diseases of the eye — Fuchs — is utterly wanting in its teaching as to all the essentials of accurate diagnosis and treatment of astigmatism and anisometropia, and the American editor felt it necessary to indicate the fact. Following only this great authority the refractive error of a patient could not be rightly diagnosed by the most expert refractionist.

It is not here a question of "fairness;" it is one of truth and accuracy of statement.

(3) Neither do I care for "judicial quality" in the sense charged, for it is to me usually very injudicious. Much of our editorial writing and textbook-making in medicine is thus injudicious — a *dilettante* averaging of conflicting opinions and taking some meaningless compromising, middle course, with no close scrutiny whatever of the facts. How much of our literature is this sort of word-making, opinion-mongering, theorizing, dealing

with ideas, avoiding extremes, — colorless echoings and fused repetitions! The essence of science is correct observation of facts and logical conclusions from them. I repeat that for twenty-eight years there has been no medical blunder and crime against both science and humanity equal to that of the willful ignoring of the rôle of eyestrain by the profession. Concerning the "unprejudiced statements" as to this professional neglect, I am not a defender of such errors because I am a journalist or a member of the erring profession.

Respectfully yours,

GEO. M. GOULD.

SCABIES AND IMPETIGO CONTAGIOSA.

BOSTON, Oct. 30, 1903.

MR. EDITOR: Although communications have from time to time appeared in the JOURNAL calling the attention of general practitioners and those who include the treatment of cutaneous affections in their practice to the modern prevalence of scabies in this community, it would seem probable, from the experience of dermatologists, that a large number of practising physicians, in particular those whose hospital and dispensary work dates back to an earlier period, are still unaware of the present frequency of this affection, especially among the more cleanly classes. That it is not uncommon for this disease to be overlooked in the better classes, and for lack of simple and appropriate treatment to be allowed to continue for an indefinite period, thus affording a chance for its continuous propagation to new subjects, is an undoubted fact. In any affection accompanied by much pruritus, and not exhibiting the type of some other well-defined dermatosis, the *possibility* of scabies should always be entertained, no matter how cleanly and above reproach may be the person and surroundings of the patient. Abundant opportunity for acquiring scabies is offered to those who travel or camp out, and once acquired it may be innocently transmitted to many others. As an illustration of its frequency of late, the following figures are cited, which represent the number of new cases observed during the last month at the Out-Patient Department of the Massachusetts General Hospital.

During the week beginning Sept. 28, 15 cases.
During the week beginning Oct. 5, 13 cases.
During the week beginning Oct. 12, 7 cases.
During the week beginning Oct. 19, 15 cases.

In other words, an average of two new cases a day has been recorded, and in most of these instances a history of a probably similar condition in one or more members of the patient's family has been obtained. And it should be further emphasized that these patients were by no means always of the more uncleanly class; in fact, the average of cleanliness was quite as high as that of the other patients treated at this institution.

Another cutaneous affection that may be referred to in this connection is impetigo contagiosa, meaning by this unfortunately long term the local, superficial, cutaneous abscess caused by the pyogenic micro-organisms. Formerly most of these cases were roughly grouped with the pustular forms of eczema, with which latter affection they are sometimes complicated. Apart from the common form observed in young children, which is usually seen in the form of superficial, as if "stuck on" crusts, common about the mouth, nose and ears, and often associated with pediculi capitis, cases in older children and in adults are frequently seen, of a more discrete rounded type, and sometimes looking at first sight not unlike ringworm. This form is not infrequent on the bearded face, in people whose habits of cleanliness are most scrupulous. Frequently this form appears as an epidemic in workshops, schools and factories. During the past week two such epidemics have been observed, one in the workmen employed in a machine shop and a second in a private school for boys of the first rank. Both scabies and impetigo contagiosa belong to the affections that are, as a rule, easily and quickly cured when recognized, and also to the class of affections that may be widely disseminated if allowed to remain without appropriate treatment.

Very truly yours,

JOHN T. BOWEN, M.D.

RECORD OF MORTALITY
FOR THE WEEK ENDING SATURDAY, OCT. 24, 1903.

Deaths reported, 2,925; under five years of age, 830 (Pittsburgh not reporting); principal infectious diseases (smallpox, measles, scarlet fever, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 746, acute lung diseases 263, consumption 354, scarlet fever 12, whooping cough 9, cerebro-spinal meningitis 7, smallpox 17, erysipelas 1, puerperal fever 7, measles 9, typhoid fever 57, diarrheal diseases 169, diphtheria and croup 103.

From whooping cough, New York 3, Philadelphia 2, Chicago, Pittsburg, Boston and Gardner 1 each. From erysipelas, New York 1. From smallpox, Pittsburg 9, Philadelphia 8. From measles New York 7, Boston and Providence 1 each. From cerebro-spinal meningitis New York 3, Boston 2, Baltimore and Watertown 1 each. From scarlet fever Chicago 3, New York, Philadelphia and Providence 2 each, Baltimore, Pittsburg and New Bedford 1 each.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Oct. 10, the death-rate was 15.8. Deaths reported, 4,554; acute diseases of the respiratory organs (London) 146, whooping cough 46, diphtheria 45, measles 34, smallpox 5, scarlet fever 42.

The death-rate ranged from 4.7 in Hornsey to 24.0 in Bootle, London 15.8, West Ham 5.7, Brighton 12.1, Portsmouth 19.8, Southampton 13.7, Plymouth 16.8, Bristol 12.0, Birmingham 17.7, Leicester 14.7, Nottingham 16.3, Bolton 18.0, Manchester 19.2, Salford 17.3, Bradford 14.2, Leeds 16.5, Hull 14.8, Newcastle-on-Tyne 21.1, Cardiff 13.0, Rhondda 13.9, Liverpool 19.1, Handsworth 9.1, Middlesbrough, 21.4.

METEOROLOGICAL RECORD.

For the week ending Oct. 24, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE TWENTY-ONE DAYS ENDING OCT. 22, 1903.

BAILHACHE, PRESTON H., surgeon. Detailed to represent the service at meeting of the American Public Health Association at Washington, D. C., Oct. 26. Oct. 15, 1903.

CARMICHAEL, D. A., surgeon. Granted leave of absence for thirty days from Oct. 16. Oct. 5, 1903.

KALLOCH, P. C., surgeon. Granted leave of absence for three days. Oct. 5, 1903.

WHITE, J. H., surgeon. To proceed to Gulf Quarantine Station and assume temporary charge. Oct. 8, 1903.

CARRINGTON, P. M., surgeon. Two days' leave of absence from Oct. 15, 1903, under paragraph 189 of the regulations.

MAGRUDER, G. M., surgeon. Granted extention of leave of absence, on account of sickness, for two weeks from Oct. 7. Oct. 13, 1903.

WERTENBAKER, C. P., passed assistant surgeon. To proceed to Beaumont and Houston, Texas, for special temporary duty. Oct. 2, 1903. To proceed to El Paso, Texas, for special temporary duty. Oct. 5, 1903.

PERRY, J. C., passed assistant surgeon. To proceed to Charlestown, W. Va., for special temporary duty. Oct. 12, 1903.

NYDEGGER, J. A., passed assistant surgeon. Bureau letter of Sept. 4, granting Passed Assistant Surgeon Nydegger leave of absence for one month from Sept. 13, 1903, amended so that said leave shall be for one month from Sept. 23. Oct. 10, 1903. Granted leave of absence for ten days, on account of sickness, from Sept. 13. Oct. 13, 1903.

MATHEWSON, H. S., passed assistant surgeon. Department letter of Sept. 23, granting Passed Assistant Surgeon Mathewson leave of absence for forty-five days from Sept. 22, amended so that said leave shall be for forty-five days from Oct. 3. Oct. 7, 1903.

GRUBBS, S. B., passed assistant surgeon. Granted leave of absence for five days. Oct. 8, 1903.

LUMSDEN, L. L., passed assistant surgeon. To proceed to Beaumont, Texas, for special temporary duty. Oct. 2, 1903. To proceed to Eagle Pass, Texas, for special temporary duty. Oct. 5, 1903. To proceed to El Paso, Texas, and assume temporary charge of the station. Oct. 13, 1903.

ANDERSON, J. F., passed assistant surgeon. To proceed to Baltimore, Md., for special temporary duty. Oct. 1, 1903.

FRICKS, L. D., passed assistant surgeon. Granted leave of absence for one month from Nov. 1. Oct. 17, 1903.

RICHARDSON, T. F., assistant surgeon. To proceed to San Antonio, Texas, for special temporary duty. Oct. 21, 1903.

FRANCIS, EDWARD, assistant surgeon. To proceed to the City of Mexico, Mex., for special temporary duty. Oct. 6, 1903.

BAHRENBURG, L. P. H., assistant surgeon. Granted leave of absence for seven days from Oct. 14, 1903, under paragraph 191 of the regulations. Granted extension of leave of absence for seven days from Oct. 22. Oct. 17, 1903.

FORD, C. B., acting assistant surgeon. Granted leave of absence for three days from Oct. 24. Oct. 22, 1903.

JACKSON, J. M., acting assistant surgeon. Granted leave of absence for thirty days from Oct. 5. Oct. 9, 1903.

SIBREE, H. C., acting assistant surgeon. Granted leave of absence for six days from Oct. 6. Oct. 6, 1903.

STANTON, J. G., acting assistant surgeon. Granted leave of absence for thirty days from Oct. 10. Oct. 13, 1903.

BROWN, F. L., pharmacist. To proceed to St. Louis, Mo., and report to medical officer in command for temporary duty. Oct. 10, 1903.

GOODMAN, F. S., pharmacist. To proceed to Laredo, Texas, and report to Surgeon G. M. Guiteras for special temporary duty as special disbursing agent. Oct. 2, 1903.

WOODS, C. H., pharmacist. To rejoin station at Chicago, Ill. Oct. 10, 1903.

MASON, M. R., pharmacist. Relieved from duty at Nome, Alaska, and directed to proceed to San Francisco, Cal., and report to medical officer in command for duty. Oct. 8, 1903.

PROMOTIONS.

G. A. MORRIS, pharmacist of the third class. Promoted to be pharmacist of the second class, effective Sept. 5. Oct. 3, 1903.

CHARLES NAPLES STEGER. Recommissioned as assistant surgeon in the Public Health and Marine Hospital Service to correct original commission, effective Sept. 16. Oct. 12, 1903.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING OCT. 31, 1903.

C. N. FISKE, passed assistant surgeon. Commissioned passed assistant surgeon, with rank of lieutenant, from May 15, 1903.

E. T. MORSE, pharmacist. Detached from Navy Yard, Boston, Mass., and to the Navy Yard, Portsmouth, N. H.

D. N. BERTOLETTE, medical inspector. Detached from duty at Naval Dispensary, Washington, D.C., and to continue other duty.

F. L. PLEADWELL, surgeon. Detached from the "Kearsarge" and to duty at the Naval Dispensary, Washington, D.C.

C. H. T. LOWNDES, surgeon. Detached from Naval Hospital, Boston, Mass., and to the Naval Academy, Annapolis, Md.

J. J. SNYDER, passed assistant surgeon. To the "Kearsarge."

KARL OHNESORG, assistant surgeon. Detached from the Naval Academy and to the Naval Hospital, Boston, Mass.

H. A. DUNN, assistant surgeon. To the Naval Proving Ground, Indian Head, Md.

SOCIETY NOTICES.

NEW YORK STATE ASSOCIATION OF RAILWAY SURGEONS. — The Thirteenth Annual Meeting will be held in the New York Academy of Medicine, Thursday and Friday, Nov. 12 and 13, 1903.

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL. — The trustees of the New York Orthopedic Dispensary and Hospital announce that the surgeon-in-chief, Dr. Russell A. Hibbs, will give a course of clinical lectures on orthopedic surgery at the institution, on Tuesday and Thursday afternoons, at four o'clock, from Nov. 10 to Dec. 15 (both inclusive). The course will be free to the medical profession and students. No lecture will be given Thursday, Nov. 26.

J. ARCHIBALD MURRAY,
Chairman Committee on Clinical Instruction.

NEW YORK STATE CIVIL SERVICE COMMISSION. — Examinations for Superintendent and Resident Physician in the New York State Hospital for the treatment of incipient pulmonary tuberculosis. The State Civil Service Commission will hold open competitive examinations for the above-mentioned positions, Nov. 28, 1903, in various cities throughout the state. Intending competitors must fill out application blanks and file them in the office of the Commission before noon of Nov. 23. Applicants will be duly notified of the time and place of examination. Non-residents of the state will be admitted. For further particulars and application blank, address Chief Examiner,

STATE CIVIL SERVICE COMMISSION,
Oct. 29, 1903. Albany, N. Y.

THE AMERICAN SOCIETY OF CLINICAL SURGERY. — The first meeting of this Society will be held in Baltimore and Philadelphia, Nov. 13 and 14, 1903.

APPOINTMENTS.

DR. WALTER C. HOWE and DR. DAVID D. SCANNELL have been appointed Third Assistant Visiting Surgeons at the Boston City Hospital, dating from August.

BOOKS AND PAMPHLETS RECEIVED.

A Manual of Hygene and Sanitation. By Seneca Egbert. A.M., M.D. Third Edition. Enlarged and thoroughly Revised. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

The Proper Perineal Prostatectomy Incision. By Nicholas Senn, M.D., of Chicago, Ill. Reprint. 1903.

Address.

PRESENT PROBLEMS — AN ADDRESS TO THE NURSES OF THE LAKESIDE HOSPITAL.[1]

BY J. G. MUMFORD, M.D., BOSTON,

Assistant Visiting Surgeon, Massachusetts General Hospital.

Good nurses are born for their work.

Poeta nascitur, non fit is as true of you as it is of the lawyers, doctors, ministers and policemen. You can manufacture out of the most unpromising material a good engineer, or carpenter, or sailor, or even janitor; but when it comes to those persons whose work depends on their contact with other people, who deal in personal equations and not in impersonal figures — then there enters into the problem a new and wonderful group of elements which are a part of the birthright of some, while the others without them stagger through life, blind, puzzled, indignant with the fates: tact, humanness, womanliness, manliness, the appreciation of proportion, the attribute of "sweet reasonableness," the rare sense of humor. And of course you are to take this reflection as meaning that some of us are better workmen than are others. To him that hath, is as true as ever it was, but we should have to despair indeed if we were to believe that from him that hath not shall be taken away even that which he hath.

You trained nurses have had your place in the world's work now for more than a generation, and it seems to me it is time to look about occasionally and ask what you have made of yourselves.

I have heard and read many addresses given to nurses on such occasions as this, and in the main the speakers have devoted themselves to two topics — your usefulness and your education. Nurses have been told a thousand times that theirs is the noblest of professions; that nursing is woman's true sphere. Poets have been invoked to demonstrate that by day you comfort the sick, by night you soothe the dying. *Weeping willows* have been made to rhyme with *lonesome pillows*, and the rest of it.

It's all true enough. No one appreciates it all more than I do. It *is* a noble profession, and the good you do is beyond measure.

Then there is that other subject — your education. That is a great subject. You have begun it well here in this training school, but the most important part is to come, and I want to talk with you in some fashion about that.

At the outset of your work in life after leaving the training school, you are in a position quite different from that of any other professional people known to me; you are equipped for practice and you assume at once the full standing of the experienced workman. You are deemed — for so tradition has arranged it for you — as competent as the women who have grown gray in harness. You expect as a right the maximum wage, — twenty-one or twenty-five dollars a week, or whatever the sum may be in your particular locality, — and as a general thing you get no less. Did it ever occur to you what that state of affairs may mean? Try to apply the same principle to other professions or trades, if such a conception is possible. What would you say if you had to pay a young journeyman plumber or carpenter the same wages that you pay the master craftsman? How readily would you call in the youthful doctor or lawyer if his fees were those of the eminent specialist or jurist? The thought is inconceivable. But you will say there is no parallel in the two cases; the young nurse is equipped for her work as well or better than the old one. The nurse fresh from the hospital is likely to be better than the nurse grown stale. She is familiar with the latest methods; she knows the new drugs and the new instruments; she has served only with physicians who are leaders in their several departments; she is keener, more alert, more interested. All that is so true that it seems unanswerable, but if followed to its logical conclusion it means this — that the younger the nurse, the better the nurse; the older the nurse, the worse the nurse. Is that a pleasant prospect? Is that creditable to a noble profession? The youngest nurse is best for the community, if you choose to put it so, but is that a condition best for the nurse herself? I have had old nurses — women with fifteen or twenty years' experience — come to me complaining bitterly that their practice was leaving them, that their old patients never sent for them, that the doctors no longer employed them. We have in Boston an institution called "A Home for Aged Women," part of the income of which is specifically devoted to helping women who have grown old in the care of the sick. That fund is called the Doane Fund, and I assure you the beneficiaries under the Doane Fund are but a fraction of those needy ones who clamor for relief.

All this is a very serious business; it is not a cheerful topic to air before you as you start generously forth on your life work, yet it is a very significant fact, and it must give pause to those of you who are wont seriously to consider the life problem.

When the trained nurse became an accepted fact twenty-five or thirty years ago, she was looked upon as an exponent of our modern altruism — as a secular sister of charity, so to say; but she was not taken seriously as a professional woman. Of course she had to live and she had to be paid. Nurses are few in number, and they were greatly needed. The cost of a nurse was fixed high, for it was a matter of supply and demand; but a nurse was a nurse, the laborer was thought worthy of his hire, and so from the outset the pay was good while work was to be had. But there was no progress for the individual.

There was no progress. It was there, and it is there that the fatal weakness in the nurse's profession inheres. Of what other toilers in this busy world can the same be said? The chore boy can rise to be head waiter; the unskilled

[1] Cleveland, Ohio, May 25, 1903.

laborer can rise to be boss of the gang; the apprentice may become a foreman; the office boy may become a judge of the Supreme Court; the house officer may become a great surgeon. That is what life means to most of us. Work; steady unceasing, increasing work; with widening opportunities, with proportionate returns, with an honorable goal. Those are some of the things that make life worth the living; and with them go other things which to some count for more even than material success — increased occasions for usefulness, a broadening horizon, a closer and more generous contact with our kind, a full career, and at the end the unspeakable satisfaction that we have not lived in vain.

I fear we are all of us very weak human beings. Few of us were born to be great, but that is no reason for curtailing our chances, and as yet it seems that the chances of nurses are not what they might be made.

My predecessors in this office have said some very stirring words about what nurses are and what they are to be — words very stimulating and instructive. Those gentlemen have told how your education is to be broadened and how your place among the world's workers is to be made more honorable and more secure; but I cannot help feeling that those happy prophecies of theirs were addressed more to the nurses of the future than to you who here and now are taking up the task of caring for the sick.

I wish I had some ready, practical solution for the problem which I have suggested; some method by which you could become stronger and wiser, more learned, more skillful and more in demand individually as the years pass; but the problem is one which cannot be answered offhand. It is one which you yourselves must solve, painfully, laboriously, by the slow process of evolution. I have some thoughts, however, which you may take for what they are worth — old thoughts many of them, futile perhaps in some sort, but occurring not infrequently to those of us who have your welfare at heart.

In the first place let me tell you that unless your circumstances and training are very different from those of most of the nurses known to me, it is a mistake to start in as specialists. Such specializing may come later as your careers develop, but at the outset take everything that comes to you unless you feel yourselves unqualified. Don't pose as surgical nurses or medical nurses or obstetrical nurses, and, above all, don't refuse to nurse men. For a good while yet you will need all the experience you can get, and you can get it only in general nursing. Don't tie yourselves to one doctor. He may fail you, for he too is but mortal, and nurses can quickly be lost to view and hopelessly sidetracked.

Don't refuse poor cases. I wish some fashion might be devised by which the poor could be effectively cared for in their homes. By the poor I do not mean the starving and the destitute. They are looked after by the hospitals and the district nursing associations, but I mean the families of men on small salaries. If the father earns forty or fifty or even one hundred dollars a month, he cannot well pay out twenty-one dollars a week for a nurse in addition to all the other heavy expenses which illness entails.

Such people get often the best of *medical* care, because competent young doctors will treat them for the sake of practice and old doctors from a high sense of the sacred obligation that rests upon their calling.

Don't mistake me! I am perfectly well aware that nurses do take poor patients, but I think if you consult some of your older sisters and listen to some of their talk you will find that they often look upon such service as a hardship and feel that the good-natured charitable ones are imposed upon and even lose caste.

Remember that what I am saying is suggestive merely and is crudely sketched; but would it not be possible to establish traditions in your profession similar to the traditions of physicians — that in some fashion no call for help should be refused? You are banding yourselves together into clubs and associations, and such banding is distinctly for your best interests as well as for the best interests of the community. In some way which should not interfere with the liberty of the individual would it not be possible for such associations to see to it that its younger members, without serious pecuniary loss, might give a portion of their time to the poor, and that the doctor, when asking for such help, might not have to approach you with an apology? To such suggestions as this, nurses have replied to me: "Very true, some nurses do take cases for small fees, but they soon come to be known as cheap nurses and lose their chances for the paying cases." Truly that is a lamentable fact and a lamentable tale. It does not count for better things that such is the case, and it rests with you in your organizations and in your public spirit to see to it that such things cease to be.

There is our first thought: that poorly paid, little regarded work be done, that thus the field for the work of all be widened and that out of such small beginnings great reputations may be made. For mark me, this thing that I tell you is true: a professional reputation, whether of lawyer, doctor or nurse, must rest on foundations broader than the flatterings and praises of a few wealthy clients or patients. Such thin reputations are erected in years and are shattered in days. None of us is safe who depends for work on the fickle fancies of the few. Gain the confidence of the whole community, of the poor and the rich, of the little doctors and the great ones — then you may rely upon an assured future.

You will tell me that this may all be true, but that it does not meet my earlier query: Is the young nurse the better nurse, the old nurse the worse nurse? There indeed is another problem. So far as "up-to-dateness" goes, perhaps in a superficial sense the young nurse may be the better; but the fault will be your own if that remains true in the future. Remember that I am speaking now of the great majority of your number — of those who go out into private prac-

tice. You must not allow yourselves to grow rusty and inefficient. Already in your school you have been taught to study and to use your minds and to do your own thinking. That is the best thing you have learned here. Having learned that, you must apply it ceaselessly. I need not insult your intelligence by telling you to keep up your reading. You must do more than that; you must continually cultivate the habit of observing, deducing and recording — those three attributes of the trained mind. The ward and the sick-room are your laboratories, and with due regard to the humanities you must take advantage of that fact.

Lately at the Massachusetts General Hospital, and at some other hospitals I believe, we have established ward courses for graduates. As yet those courses have attracted all too little attention; but nurses are beginning to appreciate their value, and before long I hope to see alumnæ returning in increasing numbers for such work.

As you progress, too, you will find, or you will make, various opportunities for reviewing and for supplementing your present knowledge. You will gravitate towards special lines of work in which you will be regarded as expert. For many of you whose temperaments so lead you, an occasional course in some hospital or other institution will appeal, and you will find such experience of advantage. I am not referring to those who propose devoting their lives to institution work, but to the private practitioners among you. A summer spent every few years as operating assistant or substitute head ward-nurse will keep you in touch with the new things, for, indeed, new things come slowly in the active lives of most of us.

But, after all, the best and most important thing will be constant serious coöperation among yourselves for the betterment of your profession, and that coöperation, to accomplish its purpose, must be along democratic lines. It is all very well to have small clubs and cliques for social purposes and for special work, but when it comes to those organizations which really strengthen your profession and deepen its foundations you cannot afford to depart far from the democratic idea. This I say from a considerable knowledge of how similar problems have been met and solved in my own profession. There is a democracy of science, and in a true sense you nurses are workers in the scientific field.

Last year Dr. Osler gave a delightful address to the Canadian doctors on what he called "Chauvinism in Medicine." He pointed out how we all, regularly educated and licensed practitioners, belong to one great family; how there are no school, city, state or national boundary lines among those whose pursuit is the truth; how jealousy and local conceit and the decrying of those whose work lies without our little circle lead to narrowness, to self-stultifying and to the destruction of that very edifice of science which the best among us are faithfully and laboriously building. The address was a fine plea for the brotherhood of science and of man; a plea which nurses as well as doctors might well listen to and heed. It is by a banding together of all the efficient in one great sisterhood that you can raise your profession to the stability of those other professions with which you must come to be ranked. I beg of you to note that word *efficient*. I am not asking you to open your ranks to the incompetent, the unscrupulous, the impudent, the charlatans untrained. You must steadfastly refuse them your countenance as you are doing; but you must recognize the efficient among yourselves — those who have proved their worth by years of work and the winning of recognized diplomas, no matter whence they come or what their school. If you do not do this, if you do not so strengthen your own hands, you will continue to invite the competition of the pretenders, and you will be emulating the example of some of the labor unions, which destroy their own ends by encouraging a fatuous mediocrity.

I could specify easily examples of what I mean, and tell of certain groups of nurses, graduates of certain hospitals, who persistently look down with a silly and irritating jealousy upon those outside of their own little circle. Perhaps such conditions do not exist in this part of the world. I certainly hope they do not, but let the warning stand, nevertheless.

It will not be long, I believe, before a recognized and legalized sharp line of cleavage will be drawn between trained or registered nurses on the one hand and the masses of the untrained on the other. In the bill providing for the examination and registration of trained nurses, which is before the New York Assembly, Miss Palmer pointed out that in that state there were *twenty-five hundred trained* nurses and *fifteen thousand* untrained nurses. The bill is being introduced through the agency of the New York State Nurses' Association, and will prove a great step in advance. The other day in Massachusetts a similar organization was formed by some three hundred and fifty nurses, assembled in Faneuil Hall for that purpose. Many hospitals and schools throughout the state were represented. The same work is going on in other states. It is a very real and important work, I believe; and I do sincerely trust it will lay the foundation for that catholicity of purpose, that broadening of horizon, that capacity for true progress, which must attach to every vocation that is to succeed.

There is another aspect of the nurse's problem which will be more immediately obvious to most of you than are any of those questions which I have raised; I mean the attitude towards you of the public and especially of individuals among your patients. The public has long since come to recognize vaguely your value and to turn to you for help, and the public approves of the trained nurse as an institution. But there are many dull and wrong-headed people who persistently think ill and speak ill of the nurse as an individual. This sentiment rises usually, you will find, from some unfortunate or unpleasant

experience with some special nurse. You will hear a foolish person say, "I don't believe in trained nurses," and he will say it to you with a smirk of self-approval. But you will just as often hear the same individual remark that he does not believe in doctors. When that sentiment has been addressed to me I have always felt soothed and stimulated, glad that the world has produced one more person of tact and sensibility.

There is, however, a very considerable number of reflective men and women who will tell you that they do not regard nurses as professional persons very seriously. Their reasons are in part those I have already suggested in this address; but these critics feel, in addition, that most nurses in the very nature of their circumstances, from the fact that they are young, single women, do not look forward to nursing as their life work. It is said that they take up nursing from a great variety of inadequate reasons — to kill time, to find new sensations, to make a little money, to become independent and the like; but, that as a matter of fact, they do not intend to remain nurses; that they expect a more secure settlement and to become wives and home-makers like the rest of their sex. In all candor, we must admit that there is a great deal of truth in this, for such is the state of mind of many nurses. If the anticipated events occur, the nursing lives of many nurses are to be short ones. Now, as a matter of fact, the average nursing life is about ten years, and is not ten years of professional life something seriously to be regarded? The lawyer and the doctor have average professional lives of about twenty years; twice as long as the nurse's, but sooner or later the lawyer and the doctor leave the stage — they die, they grow old, they retire. Of what consequence is the reason? Where then are to we distinguish? The doctor dies, the nurse marries,, if you choose. Is the career of the doctor, which lasts twenty years, to be applauded, and the career of the nurse, with her ten years, to be dismissed with flippant words?

But there are other more immediately obvious hardships than this skeptical estimate in store for you — so you will be told with much truth. The great and standing grievance which very many nurses come to cherish against their patients and their patients' friends is a lack of consideration. Many persons employ a nurse not for her knowledge, experience and skill,— those things they are apt to question,— but in order to spare themselves. To them a trained nurse is a human machine to be secured, wound and ready to go indefinitely. Such persons will not spare *you*. They will keep you busy day and night. It is such treatment, which I regret to say is all too common, that helps to breed in nurses a sense of antagonism, a certain hardness, and brings about that state of mind which thinks of and refers to patients as *cases* and not as afflicted human beings. Perhaps, too, the doctors are in a measure responsible for this attitude of nurses, because, as your training in the hospitals shows you, the doctors, with their press of work, unavoidably regard their ward patients as cases and as material. Of course that is a mental attitude deplorable alike for doctors and nurses. The doctors with their wider experience and more diversified lives, are able mostly to subdue the tendency at will. For you it may be somewhat more difficult, but it is a task to be done.

Another remedy for this tendency, perhaps the most important remedy for you as your lives develop, is to seek the special line of work that you do best. At present there are three broad classes among nurses, each class having its subdivisions. The three classes are: private nurses, institution nurses and district nurses. Their three lines of work are quite distinct, each having its particular interests, suited to different temperaments. I think I should choose to be a district nurse if I were a nurse. The private nurse earns more money, the institution nurse sees a greater variety of practice and has regular hours, the district nurse has greater independence and comes into the closest contact with humanity. So let each one choose.

Such very briefly are some of the problems which must be met and solved by nurses and nurses' associations. I fear I may not have told you very much that is going to be of immediate practical value, but how is that to be done in a fifteen-minutes talk at the end of a three years' course?

The question is often asked, What is the one thing most essential for a nurse's success? The answers are as various as the questioners, — good health, yes, that is essential; cleverness — you can get on without too much of that; good temper, tact, courtesy, gentleness, courage, interest, fidelity, unselfishness — all those are fine, useful traits; if you have them not, perhaps you can cultivate them. Sometimes I have thought that the attitude of the sister of charity is the best thing a nurse can attain, that self-effacement, that thought only for the patient which those good women are supposed to have. To this some nurse will answer: Yes, but we are taught to consider the doctor first and the patient second.

Truly, it is a thorny path, to be sought and followed by each individual according to her best lights and endeavors, and when you argue it all out to the last analysis, why is it not true that the great essential for success in nursing is the same as for success in the other walks of life? Saneness, a sound philosophy, a clear-eyed outlook on the world as it is — there is nothing new in that thought. Socrates, Epictetus, St. Paul and Marcus Aurelius held this view.

While you work preserve your health; find recreation, physical and mental. Don't forget how to play, but play in season. If the patient overworks you, tell the doctor you need help. Get an hour or two of exercise in the fresh air every day; get six to eight hours of sleep out of the twenty-four; eat three regular meals and eat them slowly. Faithfully keep up the routine of cold bathing as you do the wearing of fresh linen. Keep your mind alert and interested;

know things outside of your profession; cultivate a hobby. That eminent lawyer and writer John C. Ropes once told me that it was necessary for every successful professional man to have some constant outside pursuit. His own hobby was Napoleon and matters pertaining to military history. During his later years I suppose he knew more about Napoleon than did any other living man. His hobby kept him fresh, eager, interested and supremely interesting. You women can have your hobbies, whether you take to Napoleana, or the D. A. R., to botany, painting, embroidery, stamp-collecting, astronomy or wood carving. All such things are honest, instructive, wholesome, and they count for good.

And mark you this, that as you broaden yourselves you acquire more of that true sense of humor which is a large part of the philosophy of life. As the years pass, it makes that life more abundantly worth the living, "for truly, this humor is an adjunct divine, and as far beyond the trivial word for it as 'love' is or 'charity.' No definition or happy phrase sums it correctly or rates it high enough. It is a balm of life. It makes for greater things than clean laughter from the lungs. It is the root of tolerance, the prop of patience. It suffers long and is kind; serves to tune each little life-harmony with the world harmony about it, keeps the heart of man sweet, his soul modest, and at the end when the light thickens and the mesh grows tight, humor can share the suffering vigils of the sleepless, can soften pain, can brighten the ashy road to death." [2]

This is not a sermon. It is not even a lecture, but a plain talk by a working man to working women, and remember, as the Cambridge poet said two hundred years ago,

"A woman's work, grave sirs, is never done." [3]

STOMACHAL AND INTESTINAL DERANGEMENTS AND AFFECTIONS OF THE FAUCES, PHARYNX AND AIR PASSAGES.

BY BEVERLEY ROBINSON, M.D., NEW YORK.

One reason why the older practitioner of medicine is less enthusiastic about new findings is doubtless to be explained by the fact he has noted many times, *i. e.*, that the current of medical thought and action revolves, as it were, in a circle. Given a certain period of time, more or less, and the opinions and treatment of physicians which had become banished almost completely for a while return and become again the rule of thought and action. It may be, and in this wisdom has taught the lesson which is born of ripe experience, that convictions and measures which had been pushed to their uttermost are once more received and followed, but in a far more rational and conservative manner.

I shall only cite a few examples familiar to all to prove my statement. Take bleeding in pneumonia, for example, and mark the generally received judgment in former years — on the one hand, a local inflammation of the lung and on the other the curative effect of excessive depletion. Take calomel — in massive doses, repeated more than once, it might be, to jugulate an incipient inflammatory process of the pleura. Take opium — the panacea of peritonitis (so called) in its acute form when declared, and repeated frequently until both pulse and respiration were reduced very markedly in frequency or affected sensibly as to rhythm or volume. These ideas, this treatment, based probably upon erroneous convictions to a certain degree, were without question, according to actual knowledge, excessive, and hence often resulted in direct injury to patients. At times, however, benefits great and evident followed, and many notable and direct cures were surely established. To-day mercury, opium, bleeding, are employed more judiciously, as our knowledge of morbid processes has advanced, or at all events changed. We may fairly add, I believe, that just as formerly our notions about certain things were excessive, at present, perhaps, they are somewhat too conservative, and only later we shall know when and to what extent to make use of these and other very valuable remedies in the best way. And we shall also modify our present convictions about many diseases, and thereby, perhaps, approximate greater truth.

Not very long ago, and in my own experience, those who recognized a very manifest correlation or dependence between gastro-intestinal troubles and those of the respiratory organs were regarded by many, especially prominent specialists in laryngology, as being behind the times, prosaically so, and as requiring new lights and fresh guidance. They argued with the German school of the day that local treatment, medical or surgical, was the main essential object to keep constantly in view, and a great deal of the talk or doing about dyscrasia, constitutional defects, the influence of climate, of season, of habits, of occupation, etc., was drifting far away from the best that could be accomplished in actual practice. And thus sprays to the nose and throat, inhalations of divers sorts, local applications with brush or sponge to diseased parts, cauterizations, burnings with electro-cautery, the use of trephine and saw, knife and chisel, were the order of the day.

To talk of Epsom salts, nitre, aconite, blue mass, spirits of mindererus, cubebs, etc., was to raise an incredulous sceptical smile, and to court more or less immediate and forcibly expressed opposition. And yet look how the pendulum swings! how we are returning once more to time-honored methods which have disappeared for a period, only to return with renewed and accentuated truth and power. This belief has been forced upon me again, I am glad to say, by more than one paper I have read or listened to within the last few years. It has been rendered doubly

[2] Eden Phillpotts, in "Sons of the Morning," p. 479.
[3] Mr. Eusden, at the Cambridge Commencement, 1714.

true by the tenor of more than one debate, and the remarks of more than one able and expert speaker.

Having introduced my subject, I shall in a brief way refer to several instances in my own experience, to corroborate my statements and further, if possible, to carry conviction to some wavering minds which need yet to be instructed, as I believe, and thus to acquire correct appreciations of what to me and others seem almost obvious facts. Of course I do not wish to be understood as telling what is new; I know indeed a great deal is threshing again old straw, but this is a good, almost essential work for some one, especially when the younger men in the profession seem ignorant, practically of what has been known, considered and has guided many in the counsel towards and care of patients. The importance of the recognition of the facts referred to is to me unquestionable. And this is a truth both in acute and chronic diseases of the digestive organs as causing morbid determinations in the air passages. In a similar way the latter affections are occasionally causative in producing both acute and chronic digestive derangements. Such effects are, however, much less frequent. In such instances the nature of the disorder may be nervous in origin. Again there are a few clear instances of chronic inflammation of the stomach and bowels which are of catarrhal nature.

It has been taught and understood pretty generally in the past few years that chemical analyses of stomachal contents after a test meal were very important from the point of view of diagnosis and also of treatment. So far as curative interference with patients is concerned, I must take exception to this statement as being always true clinically. From a scientific point of view, I do not question the value of every accurate acquisition of facts. But when from facts we adopt theories, which, although true many times, are not invariably so, but have numerous exceptions, we are liable to be led astray ourselves, and to mislead others. I have noted occasionally that the very diet and drugs which from any rational standpoint we could discover were least well adapted to a given patient were just the ones most useful or effective. Not infrequently the discovery of this fact has been the result, not of study, or previously acquired knowledge, but of the merest chance apparently. Again, I have remarked, as we all have, that whenever a patient has a great and persistent longing for a particular food, or drink, it is unwise always to deny them the satisfaction of eating or drinking as they would, on the ground that the craving was irrational and that the patients would surely suffer from wrong indulgence. Time and again by permission accorded to the patient to partake of what he or she desired the experience has proven very beneficial, and that too, not only for a short time, but also during a period more or less lasting. On the other hand, I would not deny that now and then this yielding to the importunity of a patient about food, or drink, has seemed like weakness on our part, and as being opposed to our sober, better judgment, and subsequently, when bad consequences were observed, we have reproached ourselves bitterly for having done an absolute wrong and having been inimical to our patient's progressive improvement. How to avoid just such instances, how to give information which in advance will guide us to right conduct unerringly, we do not know at present. Later, perhaps, the unfortunate exceptions will be explained on rational grounds, and with improved knowledge. Until then we must simply watch and wait.

It is a trite statement to make when we affirm to-day the great utility of the laryngoscope and rhinoscope to general medicine; and because the overzealous or narrow minded and ignorant have been led away by its frequent and great usefulness to see things and to perform operations which their blinded vision mistakes and their deft hands had better have let absolutely alone, is not reason enough to ignore just claims or to fail to recognize facts and observations only possible through the employment of special instruments. One can see and note the very rapid effects produced on the nasal, pharyngeal and laryngeal mucous membrane of a dietary indiscretion and of its resulting digestive upset. And this is surely more satisfactory in every way than merely to make guesswork of it. The pituitary membrane becomes engorged, irritable looking, more vascular; the larynx becomes congested and infiltrated. Frequent sneezing, nasal obstruction, hawking, secretion of mucus; or cough, expectoration, wheezing, mucous râles, dyspnea, may be observed rapidly to occur. And with the occasional, frequent or habitual recurrence of the cause of these sequelæ their presence will be remarked more or less continuously. Acute coryza is ordinarily attributed to the effects of cold, of sitting in a draft, wet feet. It is also due to a contagion transported directly from another similarly affected. Dust laden atmosphere or close, confined, badly ventilated, overcrowded rooms may cause it; so too it may be the expression of an overloaded system, or indeed of a manifest gouty state. Finally, however, I believe a disordered stomach or bowels is not infrequently causative, and it is only by attention to these derangements, either by diet or suitable medication, or both combined, we may combat it in the best, shortest manner. I admit that to make the differential diagnosis of these cases is very difficult at times, and I am inclined to believe it is made sometimes therapeutically by observing how ineffective usual remedies, local or general, are.

What is true of simple coryza is also true of acute catarrh of the naso-pharynx and of superficial acute tonsilitis of the simple variety. It is no unusual observation to make that within an hour or two after a meal too abundant or rich, or after partaking of a particular food or drink that occasions stomachal distress or malaise of one sort or another, repeated hawking and spitting of frothy or gelatinous-looking mucus

from the throat and naso-pharynx occur. If the throat is examined at the time, the tonsils, pillars of the fauces and pharynx are partly covered with secretions of this nature. If the disturbance has been recurrent the uvula is relaxed, pale, elongated, glistening and somewhat edematous looking. Where the tonsils are inflamed superficially, there is some swelling and redness locally, with stiffness of the neck, or some soreness or difficulty in swallowing. The follicular tonsilitis of children usually, and the same disease in adults, which relatively is infrequent, seems often to follow excessive indulgence in rich or sweet foods (pastry, cake, candy, etc.). There may be, and no doubt is, at times a complicating dyscrasia, rheumatic or gouty perhaps, or an infection which localizes itself here, the nature of which is far from being accurately determined always, yet it is surely correct to assume or believe that the dyscrasia, or infection, would not become evident unless the imprudence or wrong doing had occurred. The fact that the white deposits over the mouths of the tonsillar follicles are not seen always immediately, and that twenty-four or forty-eight hours may elapse before they appear, is not sufficient reason to make me change my belief about the nature or manner of their growth. Even presuming the deposit on the tonsils be of microbic origin, it would not find a favorable site for its development unless the mucous membrane were morbidly changed so as to favor it. Of course there are grades, differences of this disease termed follicular tonsilitis. In some instances the general disturbance of the system is of such a nature that I am satisfied as to its infective character. Not only is there much depression, fever and great weakness during the immediate attack, but subsequently, for many days, and after all signs of local disturbance have entirely disappeared, the patient is visibly in a weakened state that shows itself by pallor, inappetence, weak, rapid pulse and marked prostration of bodily energy.

The dividing line between some such cases and diphtheria is far from easy to determine. Clinically almost all the symptoms of diphtheria may be defined, barring the bacterial finding of the real Löffler bacillus, and we may have just as much, nay, even more, cause for anxiety about the patient than if the diphtheria bacillus had been found. In just such a case I have known antitoxin to prove almost immediately and wonderfully remedial when other means had signally failed and the patient's condition was very serious, indeed imminent. It is not uncommon to encounter asthmatic seizures which are evidently due to an attack of acute indigestion. A too abundant meal late in the day will frequently be followed by a wakeful, distressing night, and very great dyspnea, with loud, sonorous rhonchus stamp the attack. These attacks may also be occasioned by what appears perfectly simple food, and yet which from one cause or another disagrees. In a young child, many years ago, I saw an instance where a tumbler of milk taken at bed-time would bring on an attack of asthma soon after the little one had been asleep. With the attack of asthma there was a severe eruption of urticaria. If this child ate a slice of bread with the glass of milk, the asthma did not occur, showing the effect of the cereal doubtless in breaking up the curd and making it more digestible. The most efficacious and quickly acting remedy was found to be frequently repeated doses of lime water, neutralizing in this way, as I believe, the organic acids formed in excess. While this "peptic asthma" is a well-defined entity and generally described, it is not taught that nervous dyspepsia is at least an accompaniment occasionally of asthma, and may be to a certain degree caused or aggravated by the latter. Such cases are unusual and not readily determined. Instead of causing stomachal intolerance or an attack of diarrhea, I have known eating fresh mushrooms to occasion very pronounced edema of the uvula, so much so indeed as to cause very distressing symptoms of choking. I have not known such an attack to be caused by canned mushrooms. Although the apparent symptoms of gastro-intestinal indigestion may not be discovered, I feel confident that a closer scrutiny would reveal them. The treatment of such a case resides in the immediate application repeatedly of burnt alum to the uvula and a cathartic dose of mineral water or salts. The cause of the throat irritation proceeds in many instances from direct contact with the acid renvois which come from the stomach. At the same time, the ptomaines generated in the stomach or bowels cause a general poisoning of the economy through the blood after absorption from the peptic or intestinal glands.

One important fact is undoubted at times, *i. e.*, that we find the same micro-organisms in the throat and in the stomach. As to whether they were swallowed, and their presence thus explained in the stomachal contents, or they were originally developed in the stomach and brought into the throat by regurgitation, is not settled. The relations of chronic disorder of stomach and bowels to nasal and naso-pharyngeal catarrh were first insisted upon in this country by Wm. H. Daly as far back as 1882. In the former, Daly saw the cause of many catarrhal conditions of these passages. Where it was not evident that the digestive disturbances preceded those of the respiratory tract, they always aggravated them when present. And if through judicious dietary and treatment we got the stomach and bowels in good working order, we found that frequently there was no occasion to make local applications to the throat or nose, or to do many operations for the relief of hypertrophic rhinitis or for obstructive disease in this organ (the nose), of divers sorts. On the other hand, chronic naso-pharyngeal catarrh may become the "fonsetorigo" of digestive troubles, mainly through repeated dropping of unhealthy secretions from the throat and subsequent swallowing them. In these instances there is no doubt in my mind that moderate and sensible local treatment of the nose and throat is much to be followed and praised.

Indeed, unless we free up nasal or throat obstructions in many such instances through proper septal operations, or the removal of adenoids, or enlarged, chronically diseased tonsils, we shall fail signally to benefit or relieve the consequent digestive disorders. The two conditions of inflamed throat and chronic dyspepsia may march together, and as one organ or condition improves so will the other. If, likewise, one organ grows worse, so will the other. It is, however, difficult or impossible invariably to discover through symptoms and the patient's history in which organ the trouble started. Therapeutically we must make use of our brains first of all and act intelligently according to the case we have in hand. If there be evident faulty conditions in the nose or naso-pharynx, these should often be corrected as far as may be by local applications or operatory procedures. At the same time, the habits should be regulated and the diet made simple, nutritious and moderate.

Nervous, run-down women of middle age, who suffer also from menstrual difficulty, are apt to have atrophic nasal catarrh. A wisely adopted rest cure and the continuous use of the glycerophosphates of lime and soda will prove helpful. To club men who are bloated, red, corpulent, and also suffer from a thickened engorged mucous lining of nose and throat, low diet, abandoning the use of alcohol and free diuresis through Poland water or Celestins Vichy, will prove useful. The presence of incipient or more advanced cirrhosis of liver and veinous engorgement of the entire upper air tract among these men is also what we encounter time and again. It is clear from the foregoing how essential it is for throat specialism which is broad, conscientious and useful to be guided and directed many times by a knowledge of general medicine. This statement does not prevent my recognition of the great advantages derived directly many times from the rhinoscope and laryngoscope in skilled hands. It is against their abuse that I and others cry a halt.

ROUTINE TREATMENT IN A GENITO-URINARY CLINIC; FUNCTIONS OF SUCH A CLINIC.

BY F. J. COTTON, M.D., AND R. F. O'NEIL, M.D., BOSTON,

Surgeon and Assistant Surgeon, Genito-Urinary Department, Boston Dispensary.

THE study of records which forms the basis of this paper was undertaken for the writers' private information, with the added hope that we might extract something that would help in treatment. In the end, however, it is published, not because anything of especial technical value has been found, but because the study has raised broader questions as to the functions and use of a clinic of this class which seem worth discussing.

The paper is, therefore, presented in two parts, on the one hand the technical data, on the other the discussion of these broader problems.

PART I.

In the mere impressions left with us by routine medical work there is always a large element of error. To check this in regard to this particular clinic the writers have looked up the records of part of their last service, covering August and September, 1902, in the Genito-Urinary Department of the Boston Dispensary.

This clinic is a large one and seems to enjoy the confidence of the afflicted throughout and beyond the South End. The year's average of new cases is, roughly, 2,000. The daily total of all old and new cases varies from 15 to 50. For this paper 328 case records were worked over.

The diagnoses recorded were as follows:

Chancres or early syphilis	13
Chancroids	27
(with bubo)	2
Bubo (alone)	1
Acute gonorrhea	130
Chronic gonorrhea, anterior	48
Chronic gonorrhea, anterior and posterior	26
Chronic prostate and vesicular disease	11
Follicular or periurethral infection	3
Epididymitis (alone or without urethral dis'ge)	4
Gonorrheal rheumatism	2
Stricture	13
Balanitis	5
Venereal warts	6
Torn frenum	1
Non-Venereal.	
Hydrocele	6
Varicocele	2
Senile prostate	7
Retention from spasm	1
Irritable prostate	2
Impotence	1
Neurasthenia (sexual)	7
Hematuria	1
Paraphimosis	1
Edema of prepuce (no known cause)	1
Induration of corpora cavernosa	1
Eczema of scrotum	2
Scabies	1
Pediculi pubis	1
Genito-urinary tuberculosis	2

The relatively small number of syphilitics is in part explained by the fact that all definitely diagnosed syphilis at the dispensary is referred to the Skin Room.

TREATMENT.

Chancres were treated expectantly with washes and powders until such time as the diagnosis could be confirmed — then transferred.

Chancroids were usually disinfected so far as possible by the use of strong carbolic acid, followed by alcohol. With this (and sometimes as sole treatment) frequent cleansing at home with creolin or other washes, and the application of boric acid or other non-cohering powder, formed the routine. In the period covered there chanced to be no circumcisions for chancroids — splitting up the dorsum for chancroids with phimosis was done in one case only.

Buboes were always treated by simple drainage without very free opening or dissection. Abortive treatment was not tried, as we had only broken-down and "ripe" buboes to treat, and

were fortunate enough to have none form from chancroids under treatment.

Gonorrhea in hyperacute cases was treated in the beginning with internal medication, — copaiba or santal with diuretics and alkalines, — under the usual rules of relative rest and hygiene. In all other acute cases where it was possible, copious and frequent irrigations, with hot permanganate solutions or with weak silver nitrate or weak corrosive solutions, were used. In selected cases, especially when seen early in their course, definite attempt at bactericidal treatment was added to the above routine.

In cases with a developed acute posterior urethritis, the general trend of treatment was conservative. Treatment of the anterior disease was continued, and every two or three days in quieter cases a posterior (Diday) irrigation added.

In the later stage of anterior disease astringent injections, medications through the endoscope and mechanical dilation (Kollmann dilators usually) were the means most used.

Late stages of posterior infection were combatted with strong instillations with the Ultzmann deep syringe, and prostatic massage was occasionally used.

Home treatment with injections was not advised or prescribed in any stage f the disease.

As to the comolications. No cases of suppurative prostatitis were met in this service. There were but three cases of follicular or periurethral abscess — one lost track of, two sent to hospitals for operation. There were but two cases of true cystitis secondary to gonorrhea — both were treated with bladder irrigations.

Epididymitis was treated by suspensory, relative rest and hot fomentations or poultices in the acute stage; later with suspensory and with nitrate paintings, or, more often, ointment of mercury and belladonna.

Of the late sequelæ the *chronic prostatic* conditions (including many of those often classed as vesiculitis, neurasthenia, etc.) were treated by urethral dilatation, topical applications to the deep urethra and prostatic stripping by rectum — usually with good, if not permanent, results.

Strictures were treated by gradual dilatation — successfully in all of our series but one, which was referred to hospital for operation.

Venereal warts were treated by snipping off and touching up the base with chromic, nitric or acetic acid.

Balanitis was satisfactorily treated by the usual means of surgical cleanliness.

The few cases of senile prostatic disease were treated for the complicating cystitis, one had had a prostatectomy performed ; others were advised to submit to operation, but none of those in this series accepted this advice.

RESULTS.

As to the results of treatment, we may preface by saying that these probably represent good average results, certainly no worse than average for this or other clinics of this class. Certainly in this clinic within the past few years, with graduate assistants replacing undergraduates, there has been a marked improvement in the detail work and apparently in the results. Accordingly, though it was obvious that some patients were attending too irregularly to get much benefit of treatment, yet we were not prepared for so poor a showing as to attendance and finished results. So far as we know or can judge, the attendance, or lack of it, would be much the same for other months of service.

The net data are as follows:

As to syphilis there are no data beyond those of diagnosis and transfer.

Of 29 chancroids, 11 were discharged cured or practically healed; 10 disappeared improved but not healed; 5 disappeared after only one or two visits; 4 disappeared early, unimproved; 2 were sent to institutions; 2 were doing badly when last seen. Two cases had buboes when first seen and there was one bubo with a healed chancroid. No buboes developed under treatment.

Of the acute gonorrheas, 20 were cured in four to twelve weeks; 30 quit uncured after some treatment; 80 did not return at all after one or two visits.

Of the chronic anterior gonorrheas, 22 were discharged cured; 11 were uncured at the time of the last entry.

Of the chronic posterior and anterior infections, 7 were cured, 9 were not. Fifteen others came but once or twice.

Of the chronic prostate and vesicle cases (including post-infective infiltrated prostate with vesicles obstructed but not infected), there were 11 in all. All were temporarily relieved, though none were discharged as cured.

Of the strictures one was sent to the hospital for operation, the rest were effectively treated by gradual dilatation.

METHODS.

From these results it is possible to deduce relatively little as to the most useful methods. The series of chancroids is perhaps best worth study, for a series of 29 cases of soft sores with 25 fairly well followed and without a fresh bubo is not the usual showing, nor was it previously the rule in this clinic under other older methods. We believe that the disinfection with strong carbolic acid for one minute, followed by alcohol, while it does not always cut short the infection, at least helps to disinfect, and certainly has a marked advantage in that it leaves no slough. It is to the fact that no sloughs were left, and that the patients were elaborately cautioned to remove all scabs at each of the frequent home dressings, that we would attribute the good results. It is apparently a fact here, as in general surgery, that a thoroughly drained wound however infected will rarely give serious glandular infection. Certainly this aim in treatment will bear emphasizing in relation to chancroids and bubo formation.

As regards the treatment of the urethral infections, the moral as to methods is less simple. It is a question if the *totals* here given show anything except rather poor average results. From the study of *individual* cases and records, however, the writers are only confirmed in their conviction gained by observation in private practice, that it is desirable in all save a few very acute cases to give all acute anterior gonorrheas active local treatment with copious and frequent irrigations, combined in favorable cases with the use of protargol or other silver germicide. This seems to be the ideal treatment up to date. Later in the disease astringent irrigations, medication by the endoscope and graduated stretching have their place. Posterior infections seem to do best under not too frequent local treatment, begun only after the stormy stage is past.

On this basis of treatment we get results pretty consistently in proportion to the faithfulness, frequency and skill of the local treatment.

In past years we have all had a relatively large experience in this same clinic with the results of the usual home injections with the old-time clap syringe, using all sorts of injections, including some of the organic silver germicides. As a consequence nearly all of the surgeons have abandoned this scheme of treatment as far as possible. The average results were no better, the number of relatively serious mishaps much larger, and we did not then get the early and excellent results now not infrequent under proper care.

Properly carried out, irrigations in the hands of the physicians are much safer, and the method if persistently followed is capable of curing some early cases in two weeks or less, of greatly diminishing the frequency and severity of posterior urethral involvement and consequent complications, and of greatly promoting the comfort of the patient during treatment even where cure is not prompt. The method has no disadvantages *per se*, except the time and trouble required.

It is satisfactory, however, only when consistently carried out; on an irregular and irresponsible class of patients it does not therefore show greatly better *average* results than may be seen with average treatment — or perhaps with no treatment at all.

We see, however, no reason for dropping desirable methods because patients who do not come fail to get cured, and we are still confident that except for better technique we are not now likely to benefit by any change in routine.

PART II.

THE BROADER QUESTION.

The broader question for which we ask further consideration is that of the conduct of gonorrheal cases in a public clinic — the other classes of cases require no special remark.

With regard to the gonorrheal cases the real question is, not what is the best treatment, but what is the best clinic routine. We believe there is no question that active local treatment is the ideal method, and feel sure that few of those who have thoroughly worked over the curative (as distinct from the palliative) treatment of gonorrhea will disagree with us.

Such treatment we have attempted to carry out as a clinic routine — what the results are under routine conditions we have seen. Certainly they do not show up very well, and the discrepancy between the results here and in properly handled office practice is obvious. Certainly we can hardly be satisfied with curing only one-quarter to one-third of our cases as we now do. As we have said, it does not seem wise to return to old methods — they were no better even in the general average and with much less possibility of doing good: the newer methods we are carrying out as well and as faithfully as we can. Can we do anything to change the conditions under which we work?

The problem is a rather complex one, for a clinic that treats venereal disease has various responsibilities. The ordinary out-patient clinic provides opportunities for the cure or relief of the patient, for the education of the attending surgeon, for the instruction of the student. All this the venereal clinic must do, and beside this must discharge a duty to the public in combatting, so far as may be, the prevalence of venereal disease and that neglect of its treatment which so largely favors its spread. Through education of the practitioner and of the student, and by direct education of the public, this must be accomplished. Let us take up one by one these objects of our work, and it becomes clear that in no respect are we accomplishing what might be desired.

CURE OR RELIEF OF THE PATIENT.

As things stand, a proportion of patients are rapidly and permanently cured without complications. A smaller proportion recover after some weeks as a result of our treatment — so far good; but both these classes in our list together include but 15%. What have we done for the rest? 61% we certainly did not benefit, for they came to the clinic but once or twice anyhow. The other 24% drifted off — somewhat relieved in many cases, but not cured. Undoubtedly many of these cases got well, but it is too large a stretch of optimism for us to consider ourselves responsible if they did. We are very apt, it is to be feared, to consider ourselves very useful and to give ourselves the benefit of every doubt. Would it not be fairer to say frankly that we are curing something under 20% of our gonorrheal patients and that 80% of them receive no substantial benefit from our treatment?

EDUCATION OF PATIENTS AND THE PUBLIC.

This is most important perhaps of all our aims, save that of cure. If a patient has a broken leg it matters little what he thinks about it — he usually believes what we tell him and lets us do what we can. Not so with gonorrhea — the public is too amply misinformed. Every man has heard that it is "no worse than a cold," and

as a rule he knows several liars who "always cure their doses right up without any trouble." If we tell him that the disease is a serious one, and that safe and effective treatment involves much trouble and may take some time, he has no notion of believing us.

Time is likely to modify his personal notion of the seriousness of his case, but he does not change his theory; he simply considers himself "a hard luck case," and blames any treatment he may casually have subjected himself to as the reason for his continued trouble, and tries something else. The old rooted idea that gonorrhea is a troublesome trifle, and serious trouble the rare exception, sticks like a burr.

Beyond this the patient may in a public clinic learn by observation that venereal disease is not always a jesting matter, and he learns that we doctors consider gonorrhea serious, possibly very serious, and not likely to be quickly cured. What he does not learn is that it is curable in most cases under proper conditions, with proper skill and care, in far less than the time usually taken. The difference in results between "santal-midi" and the average of the clinic is not obvious enough to him to outweigh his inertia.

This is not theory but fact, and humiliating as it is to admit, it must be admitted that a very large share of the popularity of our dispensary clinic is due to the fact that "Mixture XVI" is good and cheap and is dispensed only to its patrons. It is certainly a good copaiba mixture, but it has no virtues different from those that other mixtures have, and at best can only shorten an attack, and usually only masks it. But it must certainly not be seriously contended that we are having full success in educating the public so long as it uses us, with our consent, largely as a cheap and handy drug store.

PROTECTION OF THE PATIENT'S FAMILY AND OF THE PUBLIC.

In so far as we cure — definitely cure — our cases, we help in this direction of course. In so far as we simply palliate and diminish a discharge with copaiba or the like, we probably do more harm than good so far as the public protection is concerned. The man who transmits gonorrhea is not the man who has a florid discharge, but he with whom "it comes back when he stops taking the medicine," in short, the man who is fooling around a clinic or drug store. In so far as we make the patient comfortable and tacitly agree that he is doing very well when he is really doing very ill, we encourage indifference on his part, and endanger rather than protect the public.

EDUCATION OF THE PHYSICIAN OR SURGEON ATTENDING.

Such of us as have the privilege of working in a clinic of this sort year after year have an opportunity for learning to treat minor genito-urinary surgery and venereal disease that is of the greatest value. What we learn is pretty directly proportionate to our intelligence and effort. Personally we can complain in no way of the present status except in so far as we are forced to waste time on irresponsibles.

EDUCATION OF THE PRACTITIONER.

It is obvious that this is very important, both in regard to the indirect education of the patients and in regard to improving the routine treatment. In this community, at least, it is apparently inevitable that gonorrhea should as a rule be treated by the general practitioner rather than the surgeon or specialist. The rôle of the latter is to run a clinic, to treat a few cases, to serve in times of trouble and consultation, and to impart what he may of knowledge acquired by special experience to his fellow practitioner.

It requires no argument to prove that the average practitioner has a somewhat scanty knowledge of the cure of venereal disease, and is over much under the influence of the older palliative methods of treatment or the spell of advertised "ethical" cures. That this may be helped is obvious, but this must be done in large part by example rather than talk. Such example is best given in the practice of public clinics. That the effect of such example is nullified by the ragged and apparently inconsistent results under present conditions is obvious. If we are going to convince others we must have not occasional but consistent good results to show.

EDUCATION OF STUDENTS.

The present system is gravely defective in this respect. The student has been taught in the schools as a rule a somewhat theoretical and incoordinate idea of the pathology and treatment of gonorrhea. The textbooks are, with few exceptions, full of the history and natural history of genito-urinary disease, and hopelessly vague and behind the times as to actual treatment.

The student brought in actual contact with cases is naturally and logically impressed with the fact that the cases he sees under treatment are mostly doing rather badly. He must, if normally skeptical, conclude that the statements given as to the better results of better conditions are rather likely to be rose-tinted. So far as can be judged, the average student who has had clinical instruction in genito-urinary work usually learns to do irrigations rather inefficiently, while he not infrequently acquires a profound distrust of their efficiency, or of the use of any local treatment.

Having been a layman before he was a student, he usually knows that the drug-store type of treatment is the one under which most of those infected do well or ill, and against a return to it in his practice he has to balance only an assurance on our part of the better results of a better method which we demonstrate, but the actual results of which he has seldom, if ever, seen.

This running survey will perhaps illustrate our meaning when we say that the present routine fullfils none of its functions to any satisfactory extent, except in so far as it offers opportunity to the surgeon in charge to learn his work.

Self-deception is very easy, and no doubt we all feel that we are doing a vast deal of good to such cases in our clinics, but on closer inspection is it so? It seems to us doubtful to say the least.

It does not seem in our judgment that we can accomplish more by any change from the present general routine; our change must come from a more rational attitude on the part of the patient.

Mere talking (telling patients what we think and believe they should do) is useless.

It may be argued that better work and better results will bring about a better attitude on the part of our clinic. To this may be answered that in the past few years there has been an improvement in the work of this clinic in all respects and an improvement in the results in patients that are attending to the business in hand, but no visible improvement in the general attitude. At best not all results can be good, and now the good results are swamped in the flood of "casuals," with whom we are temporizing.

We are, in short, temporizing and playing with a problem we should confront, with the result that we are not in any direction accomplishing what we should for the energy expended.

Our duty as medical men is to cure disease where we can, and it would be neither humane nor wise to exclude from our help those with venereal disease. However, despite the tales we hear, gonorrhea in males is very rarely acquired, save in the usual way; when the patient has so acquired it, we may be sorry for him, but it is a question if our professional duty must impel us to look to his comfort alone — to let him do as he pleases, when he pleases, and in so doing to jeopardize what power we have to improve the standard of treatment and to combat the prevalence and spread of gonorrheal disease in general.

It seems to us of first importance that we should help the patient in proportion as he will help himself, but that our larger duties should be paramount to our obligation to try to help those who care little or nothing for our help. It is far better that we should help educate the profession and the public and raise the standard of treatment in gonorrheal and venereal disease at large by limiting ourselves to conditions where we can give adequate example and instruction, than that we should confine ourselves to the vague philanthropy of doing what little we can for everybody. If we were to adopt a sort of discipline in a clinic of this sort, consent to treat only such patients as would consent to follow out directions and come back when told to, entirely discontinue the complacent ordering of copaiba mixtures and Royal P. syringes; and refuse to tolerate the man who "meant to come back earlier, but got to drinking last week" and all the other irresponsibles who fall from good but weak intentions, we should be better off.

There would be some apparent, but only apparent, hardship. Patients can always go elsewhere — even now they drift from clinic to clinic; they can always be treated somewhere as we now treat them — on their own terms. We have rather an excess to-day of all sorts of clinics. There is no danger that the poor will be neglected if they seek aid. As to others than the poor, they do not belong in a clinic. The single man with gonorrhea whose work makes it impossible for him to attend regularly at any clinic should not in most cases be obliged to depend on a clinic for his care.

By limiting our care, then, to those who deserve it, we should inflict little or no hardship. Should we not better discharge our professional duty? Surely we could under such conditions give more and better care to the patients who did attend to business. We could do better work in observation for the benefit of ourselves and others. We should be in better position to influence the work of our brother practitioners in this line of cases, and we should be able to ensure much better work by the practitioners of the future by giving adequate and really demonstrated instruction to the student of to-day.

What has been written here is on our part a deduction from past experience in clinic work as well as from study of the data cited above. So far as possible we have given our reasons, and our conclusion, debatable of course, is here presented for discussion.

We believe that it would be for the best interests of all concerned that a special genito-urinary clinic should treat cases of gonorrhea only under such conditions as are in the surgeon's judgment consistent with proper treatment and good results. This is not to be taken in any way as a criticism of the present use of genito-urinary clinics at large, — the good done in other classes of cases more than justifies them, — it is simply our answer to the question as to the proper treatment of gonorrhea in such clinics — an expression of our conviction that some discipline and regulation is needed in such clinics if we are to make them of proper service.

SOME PRINCIPLES INVOLVED IN THE THERAPEUTIC APPLICATIONS OF RADIOACTIVITY.[1]

BY WILLIAM ROLLINS, BOSTON.

IN 1900 experiments were made on animals to determine the value of radioactivity in diagnosis and therapeutics. The results as relating to diagnosis were briefly referred to so far as they were apparent with radium 1,000 in a paper, "The Cathode Stream and X-Light," in the *American Journal of Science* for November, 1900. With the more powerful radium now available the results may be different. No report of its therapeutic uses was made at that time, but radium 1,000 was made into capsules, with non-radiable walls to limit the action to the diseased tissue. These were given to Dr. Williams, and recommended for use in treating lupus and superficial cancers. Later (1901), radium of greater strength was used. As the experiments on animals had shown radium to have a potent effect on

[1] This paper was submitted for publication September, 1903.

tissue, attention was called to its use in therapeutics in the BOSTON MEDICAL AND SURGICAL JOURNAL for Jan. 23,1902,while waiting for Dr. Williams to report his experience. Now that Mr. Lockwood has formed a company to extract radium from Utah carnalite, radioactive substances are certain to attract more interest in the therapeutics of the future, when ether waves and emanations will receive attention in the medical schools, professorships of ether and radioactive therapeutics being established; therefore it may be well to mention some precautions, after stating a few facts, not easily accessible, about radium which is selected as a type of radioactivity. The Curies, who discovered radium and polonium, found radium gave off ether waves of various lengths — some long enough to affect the eye as light, others longer, or heat waves. In addition to ether waves, the Curies, Strutt, Rutherford and Soddy have found radium sends off particles of various sizes: A-particles, about the mass of hydrogen atoms, which constitute 99% of the radioactivity. These have positive charges. They are easily absorbed by thin layers of matter; cardboard, for example. Their activity is reduced one-half by aluminum 0.005 mm. thick. They are about one hundred times as hard to deviate in a magnetic field as the next form, or B-particles, which are only a thousandth as large, negatively charged and supposed to be the same as the cathode stream particles in an x-light tube. They penetrate further into substances, being reduced in intensity one-half by aluminum 0.5 mm. thick. The third form of activity, or gamma rays, have not yet been certainly deviated by a magnet. They are very penetrating, their intensity being reduced one-half by aluminum 80 mm. thick. Whether they are ether vibrations or flying particles is not certain.

For the present when using radioactive substances in internal therapeutics the substances cannot themselves be employed, on account of their high price. Advantage must be taken of the investigations of physicists like Rutherford and Soddy, who have shown when a radium salt is dissolved in water it gives off "emanations," which can be collected in air in a gas-holder over mercury and used in internal medicine as first recommended by Soddy. When radium is dissolved, 75% of its radioactivity is at once liberated, the 25% remaining consisting of A-particles. When the first rush is over, radium in solution is constantly giving off more emanations, the amount being as great as in the dry state. This is important to remember, for it shows radium in solution can be depended on as a constant source of emanation to be used in therapeutics. Even the emanation itself can be employed to produce fresh radioactivity. If a small volume of air containing the emanation is put into another gas-holder containing air, the whole volume will rapidly become radioactive, the intensity increasing until balanced by the rate of decay through the metal holder. In this connection it may be well to mention that radioactivity is an attribute of many substances, all the common metals, for example, show it. From mercury Strutt has obtained so radioactive a gas as to make it probable that part of the therapeutic action of this metal is due to radioactivity, and this may be true of other substances now used in therapeutics. Air enclosed in cylinders of common metals like copper, tin and zinc becomes radioactive.

One writer has proposed placing a glass tube of radium in the middle of a cancer. The experiments on animals, which have been mentioned, indicate this would be unwise, for before the peripheral parts of the new growth were affected, the destruction of both healthy and diseased tissue near the radium would have resulted, for the intensity of the action varies roughly as the square of the distance from the radium, therefore the tissues within a millimeter of the radium would receive twenty-five hundred times as powerful a treatment as those five centimeters away, and the continued presence of the radium, which would be necessary to affect the peripheral parts, would prevent the formation of fresh healthy tissue in the interior.

But it is with reference to diseases on or near the surface that the results of the experiments on animals will be considered now, and when radioactive substances are used for this purpose the following precautions are to be observed:

As the radiations and emanations of the radioactive substances spread in all directions, and some of them have destructive powers on animal tissues, the radioactive substances must be used in tubes, cases, plasters, etc., with non-radiable walls, that the activity may escape only in the required direction and be reinforced by the induced radioactivity from the inner surface of the container. This precaution is necessary to prevent injury to the physician and healthy tissues of the patient. Particular attention must be given as with x-light to the protection of the eyes, as animals can be made blind by radioactive substances as well as by x-light.

In using the radioactive substances in disease of or near the skin, the depth of the diseased tissue to be affected must determine the distance at wnich the radioactive substance is placed from the surface of the patient, for the reason mentioned, — activity diminishes approximately as the square of the distance, though really more rapidly on account of the complex nature of the activity.

If the radium is placed ten centimeters from the skin, the intensity at a depth of one centimeter is nearly as great as at the surface for the more penetrating forms of activity. In many cases, therefore, the sound tissues below the diseased will be acted upon by a destructive agent whose activity would be nearly as great as at the place of disease. The correct way in treating a skin disease with a radioactive substance is to consider to what depth it is desirable to confine as far as possible the activity. If to a slight depth, the radioactive substance should be almost in contact with the skin, the duration of the application being of proper length but always shorter than when at a greater distance. In this case healthy tissue at a depth of one centimeter

would be acted on by radiations and emanations whose intensity would be less than one-hundredth of those striking the skin; obviously a more scientific method.

In regard to the construction of containers for limiting the radiation to the area to be treated, the plan of wooden cases, either stationary or held in the hand and made non-radiable by paint, composed of an oxide of a heavy metal like lead, which were recommended in using x-light, may be employed, metals being substituted for wood, as the fact of their being conductors of electricity is unimportant. Any heavy metal, lead, for example, is suitable. When radioactive substances are used in the form of plasters which require to be flexible to allow them to be adapted to the patient, the back of the plaster should be of material which is made fluorescent by the radioactive material, for in this way the unused radiations are rendered less destructive. The substance of the plaster is to be made like a condenser, of alternate sheets of lead or tinfoil and oiled cloth or paper, and charged from some convenient source of electricity, for such a construction is more non-radiable to the A and B-emanations than an equal thickness of metal in solid form. This condenser construction is applicable to the walls of the tubes or cases to be held in the hand, and containing the radioactive substances, when it is desirable to have the source of activity at a greater distance from the skin,— as it will be to a greater extent than at present when the price of radium is reduced sufficiently to allow it to be employed in a sufficiently concentrated form to use in treating internal diseases by allowing the activity to enter through the skin.

When this is the case, the precautions as to distance should be observed which have already been given for the use of x-light under the same circumstances.[1]

Professor Barker of Philadelphia suggested several years ago that the radioactive substances might take the place of x-light in surgical diagnosis. It was on the strength of his statement the experiments mentioned were made with radium 1,000; though with this the results were unsatisfactory, it would be well to repeat the experiments with pure radium bromide, which can now be purchased by any rich person.

Medical Progress.

PROGRESS IN ORTHOPEDIC SURGERY.

BY ROBERT SOUTTER, M.D., BOSTON.

(Concluded from No. 19, p. 518.)

ARTHRITIS is the rule if there is bone disease near a joint. This is the reason arthritis is so common in children, where the epiphysis is apt to be diseased. Osteomyelitis is in the diaphysis, away from the synovial contact. Points where ostitis are most frequent, arthritis is rare and late in coming on.

By arthritis is meant suppurating arthritis, not serous or plastic, due to neighboring inflammation. Osteomyelitis may spread rapidly, and attention will be on the joint rather than the bone.

Then there is a very detailed account of growth of bone, and particular emphasis is placed on the Y-shape of the cotyloid, at the junction of the three pelvic bones. Invasion of the hip joint comes from the head, not the trochanter of the femur. Of course infection may come from the femur neck or trochanter, but these are rarer and slower than from bones of the joint. Herein is Koenig right in his true coxitis and his osteomyelitis.

Whether the Y-cartilage of the glenoid, the cartilage of the head or the joint becomes involved, the clinical aspect and treatment are regardless of the origin; therefore the clinical aspect and treatment warrant simultaneous consideration.

There may be bone disease of ilium or of the neck and trochanter, but where the head or the glenoid cavity bones are affected the joint will be involved as a rule. Dislocation is favored by the disease of the round ligament and capsule. Perforations are commonest at the junction of the pubo-femoral and ischeo-femoral portion of the capsule, also under the psoas tendon. This is rare, but is more common in adults than in children. Generally perforation is behind. Dislocation is rare without bone lesion.

Pseudo-luxation may occur, due to:

(1) Disease of ligamentum teres and the glenoid cavity being filled with granulations.

(2) From division of the head and neck.

(3) Due to erosion of the head, which is then smaller.

Broca believes the outcome of mild and severe non-tubercular coxitis depends on early diagnosis and vigorous treatment. Disease of the femoral epiphysis or acetabular disease is nearly always complicated with purulent arthritis. Pericerticular drainage will often be sufficient. Unless there is serious disease in the capsule at the time of operation, resection need not be done. Mortality is 50%. Good results by drainage of the joint without resection. Excision is performed in very severe cases only.

H. L. Taylor[2] reports on 40,027 cases; 13,000 cases of tuberculosis, two-fifths being of the hip. Primary lesion being nearly always in the cancellous tissue near an epiphysis. Primary *synovial* tuberculosis is very rare. Insidiousness is characteristic of tuberculosis. Early symptoms are: limitation of motion, limp, anxious expression.

Suppurating arthritis of infancy is acute infectious. Aseptic evacuation is followed by recovery; it seldom becomes chronic. Taylor notes the antagonism of rickets and tuberculosis and of rheumatism and tuberculosis; also one case of gout and tuberculosis.

[1] Boston Med. and Surg. Journ., April 24, 1902; Electrical Review, July 25, 1903, Note 166; Electrical Review, Aug. 15, 1903, Note 167.

[2] American Medicine, 1902.

Shortening is due to:
(1) Lack of growth of the affected leg.
(2) To restraint of the affected leg.
(3) Overgrowth of the well leg.

Ponmiceano and Bolintineano [4] of Bucharest report a cinemetograph study of walk in hip disease. The report confirms what we are used to seeing: patient drags affected leg, does not lift till it passes the vertical; the step is longer with that leg, that is, he rests a shorter time on it; patient leans forward and toward well side; the upper extremities are flexed and used in balancing.

Lance [5] has several interesting articles on disease of the bones about the joint. Tuberculosis of the pelvic bones without coxalgia occurred but 38 times in 1,000 cases observed in nine years. Early cases of abscess with little or no limp, the coxitis must have been secondary to disease of bones about the joint. This he confirmed by x-ray very often.

John Dane of Boston [6] studied the amount of motion allowed by hip splints and points to the value of grasping the pelvis in obtaining good fixation rather than the thorax which by leverage increases jar on hip, unless the leg, thigh, pelvis and thorax are immobilized by a plaster or leather spica. The amount of motion allowed by each splint as measured by him will be given later.

Special cases have been reported:

La Gin Chagua [7] reports 16 cases of spontaneous dislocation of the hip in coxitis. Jouon, a rare form, a forward dislocation in coxalgia; the only one he has found in literature. Begoim, rapid development of tubercular disease with dislocation on pubes.

Treatment. — Lubloff [8] immobilizes in hip disease, using for position that which would be most favorable in case ankylosis should occur. He does not favor osteotomy where ankylosis is not complete, nor does he favor excision. For fixation he prefers Billroth's spica, including both hips and thighs from the ribs to the knees and the weight of body supported on tuberosities of ischium. Abscess is treated by iodo-glycerine injections.

Senn believes that where with good treatment the general health fails excision and clearing out of all diseased tissue of the acetabulum, with removal of the trochanter, is indicated. After thorough cleaning out of all tissues wound is packed with iodoform gauze. Tampon is removed and replaced as may be necessary, the whole heals almost by first intention. By removing all foci rigorous disinfection, an early change in dressing is not necessary, that is, iodoform gauze should remain one to two weeks.

Lane [9] of London makes an incision from anterior-superior spine transversely over trochanter to posterior-superior spine, including all muscles, divides glutei tensor vaginæ femoris. He says there is little bleeding (if one is quick). In this way the posterior-superior and anterior parts of the joint are exposed. The tissue and the joint are cleaned out thoroughly and filled with sulphur gauze; in 48° under an anesthetic he cleans away any slough. This is repeated in 48°, again in 48° S. O. S. When clean he puts in cyanide gauze, repeats, and when all is clean and dry the muscles and ligaments are sutured and limb put in best possible position.

Downs operates early in hip disease, especially when there is abscess —
(1) To evacuate pus.
(2) To ascertain extent of disease.
(3) To drain.
(4) To see if excision is necessary.

Excision is indicated if head and neck are extensively diseased and when epiphyseal line is involved, even if head and neck are normal. Excision of head and neck is wrong without removing the great trochanter.

Excision is indicated earlier in weak children, and always where rise of temperature shows mixed infection and when caries and necrosis are present. He uses a rapid method: a small opening is made in the capsule and the pus evacuated; then the Deyon instrument is put in; and in fifteen minutes for the whole operation, or ten minutes for actual, he is able to clean out the whole disease.

E. H. Bradford [10] reports successful dislocation of hip, with drainage of joint for acetabular disease used as an extreme measure. In another extreme case with persistent night cries, other means being exhausted, the hip was flexed and adducted and held this way by plaster of Paris. This put the adductor muscles out of commission and was successful in relieving the case.

Archambaud [11] treats hip disease mechanically without immobilization ; report of 71 cases only one death. He corrects deformed position and uses Hessing's apparatus with an axillary crutch, bodily massage, etc.

Vulpius [12] thinks that in tubercular coxitis early excision is indicated where there is profuse suppuration, necrosis and high fever. He uses immobilization with plaster of Paris.

Lovett [13] in a report on the value of traction alone or fixation alone finds that traction is the more valuable. Both are often necessary in order to limit the amount of motion well inside what nature allows. It is logical to use a splint suited to each case:

The ordinary

(1) Hip splint with three and one-half pounds of traction and one peroneal strap allows 35 to 40° of motion in flexion.

(2) With almost unbearable traction 15° of motion.

(3) Dr. Dane shows that with three and one-half pounds and two perineal bands, 16 to 27°.

(4) The Dane splint with one band, 9 to 11° motion.

(5) With two bands, 6° motion.

(6) The Lovett [14] splint allows even less. It is for this reason particularly adaptable to cases with 20 to 30° of motion in flexion and less. Severe cases will often not have to be kept in bed.

R. W. Lovett [14] advises the ordinary splint for cases with 45° or more of motion; the Dane splint for cases with 25 to 35; the Lovett splint for cases with 20 to 30° or less.

Hoffa [15] reports 30 cases of subtrochanteric osteotomy with much improved walk and with markedly less fatigue in walking.

Young [16] says operations in hip disease can be avoided by early vigorous treatment, as shown by cases in private practice. Deformity requires correction. Cases may require aspiration or incision for abscess; erosion, excision or amputation. Indications and methods are given.

There is a report by Dr. Walker [17] on the use of creosote as an anti-tubercular treatment. The urine was negative; even with very large doses the patients seemed more comfortable, had fewer night cries; but little effect on the disease and often bad temporary gastric disturbance is noted.

Jouon [17] reports a case of dislocation in tubercular coxitis reduced successfully eighteen months later.

Myers suggests the use of pneumatic perineal straps.

Leroux [18] reports great success in the marine treatment of tubercular bone and joint disease.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

SECOND SEMI-ANNUAL MEETING, HELD IN NEW YORK CITY, OCTOBER 13 AND 14, 1903.

(Concluded from No. 19, p. 524.)

(SECOND DAY — *Concluded.*)

TECHNIQUE OF OPERATIONS ON THE TONGUE.

DR. R. H. M. DAWBARN of New York read this paper. He advocated the operation of removal below the jaw, and particularly the ligation of the external carotid, before attacking the submaxillary triangle. Experience had shown that this procedure was not likely, as had been supposed, to lead to secondary hemorrhage. The author also strongly advised that the patient be so placed as to prevent the entrance of fluids into the air passages, and that after the operation no pillow should be allowed under the head. A better procedure than packing the mouth was the rubbing of aristol into all raw surfaces.

[17] Archiv. Ped., N. Y., xviii, 525.
[17] Rev. d. Orthop., Paris, 1902.
[18] Rev. Orthop. Paris, 1902.

DR. A. T. BRISTOW of Brooklyn disagreed with the author regarding making the ligation of the external carotid the first step of the operation. He liked to spend a week in such preparatory treatment as removing carious teeth and having the other teeth frequently scrubbed with an antiseptic solution.

DR. A. A. VAN DER VEER did not favor the postural treatment, and expressed the belief that the patient should not be kept in bed longer than was really necessary.

DR. W. G. MACDONALD of Albany also disapproved of the postural treatment, and said that he ordinarily expected to see his patient up the day after operation.

DR. A. ERNEST GALLANT of New York spoke of the influence of unskilled etherization in the production of post-operative pneumonia.

POTABLE WATERS.

DR. E. S. WILLARD of Watertown was the author of this paper. He said that a bacteriological examination was of more service than a chemical one in determining the potability of water. The quality of cistern water depended largely upon the material of which the cistern was constructed. If of metallic construction, these parts should be coated with asphalt and paint. There was no objection to cement except that it made the water a little harder. The two principal systems of water purification were the English system of slow sand filtration and the American system of rapid mechanical filtration. The latter method included the use of some coagulant, such as alum, by which the suspended matter was deposited.

DR. F. C. CURTIS of Albany commented upon the laxity of the municipalities in this country as compared with those of Europe. Taking the mortality rate as a measure of the purity of the water supply, he said that the rate in New York city was 20 to 25, whereas in London and some large European cities it was only 10 or 15. Previous to the installation of the filtration plant in Albany in 1899, the rate in that city had ranged from 50 to 120, but had since been 15 or less.

CONSERVATION IN PELVIC INFECTION.

DR. JOHN O. POLAK of Brooklyn argued from the results obtained in 79 cases of acute infection in favor of a modification of Pryor's iodine treatment.

DOSAGE: A PLEA FOR PROPER MEDICATION. FIRST PAPER — DIGITALIS.

DR. A. JACOBI of New York presented a paper with this title. He pointed out that although digitalis leaves after having been kept for a year in a tight tin box appeared unaltered, even on microscopical examination, physiological experiments showed that this drug had lost more than 50% of its potency. When a prompt and decisive action from digitalis was required, neither powdered digitalis nor the infusion should be prescribed. Digitalin, being a glucoside, was a very uncertain preparation, so much so, indeed,

that oftentimes a quantity equal to ten times the theoretical dose would be found inert. In chronic diseases of the valves and muscle of the heart, digitalis might be given with benefit to adults for months at a time in a daily dose of four to six grains.

THE DISPENSARY TREATMENT OF TUBERCULOSIS.

Dr. J. W. Brannan of New York described in this paper a method of treating tuberculosis which was about to be used in the city dispensaries. The plan was to utilize the dispensary for examining these patients and instructing them; to send a nurse to the patients' homes to see that the instructions were enforced and to see that the patients received proper food.

Dr. James A. Miller of New York, who had already gained experience in this kind of work at another dispensary, stated that the patients were provided with paper sputum pouches, each pouch costing one cent, and being used for twelve hours or less. The patients were weighed and inspected once a week, and once a month were subjected to a thorough physical examination. Out of 160 dispensary patients so treated during the past six months, 49 were now in active occupations.

THE CAUSES AND PREVENTION OF INFANT MORTALITY IN NURSERIES AND ASYLUMS.

Dr. E. H. Bartley of Brooklyn was the author of this paper. Among the more important causes of morbidity mentioned were inherited weakness, starvation, neglect, overcrowding, improper diet and infectious diseases. In the management of diarrheal diseases it was important to isolate the patient, disinfect the napkins and exclude or destroy flies.

A MODIFIED ALLIS ETHER INHALER.

Dr. A. F. Erdmann of Brooklyn exhibited this modification, intended to overcome certain difficulties met with in adding ether to the inhaler while the patient was in the Sims' position. The modification consists in cutting transversely through the side of the rubber sheath a slot about one-quarter of an inch wide and three or four inches long, and in using a metal or rubber cap on the ether inhaler as required.

SYMPOSIUM ON TYPHOID FEVER: A LOGICAL DEFINITION OF TYPHOID FEVER.

Dr. H. A. Fairbairn of Brooklyn in this paper discussed the general nature of this disease, insisting that its clinical manifestations varied so with the particular organ or organs in which the infection was focused that errors must needs arise if one considered only its clinical aspect.

ANOMALIES AND DIFFICULTIES OF DIAGNOSIS IN TYPHOID FEVER.

Dr. Henry L. Elsner of Syracuse presented this paper. He said that the prodromal period varied greatly, both as to length and severity. Thus it might extend over several weeks, and be practically afebrile; again, it might only last three or four days and be attended by urgent symptoms. These severe cases usually terminated in death in about two weeks. Some studies that he had made of the blood pressure showed that typhoid fever was characterized by a low arterial pressure, being 130 to 140 mm. in adults, and correspondingly low in children during the first week. The pressure was rarely high except in the presence of complications. A tremulous condition of the tongue with fibrillary twitching he had learned to look upon as quite characteristic of the early days of typhoid. In a series of 110 cases he had found diarrhea present in only 84, while many had been constipated. In only 8 of the cases was no eruption found, although in some instances only a few spots were detected, and these in unusual locations. An early and positive diagnosis of typhoid in infants was rarely made; nevertheless, continued fever in a child without localized disease and with enlargement of the spleen should lead to a suspicion of typhoid. The presence of leucocytosis would argue against typhoid. Sepsis and endocardial infection must not be forgotten. The most that Ehrlich's diazo reaction could do was to excite one's suspicion that typhoid was present; it was not to be compared to the Widal reaction for exactitude.

THE MANAGEMENT AND TREATMENT OF TYPHOID FEVER.

Dr. Egbert LeFevre of New York took up this phase of the subject. Referring to milk diet, he pointed out that, in the process of digesting milk, the latter was coagulated in the stomach into masses of variable size and hardness and that the stomach of the typhoid patient found difficulty in thoroughly disintegrating these coagula. Under an exclusive milk diet the stools were larger and contained more undigested food than when a mixed or semi-liquid diet were employed representing the same quantity of proteids, carbohydrates and fats. Another point that should not be forgotten was that whereas in other diseases in which an exclusive milk diet was considered advisable, the patient was gradually accustomed to the digestion of milk, in typhoid fever the physician usually felt called upon to pour large quantities of milk into his patient's stomach so soon as he had made the diagnosis of typhoid. For these reasons Dr. Le Fevre said he believed in varying the diet somewhat, though making it an invariable rule to give no food to a typhoid patient that could not be passed through a fine wire sieve. Water, either plain or acidulated, with hydrochloric acid or lemon or orange juice, was very acceptable to the patient, and the diet might well be varied by giving coffee, cocoa, tea, kumyss and junket. Sometimes it was well to grate up stale bread and pass this through a fine sieve. Such a dietary he had found produced less tympanites than an exclusive milk diet. The addition of egg to milk made the latter more difficult of digestion, but

when the afebrile stage had been reached, the yolk of an egg could be stirred into bouillon or soup. A cold jelly bouillon was taken with a relish by many of these patients. When there was intestinal hemorrhage, it could be satisfactorily controlled by dissolving half an ounce or an ounce of commercial gelatin in a pint of water, and giving the patient from 2 to 4 oz. of this mixture at short intervals. It was very important to clear out the bowel daily by means of an enema, and where purgatives by the mouth seemed to be indicated he preferred phosphate of sodium, sulphate of magnesium, or, best of all, small doses of castor oil. When stupor, delirium, respiratory and gastrointestinal disturbances showed the need for an intestinal antiseptic, such remedies might be prescribed, but their administration should not be governed by the degree of fever. The routine use of a bath whenever the body temperature reached 102 or 103° F. was now rapidly falling into disuse, and more than three or four baths a day were rarely needed. The speaker advocated the use of acetanilid or phenacetin in small doses, because when so given they quieted the nervous system and improved the patient's general condition without depressing the heart. If quinine were given, it should be in an initial dose of 15 gr., and followed by 5-gr. doses every six hours. He thought it was a mistake to give strychnine in large doses as a routine measure; it should only be given when the heart flagged and in doses to meet the indications. In this disease he believed alcohol was both a stimulant and a food.

THE ITHACA EPIDEMIC.

DR. L. COVILLE of Ithaca read a paper with this title, which he illustrated with lantern views. He said that there had been 1,300 cases of typhoid in the first six months, and about 80 additional ones during the past summer. The latter had been traced to the infection of a broken well by a walking case of typhoid. It was worthy of note that for nearly two years the citizens of Ithaca had received warnings of the pollution of their drinking water, and there had even been a few cases of milk typhoid every autumn for several years. Last December the type of the disease suddenly changed; the disease became more virulent, and the cases no longer failed to give a positive Widal reaction. Constipation had been the rule during the epidemic, and most of the patients presented a peculiar dull red throat, such as is commonly seen in gouty subjects. There were 79 deaths. Of the 300 cases seen by Dr. Coville, 150 agglutination tests were made, and in most instances a positive Widal reaction was obtained between the third and tenth day of the disease. Among the remarkable features of this epidemic were: the great variations in the course of the disease, the comparative freedom from relapses and the absence of milk infection. It was also interesting to note that no plumbers working in infected houses and no employees working in the sewers or at the city pumping station developed typhoid.

THE LESSONS OF THE ITHACA EPIDEMIC.

DR. GEORGE A. SOPER of the State Department of Health spoke on this theme. He said that not only was Six-Mile Creek infected, but there were probably one hundred sources of this infection. It was strange that although the citizens of Ithaca, the local board of health and even Cornell University knew of the danger which menaced the health of the city, nothing was done to avert the calamity. Nothing was done for a long time after the epidemic started to check the progress of the disease. The local board of health seemed powerless, there was no system of reporting infectious diseases, so that new cases could not be ferreted out, and several thousand of the people continued to drink the city water. So far, $25,000 had been expended in the effort to suppress the disease. About $10,000 of this sum had been spent in laboratory work and in the compilation of statistics. The State Board of Health had had the water from nearly every well in the city analyzed, and about 30% of these were either poor or positively dangerous.

THE EPIDEMIOLOGY OF TYPHOID FEVER.

DR. CYRUS W. FIELD, 2d, of New York read this paper. He said that typhoid fever was disseminated chiefly in three ways: (1) By personal contamination; (2) by pollution of the water supply, and indirectly, of the milk supply; and (3) by means of household insects. It had been proved that the typhoid bacilli could live in ice for five months and that soiled clothing might prove a source of infection for two or three months. Not infrequently the urine as a source of infection was overlooked, and it was very common to see hospital internes handle typhoid urine as carelessly as ordinary urine when making urinary examinations.

DR. J. L. HEFFRON of Syracuse opened the general discussion on typhoid fever. He said that it was rather remarkable that although typhoid had been first differentiated from typhus by an American physician, and although many important additions to our knowledge of typhoid had been made by Americans, the people of this country should allow Europeans to surpass them in the attention given to the protection of the water supply from infection by this disease. Practically every one of our public water supplies were to-day so infected, and it was not uncommon for one community to allow its sewage to pass on and infect another water supply. It was high time that physicians should move in this matter, and see to it that each city water supply was protected by the installment of a competent purification plant. With regard to diet in typhoid fever, he desired to commend to the thoughtful attention of the profession generally the admirable paper just presented by Dr. LeFevre, particularly his discussion of the exclusive milk diet in typhoid. As to so-called intestinal antiseptics, he desired to say that for the past two years he had been using acetozone, and while it was not very agreeable to take, it cer-

tainly was the most efficient remedy of this class that he had ever tried.

Dr. A. Jacobi said that as the typhoid bacilli not infrequently were present in the urine long after they had disappeared from the feces, it behooved the careful medical practitioner to look well after this too commonly neglected source of infection. He desired to take issue with Dr. LeFevre concerning the use of acetanilid, whether in small or large doses. The action of this drug was to convert hemoglobin into methemoglobin; in other words, it does just what chlorate of potassium does when it produces poisoning. Acetanilid was an anilin poison, and the most dangerous remedy of this group. It very commonly gave rise to cyanosis, showing its profound effect on the blood.

Dr. LeFevre replied that he had never seen any bad results from the use of 2 or 3 gr. of acetanilid in febrile conditions, except in persons presenting an idiosynerasy. Moreover, he had at one time made examinations of the blood of a number of persons taking acetanilid, and had been unable to substantiate the assertion that acetanilid destroys the hemoglobin.

THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

SEVENTEENTH ANNUAL MEETING, HELD MAY 12–14, 1903, WASHINGTON, D. C.

(Concluded from No. 19, p. 521.)

(Third Day — *Concluded.*)

REMARKS ON SURGICAL TREATMENT OF CHRONIC BRIGHT'S DISEASE BY RENAL DECAPSULATION.

Nephritis in both kidneys might often be found existing in connection with movable kidney on one side. In this case nephrolexy might improve the patient's condition by arresting the process, although it might not cure the disease where pathological changes had taken place to the same degree that a patient was cured of typhoid fever, pneumonia or some other disease of this nature where resolution had taken place. Pousson believed that there was a sympathy between kidneys as between eyes, and an operation on one would frequently relieve the condition existing in the other. This idea was applicable to cases of nephritis that had come under his observation, in which he found by urethral catheterization all the evidences of nephritis of both kidneys, and yet some time after nephroplexy of one organ the common urine coming from both organs showed no evidence of Bright's disease, although the percentage of urea did not come up to the normal in the twenty-four-hour specimen. In chronic nephritis tension was relieved by splitting the capsule. He did not believe that it was necessary to entirely decapsulate the organ in order to afford relief. Those who had split the capsule of the kidney over its convexity would remember the gap which developed at this point when this covering had been holding the organ tightly and this gland had been congested. M. Mongour was of the opinion that diminishing the renal venous tension would increase the arterial tension and thus favor the flow of urine. Splitting the capsule, and to a certain degree decapsulation, would also by diminishing the blood tension take the strain off the heart by necessitating a diminished flow on its part. It was still a question with the author whether it was better to partially decapsulate the kidneys and to make them fast to the abdominal wall, or fully to decapsulate and return them to the fatty capsule. From the firm adhesions which he had seen between the kidney and the posterior abdominal wall, and the scant vascularity he had observed in the fatty capsule, he felt that the former method might later be the one of choice. Again, it was not well known just how much of the blood supply could be obtained from the fatty capsule, and he had not noticed reports of the estimate of the amount of additional circulation derived in this way from autopsy records. Experiments on dogs, according to Dr. Johnson of San Francisco, tended to show that the blood supply obtained from the fatty capsule was very meager. Dr. Johnson said that the renal capsule consisted of two layers, the outer of which is thicker. In decapsulation the outer always came away leaving the inner lacerated, but adherent. After decapsulation a thin exudate appears on the surface, which with the remains of the inner layer of the old capsule became a fibrous investment resembling microscopically the normal capsule of the gland, in that it stripped readily and became more and more fibrous. In some cases it was thicker and in some cases thinner than the original. Generally it was thicker after two months, according to Albarren and Bernard. Up to three and one-half months it was simply a fibrous mass, when it could be differentiated into two layers. In no case was there a considerable anastomosis between the renal and perineal blood channels. Even if the relation of a dog's kidney to the surrounding tissues was not the same as those in man, it was still probable that the reconstruction of the capsule was the same, and this reconstruction in three and a half months would probably indicate the renewal of tension in the kidney, and consequently the recurrence of the symptoms. It might also account for the many deaths that occurred after this period. It seemed to him that as long as the patient with chronic Bright's disease was comfortable and ridding himself of sufficient solids, we should treat him in a conservative way by means of diet, waters and medicines. But if the process was advancing rapidly, and there was fear of the heart becoming overtaxed, the time had arrived for operative interference. In cases of interstitial nephritis operated upon, the albumen and casts might disappear, but the amount of solids given out in the urine might still remain the same. In almost all cases reported there had been some uremic symptoms and varying degrees of edema, while in a number of cases there had been general

anasarca. In the first group of patients, those having some uremic symptoms of chronic edema, an operation could be resorted to in case medical treatment was of no avail. In cases of anasarca, especially if the heart was very bad, it was a question whether one should operate or not. Some have said that this was the time that operation was imperative, but the histories give a mortality of 50% in these cases, 25% were unimproved and finally died, and but 25% were cured or improved. He had never had the courage to operate in these cases. After all operations the patient must be kept quiet for some time and treated medically. In chronic nephritis, when the patient was passing little or no urine, operation was imperative. Drs. Marx and Whitacre had operated in such cases with marked success. On the other hand, Rockey operated upon a case for suppression, and lost the patient in twenty-four hours. Freeman operated upon a patient who was passing a fair amount of urine and in good condition, and the patient died in eighteen hours of suppression. In order to understand these cases better the separate urine from each kidney should be obtained by urethral catheterization and examined. It must be remembered that operation for chronic nephritis by decapsulation was as yet a new procedure and might require many modifications. We could remember when hysterectomy, prostatectomy, intestinal anastomosis and even hernia were considered difficult and dangerous operations. Therefore we might hope that sometime these hopeless cases might be cured radically and without danger by the surgeon's knife.

DR. GEORGE M. EDEBOHLS of New York said that he had not yet reached any definite conclusions regarding the value of this operation, and certainly not as definite as those reached by Dr. Guiteras. It would be from two to five years before it would be known exactly just what the operation or its modification would do for these patients suffering from Bright's disease. He said he would not go into the subject fully, because his views had already been published in the *New York Medical Record* March 28, 1903. Out of 59 patients operated on 11 could safely be considered in the ranks of permanent cures. Before a patient should be placed upon the list of cures he said he should be free from albumen and casts for a period of six months at least, and continuously. The improvement that had followed this operation had been so uniform that it offered encouragement to continue the work. As one absolute result he mentioned the increased excretion of urea; where the output before operation may be below one hunded grains per day, it would be increased to five hundred grains per day within four or five weeks. In his published articles he had tried to subdue his enthusiasm, but his results had been better than pictured; every patient had been relieved of their headaches, backaches, the circulation had been improved, the heart's action improved, and some patients seemed to pass from an apparently hopeless condition to one of comfort. The operation itself he considered to be a very simple one. If Bright's disease affected a movable kidney he would not anchor that kidney unless it presented symptoms that were due to that condition; if such symptoms did exist he then anchored it. When such kidneys are returned to their fatty beds, often they become more or less fixed, due to the infiltration about them. Two weeks ago he was able to examine the kidneys removed from a patient on whom he had performed this operation four months prior. This death was independent of any kidney operation. Serial sections were made and enormously dilated and enlarged blood vessels were shown, which penetrated from the fatty capsule through the capsule proper into the kidney substance. The capsule proper was shown to be reproduced. Further findings in this examination will be published later.

DR. EUGENE FULLER of New York reported two cases he had operated upon; in one there was a marked amelioration of the symptoms; in the other no report could be made because the patient passed from his view.

DR. ARTHUR T. CABOT of Boston reported favorably regarding the operation. He thought we should discriminate more in regard to the selection of cases for operation.

SUB-PARIETAL INJURIES OF THE KIDNEY.

DR. FRANCIS S. WATSON of Boston read this paper. He said that a personal experience of five cases of sub-parietal injury to the kidney had recently led him to make a thorough study of the subject, in the course of which he had collected, formulated and analyzed clinical data of 660 cases, which included all previously published cases of importance. This investigation brought to his notice a number of points which had hitherto received little or no attention. (This paper was published in full JOURNAL, July 9 and 16, 1903.)

DR. EUGENE FULLER of New York reported an interesting case. A butcher's helper had one quarter of a beef fall on his shoulders, from which he experienced considerable pain on one side and increased frequency in micturition, and blood in the urine shortly after the injury. He had been around to different places, and cystoscopic examinations revealed nothing. Dr. Fuller cut down upon a tumified mass and found an immense cold abscess holding over a pint of thick pus. The walls of the abscess cavity were three-quarters of an inch in thickness and very dense and fibrous. No kidney could be found. He thought that, at the time of the injury, a rupture of the kidney occurred with extraperitoneal clots of blood, which gradually broke down into pus; the back pressure probably destroyed the kidney.

OBSERVATIONS ON THE EFFECT OF CATHETER DRAINAGE ON THE FUNCTION OF THE KIDNEYS IN INTERSTITIAL NEPHRITIS AND PYELONEPHRITIS.

DR. ARTHUR TRACY CABOT of Boston read this paper. He termed his paper a study in patho-

logical physiology. He urged operating surgeons to observe more closely the behavior of organs under the varying conditions which they themselves imposed. By such observations many important contributions to pathological physiology have been made, and doubtless many others were under our eyes waiting to be noted. (For the full paper, see JOURNAL, Nov. 19, 1903.)

OFFICERS ELECTED.

For President, DR. EDWIN C. BURNETT of St. Louis, Mo.; for First Vice-President, DR. F. TILDEN BROWN of New York; for Secretary, DR. JOHN VAN DER POEL of New York. Next place of meeting, St. Louis, Mo.

Recent Literature.

A Narrative of Medicine in America. By JAMES GREGORY MUMFORD, M.D., Assistant Visiting Surgeon to the Massachusetts General Hospital and Instructor in Surgery in the Harvard Medical School. pp. 508. Philadelphia and London: J. B. Lippincott Co. 1903.

Dr. Mumford has undertaken a difficult task, and has accomplished it admirably The book is interesting from cover to cover, and if it had nothing more to commend it, this is saying much when we consider the usually uneventful lives of the persons it portrays. As its title indicates, the book does not pretend to be a systematic history of medicine, but rather a narrative of conspicuous men and events during the earlier periods of medical history in America. The narrative, for sufficiently obvious reasons, stops at about the middle of the last century, omitting, therefore, the era of greatest progress. Beginning, then, with colonial medicine in the seventeenth and eighteenth centuries, Dr. Mumford gives us an excellent sketch of the prominent men of this early time and, more important than this, a picture of the general crude character of medical theory and practice, and of the popular attitude toward medicine as a profession. As the author frequently points out, it is somewhat pathetic to see how completely the names of the men who were leaders in their day have passed out of mind, and how little impress the individual made npon medical progress. In Dr. Mumford's opinion Boylston is the only American physician deserving a permanent place among the masters up to the middle of the eighteenth century.

The more conspicuous work of Rush, Smith, Warren, Shippen, Bard, Jones, Morgan and many others, with the stirring events of the Revolution, are graphically described. One also gets from this part of the book an excellent idea of the first attempts at systematic medical education in Philadelphia, New York and Boston. The early part of the nineteenth century receives detailed description. Particularly interesting is the account of the gradual development of surgical practice, with the innumerable difficulties which beset it before the discovery of ether. Among the physicians of this period, Chapman, Francis, Gibson, Jackson, Drake, are some of the notable men to whom critical attention is drawn.

A chapter each is devoted to the discovery of ether, the founding of the American Medical Association and some tendencies in modern medicine. The circumstances attending and following the introduction of ether are told in a spirit of fairness, which cannot fail to commend this chapter to students of this curiously involved controversy. We also cordially commend to our readers the history of the foundation of the American Medical Association, a subject about which many of us are too ignorant. The final chapter of the book on "Some Tendencies in Modern Medicine" is a fitting ending to this altogether satisfactory volume. Naturally enough, the question of specialism is discussed, based on a statistical inquiry, which is suggestive, if not conclusive. Here again the author stands in the attitude of a disinterested spectator, and views the facts as they are. We may well ponder what he says of doctors new and old.

For such a book we have no word of adverse criticism. As we said at the outset, Dr. Mumford has set himself a laborious task, which he has completed in a way to deserve the gratitude of all who are interested in medicine, whether within or without the profession. The book is eminently readable, and has a style of its own, which often suggests in its characterization of men the epigrammatic manner of President Eliot. It should certainly have a wide reading.

Essays on Clinical Medicine. Being reprints of papers published at various times in the *American Journal of the Medical Sciences.* By BEVERLEY ROBINSON, A.M., M.D. Philadelphia: William J. Dornan. 1903.

Dr. Robinson has collected and published in book form various papers dating back to 1889, which have already appeared as journal articles. The papers are largely given over to disease of the heart and lungs, with the addition of an early paper on "Creosote as a Remedy in Phthisis Pulmonalis," a discussion of uremia and "A Study of Some Cirrhoses of the Liver." The papers are the result of a wide personal experience, and as such should receive an attentive and cordial reading.

A Manual of Medical Treatment or Clinical Therapeutics. By I. BURNEY YEO, M.D., F. R. C. P., Emeritus Professor of Medicine in King's College, London, etc. Tenth edition; fifteenth thousand. Vols. I and II. Chicago: W. T. Keener & Co. 1902.

These two volumes are of convenient size, the first containing 696, the second 762 pages not including the indices. The text is written in an interesting manner, and the subject matter has been surprisingly well brought up to date when it is borne in mind that this is a tenth edition. The two volumes present the status of medical treatment to-day, and do not aim at being original.

THE BOSTON

Medical and Surgical Journal

THURSDAY, NOVEMBER 12, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

PHYSICIANS' LIABILITY INSURANCE.

No physician can contemplate with equanimity the possibility of suits for alleged malpractice. The chief anxiety, however, is not that he may suffer in pocket, but rather in the high reputation and good name that he bears in the community. Most physicians, if sued, would spend their last dollar in defending themselves against what they deem a wicked and blackmailing assault upon their good reputation and their slender savings. From long experience they know better perhaps than any other class of men that many if not most actions of tort against moneyed defendants are but legalized robbery. When, therefore, a case comes home to themselves they, conscious of no wrong-doing, cannot but regard a malpractice suit as a kind of blackmail levied under forms of law.

Physicians, in the treatment of their patients, may be ignorant, careless, and neglectful, and may thus inflict injuries which will be recognized and resented by honest patients; for these injuries compensation through legal channels may be sought by the aid of lawyers of high standing and integrity. Few suits for alleged malpractice, however, can be regarded as honest efforts for the redress of real injuries. The skilful, experienced and careful practitioner may be, through no fault of his own, the object of attack. Indeed, it is the skilful and successful physician who suffers rather than the ignorant and unsuccessful.

Now for the annoyances, not to say the mental and physical distress and money loss; what is the remedy which, on the whole, will prove the wisest, the most just, the least expensive?

We have had a large experience in studying civil malpractice suits in this Commonwealth; and we have done our share in trying to demonstrate the truth upon the witness stand. We know that most suits are absolutely without good foundation, and unsupported by medical evidence worthy of serious consideration. We know that ignorance and carelessness are human, but we are convinced that human errors are less likely to occur under the responsibilities of life and health than under the responsibilities of business and property. Yet, try as one will to do his best, one may, for one reason or another, become forgetful, careless, indifferent. Indeed, in spite of the greatest care, one may do things which, from their very nature, cannot be satisfactorily explained before a lay jury. The discovery of a gauze sponge in the abdomen during convalescence from a laparotomy is, for example, an experience which few abdominal surgeons have escaped, even when more elaborate precautions against this accident have been taken than against any other in the operative technique. We know that such an occurrence is in the long run unavoidable, especially in those abdominal emergencies in which success requires the highest skill in operative technique and the greatest speed in its completion. In explaining to a jury, this, — the nightmare of abdominal surgery, — the surgeon would, at best, cut but a sorry figure. No effective defence under these conditions seems possible; and yet the surgeon, far from being careless or ignorant, has been careful, painstaking and experienced. His chief horror is in the occurrence of just this accident; he has taken care in every way to provide against it; and yet he overlooks the sponge. In every conceivable lesion, medical and surgical, he may be called upon to show, to the satisfaction of a jury, the wisdom of his treatment. He cannot see, perhaps, in any case how he has been at fault. Indeed, he may, when especially pleased with his work, find himself blamed; or, when blaming himself, find himself praised.

Now, knowing that he may be accused of malpractice with or without good grounds, mulcted in large damages, proved careless and ignorant against the evidence or the weight of evidence, harassed perhaps for years by relentless counsel, — admitting these truths, what is the sensible man to do? Ought he not to copy the man of business, who provides against disaster by timely insurance? A moderate annual premium will insure the physician, if not against the anxieties and the loss of time incident to a

trial at law, at least against the loss of money. The physician, however, is fighting rather against attacks upon his reputation than against financial loss. To preserve his reputation he would gladly sacrifice his money. Moreover, he fears that when an insurance corporation stands behind him, he will lose that sympathy which has hitherto made juries so reluctant to bring a verdict against him; that a rich and fresh field will be opened for successful legal exploitation; and that he will suffer more than he does now, if not in pocket, in what he values more, — his reputation and his peace of mind.

We ourselves fear that there is much in the last consideration. Inadmissible as the evidence may be, the court, try as it may, cannot keep from the jury the fact that behind the physician stands the rich corporation. The judge may charge the jury against the prejudice which corporations inspire, but they will nevertheless be influenced by that prejudice. Their sympathies will not be, as now, either with the physician or divided between physician and patient: they will be entirely with the patient; and the physician, fighting for his good name, will find that good name smirched by an adverse verdict. Furthermore, is not this experience likely to be more and more frequently repeated?

Again, according to some insurance policies, the company has the right to settle claims against it in its own way — at its own time. Rather than fight a case, even one in which the physician is clearly not at fault, and in which he may be sure of a favorable verdict, the corporation may choose the cheaper way of settlement. In this case the insurance company will have done that which the physician would have spent his last dollar to prevent — it will have forced upon the physician the practical admission of culpability when he felt himself guiltless, insulted and aggrieved. True, if he wishes to fight the case when the insurers wish to settle it, he can, at his own risk and expense, do so. Is it not a fair inference — or at least a grave fear — that the liability companies may at times sacrifice the physician's good name to save themselves expense?

Within the last two weeks two malpractice suits have been tried in Massachusetts. In both suits the physicians had been advised to make the best settlement that they could. In neither would they consent to compromise, even though the compromise could have been effected for a sum much less than the probable cost of trial. In one case the jury disagreed; in the other there was a verdict for the defendant. These physicians, in fighting to the last against what they considered a wrong and an injustice, have done much to discourage similar suits against other physicians. On the other hand, these suits compromised, as we feel sure they would have been under liability policies, could not but encourage other suits.

The restraining effect of insurance on the number of suits for malpractice is said by the insurance companies to be great. This may well be doubted unless the companies fight in every case. A policy of settlement to avoid the expenses of litigation would, we feel sure, encourage and multiply these actions of tort. Many physicians are undoubtedly threatened by suits for malpractice by unscrupulous men who hope, by working upon the physician's fears of publicity, to extort from him small sums in settlement. Against actions of this kind an insurance policy would undoubtedly be discouraging.

There is one form of insurance which really insures against suits. The company, for a certain premium, agrees to spend in any year the principal in actually defending the physician; it does not agree to pay the verdict. Here, it seems to us, is the real insurance that the physician needs — insurance which discourages suits by fighting them to the highest courts of the land; which tries to protect, from first to last, the physician's *amour propre* and reputation; which yields better than anything else that peace of mind so essential to the physician's welfare, and gives him the assurance that he has a friend, and a powerful one, in the time of the greatest professional annoyance that he can possibly undergo. We admit that a policy of defence of this kind, with another covering the money liability, has given us a peace of mind which the ever-dreaded malpractice threat had never before permitted. When confronted by a bad result, a complaining patient, a threatening letter, the physician turns at once to the consoling thought that he has a strong and resourceful defender.

On the whole, we are becoming convinced that liability insurance is a good thing for physicians. The faults in the systems, if any now exist, as is quite possible, will in time be corrected, and the medical profession will not so frequently be placed in the humiliating position of explaining and justifying to an ignorant jury some of the most trying and important acts and decisions of a professional life.

ATHLETICS FOR GIRLS.

ATHLETICS for men have come in for their share of criticism and discussion during the past few years. The football question is perennially discussed in the lay and medical press with no other effect visible than an increased popularity of the game. The question of athletic exercises for girls is of somewhat more recent date, but is apparently one capable of as diverse opinion as is expressed in the case of men. The growth of the athletic spirit in girls' schools and women's colleges has given rise of late to a certain skepticism as to the value of it all, and whether or not the more violent exercises in the way of competitive sports have not been carried to a harmful degree.

No doubt girls of good physical health have been stimulated by the prowess of their friends of the other sex to undertake games which of late years have brought in the element of competition, wnich secondarily has led to public games and sports. So important has the matter become in the minds of those interested in the physical training of girls and women that at a recent meeting of the Boston Physical Education Society, Miss Hill, director of physical training in Wellesley College, started the discussion which has since grown to large proportions. In her investigations Miss Hill had found that girls in a suburban school undertook the most vigorous forms of exercise, like running and jumping, and had boy coaches and no competent woman instructor. The girls also held field days.

Another instance cited was the uncontrolled playing of basket ball in unventilated rooms without proper medical supervision. As a result of Miss Hill's comments, a committee from the Physical Education Society has been appointed, with Miss Hill as chairman, to look into the matter. The committee is working slowly to determine, if possible, all the elements entering into the problem of the health of girls, and particularly of the relation between the school or college and the parents. Miss Hill is in general of the opinion that exercises for girls at school have been improperly regulated up to this time, that there is a growing tendency among young girls to indulge in sports which lead to publicity, and possibly through over-excitement and over-exertion to positive injury. Competitive games for girls she does not believe in.

To any one who has seen a modern game of basket ball played by young girls, the feeling must have been uppermost that the exercise was of such a character that a few years ago it would have been thought possible only for vigorous boys. We have no desire or intention to criticise the playing of basket ball, or any other game of skill by women, provided only, as Miss Hill suggests, their training be properly regulated; in other words, with certain modifications, precisely the same principles should apply to the training of women for athletic sports as to that of men. The question of the appropriateness of women taking part in public exhibitions does not in the least concern us. On the other hand, we are convinced that the modern athletic tendency among women has been a helpful one, and that properly regulated it should lead to a stronger and better-equipped race of women than we have had heretofore. There certainly can be no reason why all such sports should not be completely regulated to meet the physical organization of women. In the meantime it must be remembered that athleticism may be and in fact is overdone by certain enthusiasts, especially when enthusiasm is combined with the inexperience of youth.

THE NOBEL PRIZES.

WE have from time to time commented on the fact that prizes have increased in number quite beyond their usefulness and that the end to be subserved is frequently lost for various obvious reasons. In the first place, there are evidently too many prizes. The credit which comes to the successful competitor is too small to attract the best men, and there is certainly in many quarters a feeling that it is rather beneath the dignity of the scientific investigator to expose his wares for money. It is perfectly clear to any one who observes, that the ablest men do not attempt to gain the ordinary prizes, and it has frequently been the experience of prize committees that no essay worthy of the award is received. Furthermore, the offering of money is not in general an adequate stimulus for scientific work, although we are glad to admit that occasionally the combination of financial need and ability go hand in hand. In general we regret to see money left for the purpose of establishing prizes. The self-respect of the scientific world would certainly be enhanced if much of the money for this purpose could be withdrawn.

Standing in a wholly different category from this type of prizes is the foundation which renders possible the so-called Nobel prizes. We have in this foundation an ideal method of encouraging the best scientific research, and it is

a gratification each year to see very considerable amounts of money bestowed upon men who by general consensus of opinion have achieved something notable in science or literature. It will be remembered that by the terms of this foundation, made in 1895, upward of eight million dollars was left to encourage original work in five different departments of learning, among which medicine was included. Notices have been recently sent out for the suggestion of a candidate for the prize in the section of physiology and medicine to be given during the year 1904. By this general vote of the scientific men of the world, an eminently just decision is usually reached regarding the value of work done during the preceding year. The final award comes as a surprise to the recipient. He has made no effort to gain the prize beyond an abstract devotion to scientific work of the highest order.

It will no doubt be many years before another foundation of the amount and character of this is established, but we have no hesitation in expressing the hope that, if money be left for the encouragement of research, it may take some such form as this rather than make a personal appeal to the cupidity of the contestants. The one is altogether worthy of the highest scientific ideals, and the other, we are forced to admit, tends rather to detract from than to add to the ends of science.

EUTHANASIA.

A FLURRY of excitement appears to have been aroused by certain utterances of the Rev. Mr. Wright, a New York clergyman, on the subject of euthanasia. Mr. Wright has recently made the suggestion that persons with incurable disease should be relieved from their sufferings by artificial means. Naturally he has safeguarded this proposition by various suggestions, such as the consent of the person concerned, of his family and of a jury composed of physicians and possibly of a clergyman. There was nothing particularly original in the point of view expressed. It has no doubt been discussed at various times and places since the days of the Greeks. The fact remains that a public protest, both from lay and medical sources, has arisen such as Mr. Wright, no doubt, little expected. The fact of the matter is that this question of hastening death under any circumstances whatsoever is not to be talked of in public. That euthanasia is at times produced most legitimately there can be no question. That a general doctrine should be spread abroad urging the production of painless death in certain conditions as a routine measure will always receive the condemnation it deserves. This is one of the many matters which may best be left to the individual discretion of the physician and to the family, as well as to the sufferer himself.

The question continually presents itself to the physician in active practice, whether or not, in cases which are eventually fatal, it is wise to postpone death through various possible artificial means, such as stimulation of the heart or artificial feeding. We are inclined to think that the consensus of opinion now is that it is the part of humanity to allow a patient to die without such artificial stimulation when the inevitable end could in any case only be postponed. Here again principles are certainly not to be laid down. By far the safest method, and the most in accord with our principles of morality, is to judge each case on its merits and to attempt no promulgation of a general theory.

MEDICAL NOTES.

THE ORGANISM OF SMALLPOX — At a meeting of the Section of Biology, New York Academy of Medicine, held Nov. 9, 1903, Dr. Gary N. Calkins spoke on "The Life History of the Organism of Smallpox," which has been named Cytoryctes variolæ Guar. It will be remembered that Dr. Calkins has been associated with the recent work on smallpox in Boston.

ALVARENGA PRIZE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.— The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, amounting to about one hundred and eighty dollars, will be made on July 14, 1904, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the secretary of the college on or before May 1, 1904.

Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award.

ATTITUDE OF BRITISH PHYSICIANS TOWARD PUBLICITY. — It is stated that the British Medical Association not long since sent a request to the lay press urging that the names of physicians attending cases should not be made public in its columns, with the exception of those in attendance upon any member of the royal family.

LAW AGAINST THE CORSET. — The *Medical Record* makes the statement that a Dr. Maréchal of Paris is urging the passage of a law making the wearing of a corset by any woman under thirty years of age a penal offence. *Apropos* of this rather radical legislation, it is stated that a woman in Buffalo recently died through the penetration of her heart by a corset steel, and we have also been informed of a very serious x-ray burn resulting from the wearing of a corset during treatment. In spite of these occurrences, we imagine the corset will still remain in use.

KING EDWARD'S SANATORIUM. — The foundation stone of King Edward's Sanatorium for tuberculosis was laid Nov. 3 at Lord's Common in Sussex. It will be remembered that sometime since Sir Edward Cassel left about a million dollars for the purpose of providing a sanatorium for tuberculous persons in England. This is the beginning of the realization of that bequest.

A COLUMBIA UNIVERSITY HOSPITAL. — It is reported that the trustees of Columbia University are considering the possibility of constructing a hospital, to be under the control of the department of medicine. It is estimated that the preliminary cost of such a hospital will be in the neighborhood of two million dollars.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon Nov. 11, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 82, scarlatina 17, typhoid fever 13, measles 99, smallpox 0.

NEW ENGLAND DEACONESS HOSPITAL. — Exercises on the laying of the corner stone of the new Deaconess Hospital in Longwood were held Nov. 5. Among the speakers were Governor Bates, Dr. M. H. Richardson and Rev. Dr. James M. Buckley of Brooklyn, N.Y. Through vigorous attempts on the part of the management, upwards of $42,000 has been paid in, of which over $37,000 has been paid for land and other items. It is proposed to erect merely the left wing with a frontage of about one hundred feet, three stories in height. There will be accommodations for forty-two beds, together with adequate operating rooms and other accessories. This hospital has done a good work in an unostentatious way, and should receive sympathy and encouragement both within and without the profession of medicine.

NEW YORK.

MORTALITY STATISTICS. — The Health Department reports show that during the month of October the mortality in the city represented an annual death-rate of 16.05, as against 15.75 in September and 16.00 in October, 1902. The corrected death-rate, excluding non-residents and infants under one week old, was 15.19. Among the diseases which showed a decline in mortality were the following: The weekly average of deaths from whooping-cough decreased from 6.5 in September to 3 in October; the weekly average of deaths from acute bronchitis decreased from 27 to 23.5; from diarrheal diseases, from 151.5 to 86.25; and from diarrheals under two years of age, from 133.25 to 79.25. Among the diseases which showed an increased mortality were the following: The weekly average of deaths from diphtheria and croup increased from 28.75 to 34.5; from scarlet fever, from 4.5 to 5.25; from measles, from 3.25 to 4.75; from typhoid fever, from 16.75 to 18.5; from pneumonia, from 61.5 to 77.25; from broncho-pneumonia, from 36.5 to 43.5; from pulmonary tuberculosis, from 133.75 to 144.75; from cancer, from 43.25 to 49.25; from Bright's disease and nephritis, from 91.5 to 93; and organic heart diseases, from 71 to 86.25. During the month 4 deaths from influenza were reported.

ANOTHER PAVILION FOR ST. LUKE'S. — Through the generosity of Mrs. Plant, widow of the late Henry B. Plant, St. Luke's Hospital is to have another elaborate pavilion added to its buildings. This new structure will be located on the southeast corner of the hospital grounds, overlooking Morningside Park, and in its general features will resemble the two other pavilions facing on 113th Street. It will occupy the same area of ground as the others, or about seventy feet each way, although it will be somewhat taller, as the land on which it is to stand is lower than that around it. It will be connected with the Minturn Pavilion by means of a corridor, and the roof is to be provided with a garden and a solarium. The original plan of the magnificent new St. Luke's contemplated ten pavilions in all, and five of these have already been erected and occupied.

Union of Medical Societies. — At a meeting of the Medical Society of the State of New York held at the Academy of Medicine, New York, on Oct. 13, a resolution, offered by Dr. D. B. St. John Roosa, was adopted empowering the committee appointed some time ago for the purpose of conferring with a similar committee of the State Medical Association to take final action in the matter of the union of the two societies. As mentioned in the Journal, the committee of the State Association had previously been authorized by that body to take such action as would consummate the desired union.

New Appointments Columbia Medical School. — At a meeting of the board of trustees of Columbia University held Nov. 2, the appointment of the following new professors in the medical department was announced: Dr. Joseph A. Blake, Professor of Surgery; Dr. George E. Brewer, Professor of Clinical Surgery; Dr. John S. Thacher, Professor of Clinical Medicine; Dr. Frederick Peterson, Professor of Psychiatry; Dr. Samuel W. Lambert, Professor of Applied Therapeutics. Dr. George M. Lefferts, who has announced his intention of retiring from the chair of laryngology in June next, when he will have completed thirty years of service in the College of Physicians and Surgeons, presented to the university his extensive and valuable collection of apparatus for illustrating the teaching of laryngology and rhinology, and the trustees ordered that the apparatus should be hereafter known as " The Leffert's Collection."

Ratio of Street Accidents, New York and London. — It is stated that while no less than 538 persons were killed by vehicles in the streets of New York last year, information furnished from Scotland Yard shows that in the metropolitan district of London, with its 688 square miles of territory, the total number of such fatal accidents was but 158.

Correspondence.

MEMORIAL TO MR. WILLIAM CADGE.

Boston, Nov. 6, 1903.

Mr. Editor: Some members of our profession may be glad to know of the fund now being raised in England — memorial to William Cadge, the eminent writer and operator. His great success in the treatment of stone in the bladder is well known. Those desiring to contribute may send directly to Dr. Michael Beverley, Treasurer, Norwich, England. Subscriptions are limited to one guinea each.

Yours very truly,

H. H. A. Beach, M.D.

RECORD OF MORTALITY

For the Week ending Saturday, Oct. 31, 1903.

Cities.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Diseases.	Typhoid fever.

Deaths reported, 3,044; under five years of age, 681; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 726, acute lung diseases 208, consumption 371, scarlet fever 19, whooping cough 12, cerebrospinal meningitis 7, smallpox 11, erysipelas 4, puerperal fever 7, measles 9, typhoid fever 62, diarrheal diseases 140, diphtheria and croup 84.

From whooping cough, New York 3, Chicago 1, Philadelphia 2, Baltimore 1, Pittsburg 2, Lowell 1, Woburn 1, Adams 1. From erysipelas, New York 2, Providence 1, Clinton 1. From smallpox, Philadelphia 8, Pittsburg 3. From measles, New York 6, Chicago 1, Philadelphia 1, Pittsburg 1. From cerebrospinal meningitis, New York 3, Boston 1, Worcester 2, Somerville 1. From scarlet fever, New York 7, Philadelphia 6, Baltimore 3, Boston 1, Worcester 1, Woburn 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Oct. 17, the death-rate was 15.8. Deaths reported, 4,573; acute diseases of the respiratory organs (London) 175, whooping cough 42, diphtheria 43, measles 45, smallpox 0, scarlet fever 35.

The death-rate ranged from 3.3 in Hornsey to 26.3 in Middlesbrough, London 15.3, West Ham 17.8, Brighton 15.0, Portsmouth 15.0, Southampton 11.8, Plymouth 13.0, Bristol 10.9, Birmingham 18.3, Leicester 13.3, Nottingham 17.6, Bolton 15.9, Manchester 20.3, Salford 24.2, Bradford 15.6, Leeds 15.3, Hull 13.0, Newcastle-on-Tyne 19.9, Cardiff 14.8. Rhondda 15.3, Liverpool 19.5, Sunderland 17.4, Sheffield 19.0.

METEOROLOGICAL RECORD.

For the week ending Oct. 31, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING NOV. 5, 1903.

VAUGHAN, G. T., assistant surgeon-general. Appointed as member of committee to consider and report upon the matter of uniforms and insignia for officers and employees of the Customs Service. Nov. 3, 1903.

CARTER, H. R., surgeon. Leave of absence for one day, Oct. 29, 1903, under paragraph 189 of the regulations.

BILLINGS, W. C., assistant surgeon. Relieved from duty at Quebec, Canada, and assigned to duty in office of the United States Commissioner of Immigration at St. Johns, N. B. Nov. 5, 1903.

KERR, J. W., assistant surgeon. Granted leave of absence for two days from Oct. 18, 1903, under paragraph 191 of the regulations. Relieved from duty at the Immigration Depot, New York, N. Y., and directed to proceed to Duluth, Minn., for temporary duty as medical inspector of aliens. Oct. 28, 1903.

STANSFIELD, H. A., assistant surgeon. Granted leave of absence for ten days. Nov. 2, 1903. Upon expiration of leave to report at Bureau, Washington, D. C. Nov. 2, 1903.

WILLE, C. W., assistant surgeon. Relieved from duty at Philadelphia, Pa., and directed to proceed to Baltimore, Md., and report to medical officer in command for duty and assignment to quarters. Nov. 2, 1903.

BOGGESS, J. S., assistant surgeon. Granted leave of absence for three days from Nov. 3. Nov. 2, 1903.

CLARKE, F. N., acting assistant surgeon. Granted leave of absence for twenty days from Nov. 8. Oct. 29, 1903.

ECHEMENDIA, D. M., acting assistant surgeon. Granted leave of absence, on account of sickness, for thirty days from Oct. 5. Oct. 16, 1903.

TAPPAN, J. W., acting assistant surgeon. Granted leave of absence for seven days from Nov. 2, 1903, under paragraph 191 of the regulations.

ACHENBACH, JOHN, pharmacist. Granted leave of absence for six days from Oct. 26, 1903, under paragraph 210 of the regulations.

BOARD CONVENED.

Board convened to meet at Baltimore, Md., Nov. 2, 1903, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Surgeon H. R. Carter, Chairman; Assistant Surgeon M. W. Glover, Recorder.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING NOV. 7, 1903.

ELLIOTT, M. S., surgeon. To the Naval Hospital, Norfolk, Va.

EVANS, S. G., surgeon. Detached from Naval Hospital, Norfolk, Va., and to the "Cleveland."

WHEELER, W. M., surgeon. Detached from the Naval Hospital, Newport, R. I., and granted leave for thirty days.

BLACKWELL, E. M., passed assistant surgeon. Detached from the "Hancock" and to the "Castine."

SPEAR, R., passed assistant surgeon. Detached from the "Wheeling" and to home and await orders.

ODELL, H. E., passed assistant surgeon. Detached from the Naval Hospital, Norfolk, Va., and to the "Wheeling."

MURPHY, J. A., assistant surgeon. To the Navy Yard, Washington, D. C.

RICHARDSON, F. A., acting assistant surgeon. To the Naval Hospital, Newport, R. I.

SCHWERIN, L. H., acting assistant surgeon. Detached from the "Yankton" and to the "Southery."

ELMER, M. K., assistant surgeon. Detached from the U. S. R. S. "Independence" and to the "Pensacola."

DARNEY, V., acting assistant surgeon. Detached from the "Pensacola" and to duty with Recruiting Party No. 4.

CHAPMAN, R. B., acting assistant surgeon. Detached from duty with Recruiting Party No. 4 and to the Navy Yard, Mare Island, Cal.

TAYLOR, E. C., assistant surgeon, and REEVES, I. S. R., assistant surgeon. To the Naval Museum of Hygiene and Medical School, Washington, D. C.

MARSTELLER, E. H., surgeon. To the "Columbia."

KENNEDY, J. T., passed assistant surgeon. Commissioned passed assistant surgeon with rank of lieutenant.

OHNESORG, K., passed assistant surgeon. Commissioned passed assistant surgeon with rank of lieutenant from March 3, 1903.

MILLER, J., CAMPBELL, F. E., assistant surgeons. Ordered to Naval Museum of Hygiene and Medical School, Washington, D. C.

HIGH, W. E. G., assistant surgeon. To the "Constellation."

SOCIETY NOTICE.

THE fourth annual meeting of the AMERICAN ROENTGEN RAY SOCIETY will be held at the University of Pennsylvania, Philadelphia, Dec. 9 and 10, 1903.

JAMES B. BULLITT, M.D., Secretary,
Louisville, Ky.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — There will be a meeting of the society in Sprague Hall, Medical Library Building, on Monday, Nov. 16, 1903, at 8.15 P.M.

Papers: F. G. Balch will report Cases of Intussusception; Dr. A. K. Stone will present a paper entitled "Cardiac Displacement."

ARTHUR K. STONE, M.D.,
Secretary.
543 Boylston Street.

RECENT DEATHS.

JULIAN J. CHISOLM, M.D. — Dr. Chisolm, who long held an enviable position as an ophthalmologist in Baltimore, died Nov. 1, in Petersburg, Va., at the age of seventy-three. During the greater part of his active life he was a frequent contributor to periodical medical literature.

DR. EMIL ROSENBERG of New York, who was the senior medical officer of the Northwestern Life Insurance Company, and who was widely known both in this country and abroad as an authority on the subject of life insurance, died on Nov. 4, at the age of seventy-four years. He was a native of Germany and was graduated at Berlin in 1855. He came to the United States in 1868, and has been a medical examiner for the Northwestern Company ever since that date.

BOOKS AND PAMPHLETS RECEIVED.

Ein Melanosarkom des Ciliarkörpers im allerersten Beginn der Entwickelung. By G. S. Derby, M.D., of Boston. Reprint. 1903.

Ueber die Abhängigkeit der Wirkung der Augentrophen von ihrer Temperature. By G. S. Derby, M.D., of Boston. Reprint. 1903.

L'Inoscopie. By André Jousset of Paris. Reprint. 1903.

L'Inoscopie. By André Jousset. Archives de Médecine Expérimentale et d' Anatomie Pathologique, Maro, 1903.

Septicémie et Endocardite Tuberculeuses "Primitives" Diagnostiquées Pendant La Vie. By M. M. Brallion et André Jousset. Reprint. 1903.

Des Septicémies Tuberculeuses. By André Jousset.

The Community and Tuberculosis. By Beverley Robinson, M.D., of New York. Reprint. 1903.

Congenital Dislocation of the Hip, and Lorenz's Method of Treating It. By J. Jackson Clarke, M.B. (Lond.), F.R.C.S. Reprint. 1903.

The General Practitioner and his Relation to Early Surgical Operations. By E. B. Montgomery, M.D., of Quincy, Ill. Reprint. 1903.

Preventive Medicine and Natural Selection. By Chas. V. Chapin, M.D., of Providence, R. I. Reprint. 1903.

OBSERVATIONS ON THE EFFECT OF CATHETER DRAINAGE ON THE FUNCTION OF THE KIDNEYS IN INTERSTITIAL NEPHRITIS AND PYELO-NEPHRITIS.

BY ARTHUR TRACY CABOT, A.M., M.D., BOSTON,

Surgeon to the Massachusetts General Hospital.

My contribution may best be termed a study in pathological physiology.

Physiology teaches us much about the behavior of normal organs under varying conditions; but the study of the manner in which diseased organs perform their functions falls to the clinician. Modern surgery, dealing as it does with vital parts, affords opportunities for physiological and pathological investigation which are becoming more and more appreciated. Surgery is one of the most important branches of experimental medicine. The operating surgeon has opportunities of studying the behavior of organs under varying conditions which he himself imposes. His work in this respect resembles that of the physiological experimenter. The full value of his experiments depends on the thoroughness with which he investigates the conditions existing before and after his intervention. By such observation, many important contributions to pathological physiology have been made and doubtless many others are constantly under our eyes waiting to be noted.

The kidneys are organs that offer an especially favorable field for this sort of study, and I offer to-day some observations on their functions as affected by the relief of pressure. This subject is a large one, and I do not propose to speak at this time of that part of it which relates to the relief of pressure by incision or stripping of the capsule, although I have a number of observations on the beneficial results of such operations.

I am going to speak of the effect of relief of internal pressure in the kidneys. An increase of internal pressure is brought about usually by some obstructive lesion in the outer urinary passages. A sudden and complete obstruction causes a cessation of renal excretion, but when this obstruction comes about gradually, the kidneys adapt themselves to it and go on separating the urine from the blood under a constantly increasing tension. The cases in which I have made my observations on this condition are those of old men suffering from obstructive disease of the prostate. The polyuria that insidiously establishes itself in such cases is well known. The urine gradually drops in specific gravity, but at the same time increases proportionately in quantity. The elimination of solids diminishes but slowly, for the urine makes up in quantity what it lacks in quality. Presently, however, the point is reached where the dilute urine, even though greatly increased in amount, does not succeed in carrying off the waste products in sufficient amount and characteristic symptoms of systemic poisoning manifest themselves. That this series of events is in the main due to a gradually developing interstitial nephritis is generally accepted, as proved by abundant pathological demonstration. It is probably true that this polyuria is at first in part functional; but that the disturbance of function gradually tends to bring about organic changes of a sclerotic character, there can be no doubt. Some students of the subject believe that this interstitial change in the kidney is part of a general sclerotic change in the organs and blood vessels of the body, the enlargement of the prostate being only another manifestation of the general condition. This explanation of the phenomena is urged by so great an authority as Professor Guyon. Another belief is, that the condition of the kidney is secondary to the enlargement of the prostate and due directly to the obstruction to the flow of urine. This view is the one held by the writer and by the majority of observers as explaining the causation of interstitial nephritis in these cases. It is plain that when the bladder is tensely filled there is an increase of tension in the kidney. There can be no doubt about this fact, proved by so many cases of distended ureters and hydronephrotic kidneys, due to obstruction in the urethra.

Experimental investigation of the influence of the obstruction in the prostate upon the kidney is not easy, on account of the difficulty of reproducing in an animal the gradually forming obstruction which educates the kidney little by little to perform its functions under a greatly increased tension. Considerable light on this question may, I think, be obtained clinically by the study of our cases with such experimental investigations as are afforded by the surgical procedures properly resorted to for our patients' relief.

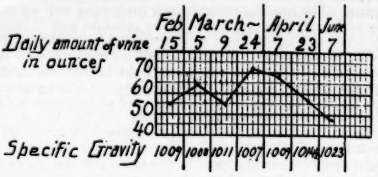
For many years, I have treated a certain proportion of these cases by the installment of an in-lying catheter. This method gives us an unusual opportunity for studying the effect of the simple relief of tension. After severe operative procedures on the prostate, there is so much general disturbance of all functions and the operation does so much besides simply relieving the tension that it is difficult to estimate exactly the cause and amount of the subsequent relief. The introduction of drainage by a catheter, on the other hand, inflicts no trauma and produces no decided change in the condition beyond that incident to emptying the bladder. Once empty, the viscus is kept drained. The urine is removed as rapidly as it flows in. The ureters and pelves of the kidneys empty themselves and afterward remain empty. We are justified in believing that the relief of pressure extends even through the uriniferous tubules into the Malpighian bodies and diminishes the tension around the vascular glomeruli. If, now, the relief of this tension in the urinary passages is followed by a resumption or great improvement of function on the part of kidneys partially disabled, we are justified in supposing that the previous interference with the function of these organs was in large part due to the tension and so primarily due to the obstruction that caused it.

It is upon the observation of this course of

events in a considerable number of cases that I base my adherence to the belief that the prostatic condition is in largest degree responsible for the changes in the kidney. Besides the interstitial change in the kidneys of these patients we have also in most of the cases that come into the surgeon's hands an inflammatory condition which has extended from the bladder up the dilated ureters to the pelves and finally to the parenchyma of the kidneys. This is the pyelo-nephritis found almost invariably in the post-mortem examinations of patients who have died of uremia consequent upon obstructive conditions in the prostate. As a rule, the micro-organisms that cause this inflammation are introduced into the bladder by the surgical use of instruments for the relief of retention. This accident is so difficult to avoid in cases requiring constant catheterization that its occurrence brings no just reproach to the surgeon. Practically, every bladder habitually emptied by a catheter is sooner or later infected. Fortunately the valvular opening of the ureter prevents the extension of this inflammation backward to the kidneys in the majority of cases. When, however, the ureters are greatly distended, the orifice in the vesical wall is opened somewhat and extension of the inflammation backward is easy. This condition of active inflammation engrafted upon an interstitial nephritis complicates the clinical picture in a certain degree. Fortunately, however, the pyelo-nephritis is quickly relieved in most cases and it is then possible to watch the gradual change in the urine which marks the slow improvement in the secreting portion of the kidneys.

I do not propose to speak of the methods of establishing catheter drainage further than to say that the plan I have followed is to put a soft catheter into the bladder and to so arrange it that it draws the urine steadily without irritating the vesical walls. It should be fastened so that it stays in place and should be watched so closely as to insure that it shall never stop running for more than a few minutes at a time. This is no new proceeding, but is usually employed for the relief of conditions in the bladder and urethra. I have found no satisfactory account of its effect upon the function of the kidneys.

Langlois and others have noted that enlarged kidneys are reduced by bladder drainage. Langlois says, "It is difficult to know to what this reduction in size is due; whether to the diminution of congestion or to the emptying of a kidney dilated by retention." I would urge, and I hope to show, that the effect of diminishing the pressure in the kidneys is *the most important good* obtained by catheter drainage in these prostatic patients with damaged kidneys. If this is accepted, it is equally clear that all operations which successfully remove prostatic obstruction must owe a large part of the good service that they render to this relief of back pressure and intra-renal tension. For the purposes of this investigation I have taken it for granted that a patient with obstructive disease of the prostate and dilated bladder may be regarded as having some degree of interstitial nephritis if the urine is abundant and of very low specific gravity. If such a patient is suffering from anorexia, nausea and dry mouth, either with or without psychical disturbances, these are to be looked upon as symptoms of uremia due to this interstitial nephritis. If, in addition to these symptoms, he has a high fever and the urine contains pus, it is to be regarded as probable that he has pyelo-nephritis. This supposition is strengthened if one or both kidneys are found to be tender or enlarged. I have found that when efficient drainage is afforded to patients offering the above clinical picture of a pyelo-nephritis, complicated by a preëxisting interstitial nephritis, in the vast majority of cases a very great amelioration or even total disappearance of febrile and uremic symptoms is brought about. It has been my practice to favor diuresis by the administration of large quantities of water. This I have done with the purpose of assisting elimination and also to flush out the kidneys and thus wash out the inflammatory products. If the kidney pelvis is not yet infected, the increased flow of urine running down the ureters without any back current offers conditions unfavorable to the extension of inflammation upwards even if the bladder becomes infected. In some cases, when the constant drainage has been too soon changed for intermittent catheterization, a return of fever and other inflammatory symptoms give evidence that backward extension has again occurred. In such cases I have found that by persisting in the continuous drainage the time has finally been reached when it could be safely dispensed with.



The most reasonable explanation that I can offer for this finally acquired safety for kidneys that have earlier shown a tendency to this retroinfection is that the ureters gradually contract somewhat when the internal pressure is relieved, and also that, the bladder being no longer stretched, its muscular coat recovers its tone and restores the valvular condition at the ureteric orifices; thus giving back to us the physiological barrier that nature normally affords. The first effect on the urinary excretion produced by drainage is a very considerable increase in the amount of urine. In one case the daily amount of urine, which had been eight pints shortly before and had fallen to six pints at the time the drainage was established, rose to sixteen pints shortly after the catheter was tied in. This was an extreme case, but a considerable increase in quantity is noted in all of these patients. I regret that I have no accurate data to show how great an increase of elimination of solids is obtained by this increase in quantity of the urine. That there is a considerable increase is shown first by the fact that the specific gravity does not diminish in proportion as the amount of urine increases and secondly, by the improvement of the patient's condition, which attests a greatly increased elimination. After this first accession of polyuria the quantity of urine gradually falls while the specific gravity rises. The amount of this improvement

differs in different cases. In some patients the quantity of urine and its specific gravity return to within normal limits; in others, while stopping short of this, the restoration reaches a point where the elimination is wholly adequate for the individual. I have one patient, a man of eighty-nine who is seemingly perfectly well and vigorous for his age, who is excreting but little more than one-half the so-called normal amount of urea.

Before proceeding to the detailed report of cases, and in order to avoid misapprehension, I wish to say that I do not regard this method of treating prostatic patients with the in-lying catheter as in any way superseding other operative procedures. It is applicable to very old or very broken patients who are not fit subjects for serious operation, also to patients who will not consent to operation and, finally, it is of great use in preparing patients for some more serious operation. Many of these patients with pyelonephritis and already commencing uremia are not fit subjects for prostatectomy, but by a course of treatment with the in-lying catheter their condition may be so much improved that they will bear, without serious risk, operations which before this preparation would have been almost certainly fatal.

In presenting these cases I have been greatly handicapped by the imperfection of my records. In many instances where frequent examinations gave information as to quantity and constitution of the urine, the written records of these observations have been lost or destroyed. Thus many cases that remain in my memory as striking illustrations of the course of events that I have described cannot be given with the documentary evidence that would make them convincing. It was this experience of my own shortcoming in a set of cases in which I take great interest that inspired the remarks at the beginning of this paper on the importance of our conducting our surgery and recording our observations as if we were engaged in laboratory experiment. All of the cases used in this study were in private practice. Hospital cases are too soon lost sight of to give an adequate idea of the amount of improvement in kidney function. The histories reported have been selected because they present uncomplicated pictures of the condition to which attention is directed. Many other cases have been met in which similar conditions have existed, but in which the presence of stone, of cardiac or of pulmonary disease has caused confusion in the symptoms.

Case I. J. D. L., sixty-seven years of age, was troubled in the autumn of 1897 with frequency of urination which greatly increased over what it had previously been. In December catheterization was commenced. Twelve or thirteen ounces of residual urine. For some weeks catheterization was regularly carried on without untoward effect, but in February Mr. L. suddenly began to have considerable fever, temperature rose to 103° F. and he became seriously ill. I now saw Mr. L. and after twenty-four hours tied in a catheter. The temperature fell quickly to normal. After a week or ten days the catheter was left out, but this was at once followed by a rise in temperature. After further waiting this attempt was repeated with the same result. Mr. L. was now allowed to be up and about with the catheter in place and he began to attend to business, stopping the catheter for intervals of one to two hours. Finally, when the bladder showed itself to be tolerant of this condition, the catheter was left out and he resumed the ordinary condition of a catheter patient passing the instrument once at night and four times in the daytime. At the present time, March 7, 1903, Mr. L. is in excellent general condition and engaging in active business. The accompanying chart is of especial interest. It illustrates the return of renal function in these cases when the internal tension of the kidney is permanently relieved and fairly presents the sort of improvement noted in greater or less degree in all of these patients.

It will be seen that on Feb. 15 and again on March 5, and again on April 23, the quantity of urine was approximately 55 oz. in the twenty-four hours. Observing the specific gravity, it will be seen that whereas on Feb. 15 it was 1009, it had risen on March 5 to 1011 and on April 23 it had risen to 1014. On the 7th of June, when Mr. L. was fully recovered, the quantity of urine was 48 oz. and the specific gravity 1023. The kidneys had thus returned to doing practically normal work.

Case II. W. B. W., old man with long-standing bladder difficulty. Seen Feb. 18, 1898, in consultation with Dr. Webber. Mouth dry, no appetite, much nausea, somnolence a marked feature. In-lying catheter established, followed by immediate improvement and, later, establishment of catheter life. Seen in 1901 and at that time had had no return of renal difficulty. In this case no systematic watch of the urine was kept, but the quick disappearance of pronounced uremia and the restoration of normal renal function made it a striking illustration of the relief that catheter drainage brings to laboring kidneys.

Case III. T. B. D., a frail man of fifty-seven, seen June 18, 1901, with Dr. Underwood of Gardner, Mass. Urinary difficulty for a number of years. Slow, small stream, shutting off at times while passing. For past year strength has been failing. In past six weeks has begun to have stomach symptoms, anorexia, nausea, dry tongue. A few days before, Dr. Underwood, finding the bladder distended to above the umbilicus, passed with some difficulty a small silver catheter and drew two quarts of very pale urine. Since then has had to draw the urine twice a day. The patient's temperature has gradually risen to 101.5° F. At the time of my examination the bladder could be felt reaching nearly to the umbilicus. Neither a soft rubber catheter nor a flexible coudé catheter would enter the bladder. With a long wire stylet a soft rubber catheter was introduced and fastened in place. Thirty-seven ounces of urine of very low specific gravity were withdrawn. Under constant drainage the temperature soon came to normal and remained there; the tongue gradually became moist and clean and the appetite returned. The urine, varying in specific gravity between 1003 and 1005, was secreted in amounts varying somewhat from day to day, but always in the neighborhood of 100 oz. On July 5, 1901, the specific gravity was 1003, the reaction was neutral, there was a large trace of albumen. The sediment was moderate in amount and consisted of pus, many large round cells (prostatic), a few normal blood cells, occasional hyaline casts, many triple phosphate crystals (probably deposited after passing). Mr. D.'s recovery was slow and it was the middle of August before the catheter could be taken out and passed only as occasion required. He returned home and gained 30 pounds in weight within the next five weeks. In December, 1901, he weighed 147 pounds, which he regarded as his full weight. Twice he had an increase of vesical inflammation due to cold and

fatigue. He finds that urotropin quickly clears up the urine when it becomes cloudy. Feb. 3, 1903, he writes that he now weighs 150 pounds and feels well if he does not overdo. July 24, 1903, Dr. Underwood writes that the quantity of urine is from 70 to 90 oz. a day, with a specific gravity of 1006 to 1008. He sees Mr. D. occasionally non-professionally and he looks very well.

CASE IV. I. D. B., a strong man of seventy-two, called upon me Nov. 14, 1900, on account of an annoying incontinence of urine. For several years had had occasional frequency of urination with some discomfort in the act. Two years before, while suffering from bronchitis, had difficulty amounting almost to a stoppage. This passed off, but since then the incontinence had gradually appeared. The bladder could be felt projecting well up into the abdomen after urination. The prostate was of about 1½ times the normal size as determined by rectal touch.

Mr. B. was passing six and a half pints of urine in the twenty-four hours. It was clear, light in color and had a specific gravity of 1003, no sediment. Catheterization was started, the instrument being used at first once a day with antiseptic precautions. From 10 to 12 oz. of urine were drawn at each catheterization. After about a week the catheter was used twice a day and very soon a slight cloud began to appear in the urine and the temperature began to rise. Nov. 26 the catheter was tied in. There was some slight hematuria when the bladder first collapsed, but this did not seriously complicate the drainage and soon cleared up. Nov. 27 the fever reached 103° F. and the patient began to be nauseated and somewhat delirious at night. The cardiac action at this time became so unsatisfactory that Dr. F. C. Shattuck saw Mr. B. and continued to care for the medical treatment for a number of days. Cardiac stimulants and free catharsis were well responded to and two days later the temperature fell to normal. The nausea and slight delirium persisted, however, for some days longer. In this case the cessation of drainage was difficult. When it was tried after a fortnight to leave the catheter out for part of the day, he had a return of vomiting, the temperature rose to 102° F. and the quantity of urine fell from 100 oz. to 65. For four days he had mild uremic symptoms, which slowly cleared up with a return of excretion to a daily amount of over 100 oz. It was not until the seventy-ninth day that the drainage was left off altogether and ordinary regular catheterization was begun. When convalescence was finally accomplished the specific gravity of the urine had risen from 1008 to 1012 to 1015. This patient has been so comfortable with the regular use of the catheter that he shrinks from the consideration of operative measures. Jan. 16, 1903, he was in perfect health and weighed 180 pounds, which is more than for many years.

CASE V. F. B. W., sixty-three years of age. Patient dated his bladder trouble from an attack of the grippe in 1901, although he had had a slight hemorrhage from the bladder the year before. In January, 1902, he consulted Dr. Albert Wood of Worcester, because he was urinating frequently and his abdomen was increasing in size. The bladder was found distended above the umbilicus. Patient was pale, had backache and was very thirsty, with a dry mouth and slight headache. Catheter was passed Jan. 27 and 40 oz. of urine drawn. The urine was pale, slightly muddy. No elevation of temperature. Specific gravity 1008. After this the catheter was passed twice a day and the urine was never fully drawn except the first time. On Jan. 30 I saw him in consultation with Dr. Wood and Dr. Homer Gage. He was thirsty, with a dry mouth and loss of appetite. On the following day the catheter was tied in. At that time the daily amount of urine was from 65 to 80 oz. For three days after the establishment of catheter drainage the urine was tinged with blood, there was a little increase of temperature and the patient was slightly delirious. Gradually, however, his mouth became moist, his mind cleared up and all his symptoms improved. Catheter drainage was continued for three weeks, after which time the catheter was passed at regular intervals. He has steadily improved in health and now obtains by the catheter from 40 to 60 oz. of urine daily. Examination of urine made Feb. 23, 1903, shows the specific gravity to be 1017.

CASE VI. H. S. P. Seen Dec. 27, 1902, with Dr. R. W. Swan and Dr. Albert Wood. A strong, large man of sixty-seven, weighing 230 pounds. Frequent urination for many months, in past fortnight every fifteen minutes. Never stoppage, never hematuria. Has lately had uneasy pain in perineum all of the time, aggravated by passing water, also some pain in lower abdomen. Three days ago his appetite failed him. Has a dry mouth. For a considerable time he has been passing a very greatly increased quantity of water. Some little time ago it was eight pints in the twenty-four hours; in the past week it has fallen to six pints. The urine is clear with a specific gravity of 1005 and contains hyaline and granular casts. The abdomen is very large and hard in the lower segment. The outline of the bladder cannot be made out. Two pints of urine were drawn in the recumbent position and the catheter was then withdrawn, although the flow was still with a good jet. Catheter was later introduced and tied in. Jan. 7, 1903, Dr. Swan reports that patient is eating better. The quantity of urine increased very much on fastening in the catheter, reaching in one day sixteen pints in the twenty-four hours. After the first considerable increase in the quantity of urine, which followed the drainage, the quantity gradually fell to three quarts. The catheter was presently removed and was afterwards passed four times daily, drawing urine to the amount of two quarts in the twenty-four hours. The specific gravity just before drainage was 1005. It rose gradually to 1012 to 1015. Feb. 25, 1903, Dr. Swan reports that the patient says that he feels better than for a year past.

Although it is not intended to enter on any full discussion of catheter drainage here, a few remarks on some of the general bearings of the subject may not be amiss. The introduction of the catheter life in the presence of a tensely distended bladder is a delicate performance. Every one is familiar with the danger of too suddenly emptying such a bladder, and those of us who formerly carried out the plan of cautiously drawing but a part of the urine at each catheterization, or of drawing all of the urine and at once introducing a proper quantity of sterile or mildly antiseptic fluid to restore the partial distension of the bladder, know that even with the greatest care in our antiseptic precautions a cystitis was pretty sure to develop. If this occurred early it was likely to lead to a pyelonephritis which, while often recovered from, led to a fatal issue in a considerable proportion of cases. Since I have learned to apply the drainage of an in-lying catheter to these cases at the outset of the cystitis, I have been able to so modify the course of things that the fear of a fatal result has given way to a feeling of considerable confidence in a favorable issue. I have even finally come to feel that immediate drainage of an over-distended bladder is often better than to make any attempt at intermittent catheterization. By thus at once establishing a constant outflow, we remove all danger of back-flow up the ureters and thus greatly diminish the chances of pyelo-nephritis.

Case VI is a good example of this plan of treatment. In carrying out catheter drainage one important question which arises is, How long shall the drainage be continued and how shall the return to catheter life with intermittent catheterization be safely accomplished? I have made it my habit to continue the catheter drainage until all symptoms have disappeared and the urine has returned to a tolerably normal condi-

tion. If on attempting to leave out the catheter there is a return of fever and the quantity of urine sharply diminishes, it is to be concluded that the ureteric orifices have not yet recovered their valvular condition, and that irritation of the kidneys has again been produced by the back-flow of infected urine from the bladder. Probably the increase of tension plays a part also in producing this renewed evidence of renal irritation. In such a case the drainings should be at once restored and continued, not only till the symptoms of trouble disappear, but for a considerable time longer. Then another attempt may be made, and if the kidneys have shown themselves prone to relapse the change should be made very gradually. Often I have begun by stopping the flow through the catheter for a gradually lengthening period of time each day; and presently I have removed the catheter in the morning, left it out for two or three hours and then reintroduced it and fastened it in place. The next step is to take the catheter out in the morning, simply draw the water in the middle of the day and reintroduce the catheter in the afternoon. In this way, gradually lengthening the intervals as safety allows, I have succeeded in every case and finally returned to the usual catheter life.

It will be seen by referring to my cases that oftentimes the duration of the drainage has been very considerable. Cases I and IV were especially interesting in this regard, for in these patients each attempt to remove the catheter was followed by a return of pyelitis until at last I allowed them to go about freely with the catheter still in place. Mr. L. (Case I) kept the flow shut off for gradually lengthening intervals and attended to his business, going to the office each day. Finally, when the bladder showed complete tolerance for two or three hours at a time, the catheter was left out and the patient has since been well with ordinary intermittent catheterization.

CONCLUSIONS.

First. The relief of tension in kidneys that owing to long obstruction are exhibiting the clinical phenomena of interstitial nephritis usually brings about a return of normal function. From this, it would appear that the renal condition is directly due to the obstruction and increased tension.

Second. It seems probable that in cases of dilated ureters, permitting regurgitation of urine from the bladder back into the pelves of the kidneys, a long drainage of the bladder will permit such a shrinkage of the ureters and ureteral orifices as to restore the normal valvular action of the ureters and the retro-flow of the urine will thus be stopped.

It is reported that at a meeting of the Montreal League for the Prevention of Tuberculosis there was much sentiment in favor of the establishment in the city of a dispensary for tuberculosis.

UNCLEAN MILK, BOVINE TUBERCULOSIS AND THE TUBERCULIN TEST — THEIR RELATION TO THE PUBLIC HEALTH.*

BY E. R. LARNED, M.D., CHICAGO, ILL.,

Professor of Physiology and Physiological Chemistry, Dearborn Medical College.

The dangers at our very doors from the sale of impure milk and from the lax administration of laws enacted to eradicate such dangers, and the incomprehensible complaisance on the part of the public, particularly the medical profession, towards these evils, compel the preparation of this paper. It requires no argument to show that the twenty-story building requires good material if it is to be solid and secure, and yet, judging by their actions, a great many people seem to think that it matters little what kind of material goes into the building of the human structure; they "feed on thorns and expect to pick roses," but later they discover they have sown germs and are reaping ptomaines. The human body is a wonderful laboratory, but it does not prevent the formation of deadly poisons within its very being, once the essential germs are taken into it. Milk has always been an article of man's diet and forms the entire nourishment of the early existence of all animals. Pure milk is the most important article of food entering into daily use, for it contains all the elements necessary for the growth of the young, and because it forms the entire nourishment of children at an age when they are unable to resist any tampering with their food.

"To relieve suffering and to prolong life" is the privilege of the physician, but to *prevent* disease is his *duty*, particularly when efficacious methods of so doing are known to him. The intelligent prevention of disease is one of the most important subjects of the day. The universal progress causes the public to be no longer satisfied that a physician enter a house, prescribe remedies and depart. The public wants to know the nature and origin of the sickness and the most suitable means of preventing its recurrence, and it is our duty to supply this important information. It is a matter of common knowledge that milk is one of the most easily and most universally adulterated of the great food products and to-day the greatest menace to the physical well-being of the American people lies in the uncontrolled sale of adulterated food products. From the importance of the subject and the ease with which milk may be contaminated, great attention has been paid to it, and we have the results of thousands of analyses and a great many investigations to guide us in our studies of the subject. Although the preservation of human health is of the first and highest importance, the perfection of sanitary methods demands that the health of the domesticated animals upon which mankind depends so largely for food and which are kept in such close proximity to the human dwelling should be likewise cared for and protected and, as will be shown

* Read at annual meeting of the Illinois State Medical Society, Chicago, Ill., May 1, 1903.

later, it is in such care of the lower animals that our own health depends in a very great measure.

As this paper, properly, deals only with impure, adulterated, or unclean milk and related conditions I will only speak briefly of pure milk as it should be. No milk should be sold as "whole milk," nor used nor offered as such if it contains more than 88% of watery fluid or less than 12% of total solids, of which 3% should be butter fat.[1] Nor should it contain any pus, mucus, nor any pathogenic germs of any kind; moreover, in my opinion, every drop should be "pasteurized" — that is — immediately after being drawn from the cow it should be aërated, strained and put into suitable bottles which have been previously sterilized, and heated to a temperature of 170° F. for at least fifteen minutes and then rapidly cooled to 45° and kept there until the bottles are delivered unopened to those intending to use the milk. Aëration removes gases which impart the "cow odor" to the milk, and rapid cooling to 45° F. prevents the formation of lactic acid, as the germs of lactic acid are almost inactive below 50° F.[2] Heating the milk to 170° F. for fifteen minutes kills all organisms found in milk, nothing remaining alive but the resistant spores of some bacteria.[3] Freeman[4] found that for the practical purpose of rendering milk safe as an article of food it is not necessary to make repeated heatings, that one heating at 167° F. to 170° F. for fifteen minutes, followed by rapid cooling by immersing the container in cold water, would kill the adult forms of most microbes, and that milk so treated remained unaltered for three days. Under all circumstances I forbid that infants shall be fed upon raw milk, when by the simple procedure of pasteurization we have the means of rendering milk *safe* and more digestible. The pasteurization of milk is an extremely easy operation, and if mothers better appreciated the dangers to which their little ones are exposed from the use of raw milk from unknown sources, especially in the summer time when it may be teeming with bacterial growth, more of them would use this simple precaution. It is estimated that one third of all children die before they are three years old, and one of the leading causes of infant mortality is unwholesome milk. Bad milk cannot be made perfect by pasteurization, but the danger from its consumption can be lessened. The process is very simple and the necessary apparatus is inexpensive.

Experiments carried out by the Maryland Experiment Station of the Bureau of Animal Industry show that there is very little difference in the digestibility between raw and pasteuriezd milk, while the latter is much the safer.[5] Milk which is from cows who are diseased in any way, or to which has been added any of the following commonly used adulterants, viz., annato, termeric, coal-tar colors, starch, salt, cane-sugar, glycerine, syrup, boric acid, salicylic acid, borax, formaldehyde, benzoic acid, sodium carbonate or chalk,[6] should not be sold as "pure whole milk," and infractions of this rule should be firmly dealt with and prosecuted according to the laws already on our statute books. Although, fortunately, the milk secretion is in abeyance during many diseases to which cattle are subject, it is not so in all, nor in every case of the same disease, and in a few conditions the milk presents somewhat definite chemical and microscopic characteristics which are fairly constant to the unaided eye, nose and palate; however, milk ordinarily is all that is to be desired. These adulterants are all used by sellers and producers of milk and may be easily detected by the appropriate chemical procedures described in technical works. To ascertain the bacteriologic and microscopic conditions of milk, however, it is necessary to have recourse to somewhat complicated laboratory processes, which, familiar to most of us, are quite mysterious to the uninitiated. The discoveries made in laboratories have worked great changes in professional opinion and at the same time have lengthened the span of life and introduced the miraculous into modern science, for the apparently impossible of yesterday is not only the possible but the common thing of to-day.[7] The use of coloring matter in milk or cream, although greatly improving its appearance, has been shown by recent investigation to seriously interfere with the pancreatic and peptic digestions.[8] As for the alleged harmlessness of formaldehyde, it is only necessary to refer to the death of the brilliant young pathologist Straub of Munich, whose death is directly attributed to his working in the gas.[9]

Young states that formaldeyhde added to milk as a preservative impairs the nutritive value of the milk and interferes with the digestive processes.[10] The people of Omaha, Neb., were afflicted with a milk supply so altered by the addition of preservatives that the sanitary authorities warned the citizens of the great danger of feeding infants with the milk.[11] Annett shows from experiments that the use of boric acid and formalin as milk preservatives are very injurious to the health of the consumer and particularly so to the health of infants.[12] He states his belief that the great infant mortality rate from "diarrhea" of many large towns may be closely connected with the almost universal practice, particularly during the summer months, of systematically "doctoring" the milk by means of preservatives, by milk dealers, etc. He intends carrying on further experiments to obtain facts for furthering the prosecution of such offenders against public health. As the dairy industry has always been one of the most slovenly conducted branches of food production, it is with the utmost difficulty that those who are engaged in it can be induced to understand or appreciate the value of modern cleanly methods, while the additional labor required will make the profits shrink to an alarming extent. Although our sanitary laws, when and where they are enforced, have improved the quality of milk, particularly as to its chemic composition, only a bare beginning has been made in regard to making certain that the supply is *pure and healthful*. Chemic altera-

tions are due to criminal tampering on the part of the dealer, while bacterial alterations and diseased conditions are due to ignorance or neglect which are almost criminal.

Lestes [13] gives the results of his investigations of milk and says that milk that contains pus, mucus, or germs is utterly unfit for human use, but that these restrictions would entail the condemnation of 80% of the samples he examined. No farmer dreams of allowing a cow with an inflamed udder to suckle a calf, so why should he be allowed to sell such contaminated milk? Lestes also shows the folly of mixing the milk from healthy and diseased cows. Lemiere [14] states that the death rate of Lille, France, under two years is 398.6 per 1,000, and in one parish 520. Gastro-enteritis is responsible for a very large proportion of these deaths and the author truly remarks that this is preventable in a great measure by insuring a pure milk supply. The difficulty of a general correction of the faulty methods of milk production and the adoption of improvements are mainly due to the increased cost of the milk production and the consequent higher price to the consumer. And if the state should undertake to at once enforce these changes, the business of the dairyman would be temporarily ruined. The farmer cries out in alarm where the "tuberculin test" is proposed and when the worst cases are to be rectified at once a great cry of sympathy goes up that some one is being persecuted and the press of the country is filled with the jargon of vote-seeking politicians who, while seeking the favor of the cities, will not do anything to incur the displeasure of their farmer, dairymen or cattle-breeding constituents. At a meeting of the farmers, dairymen and the Illinois State Board of Agriculture held in Chicago, in 1899, an organization was formed for the purpose of protesting against the enforcement and advocating the repeal of the stringent laws passed by the legislature relative to the eradication of tuberculosis in cattle. Great dissatisfaction is expressed among farmers of this state over the compulsory killing of cattle for tuberculosis. "At a recent examination on the dairy farm of W. G. Thornton by State Veterinarian Lovejoy and Live Stock Commissioner Johnson [15] eight cows of a herd of twenty showed signs of tuberculosis. The state board slaughtered them in the presence of several hundred people. Four of the cows were found free of the disease, while the other four cows were only slightly infected. Dairyman Thornton has retained lawyers and will prosecute the case." I will undertake to show that the tuberculin test, if correctly and intelligently applied, is most infallible in the diagnosis of bovine tuberculosis, and I doubt very much that "four out of eight" reacting cows were free from the disease.

Secretary Wilson of the Department of Agriculture, in an interview published in the Chicago papers in 1899, is said to have remarked that "he feared that Governor Tanner's proclamation relating to the importation of cattle was too drastic." He did not approve the slaughter of cattle suspected of tubercular infection unless the case developed *indisputable* symptoms of the disease. He sincerely hoped that the State Board of Health would not permit the indiscriminate slaughter of cattle suspected of tuberculosis, to the detriment of the dairy interests of the country. Secretary Wilson's cautionary advice is worth careful consideration, but I would like to ask what are the *indisputable symptoms* of tuberculosis? There seems to be some difficulty among scientific minds as to this question. Legislation cannot make honest men of dishonest men, and ill-directed legislation is often worse than none, but the annual sacrifice of thousands of innocent young lives upon the altar of impure milk and public sentiment will sanction *any* destruction of cattle necessary to the eradication of tuberculosis. So let us shed a little light upon this dark subject where "ignorance seems to reign supreme." It requires the strong hands of law and justice to deal with it and I demand to know if any consideration of money or politics can be permitted to weigh against a possible danger to the lives of our children.

Emmet Holt [16] points out that the most important preventative measures in the treatment of "summer diarrhea" of infants comprise careful inspection of milk sold in cities and close supervision of those selling milk and the sterilization of all milk sold. Lübbert has shown [17] that milk as it usually comes from the dairies contains bacteria which have the power of peptonizing it and as this process of peptonizing goes on the milk often becomes very poisonous, especially to individuals under two years of age, and may bring about a fatal enterocolitis or "summer complaint." Hirsh,[18] Sibman,[19] Spiegalberg,[20] Monti [21] and Escherich [22] have all lately contributed to our knowledge of the flora of the gastro-intestinal tract. Their observations agree and point to the streptococcus enteritis as the etiological factor in the acute diarrheas of infants where the stools are frequent and slimy. They also agree that these organisms find their way into the child's intestines through milk and that these identical micrococci have been recently isolated from cow's milk. Eastes writes as follows [23]: "I have also not the slightest doubt that unboiled milk containing streptococci is also to be held responsible for some of the cases of infantile diarrhea and mortality." Holst [24] observed a series of cases of acute gastric catarrh which he attributed to the ingestion of milk containing streptococci. He reports cases of gastric disturbance in four families, apparently caused by raw milk, for only those members of the families that partook of the raw milk were affected. In each instance he found that the patients had partaken of milk from cows suffering from inflammation of the udder. Niven [25] reports extensive poisoning among the patrons of a single milk dealer. The patients suffered from "diarrhea, sickness and abdominal pain," and only those persons who had partaken of the milk were seized. A bacteriologic examination revealed the presence of *bacillus coli communis* and strep-

tococci. It was ascertained that one of the cows in the dairy supplying the milk had been suffer- from garget for some time, and on the day when the milk which caused the sickness was produced, the inflammation of the udder of that cow was most marked. While the author considers streptococci to be the cause of the trouble, yet he does not present conclusive evidence in support of that belief. Stokes [26] writes: "The prevalence of the acute intestinal disorders among children using cow's milk is well known and many of these conditions are caused by the organisms of suppuration. It would seem, therefore, that milk from diseased cows, containing these germs, might often be the cause of intestinal troubles, especially in young infants. Busey and Kober [27] hold similar views based upon the authority of Kruger,[28] Bang [29] and others. Bergey [30] observed sickness in an infant fed on milk from a first-class dairy and an examination revealed the presence of streptococci in the milk. "This result led to the employment of milk from other first-class dairies and the examination of each yielded the same results, viz., the presence of large numbers of streptococci."

Nothing definite can, as yet, be stated with regard to the significance of the presence of streptococci in the milk of healthy cows. Beck [31] believes that they are closely related with the streptococci which Escherich found in infantile enteritis. Hirsch [32] has described in minute detail the progress of a fatal case of gastro-enteritis in an infant, in which streptococci was the etiologic agent. He found the organism like *streptococcus involutus*, described by Kurth, and found it to be pathogenic to white mice only. Libman,[33] Tavel and Eguet [34] and DeCerenville [35] have made similar observations. Heath[36] of Buffalo suggests the following as being worthy of being incorporated to fortify existing laws relating to the milk industry:

(1) Prohibition of sale of milk over thirty-six to forty-eight hours old. (2) Prohibition of disinfectants. Milk-house conditions must preclude their necessity. (3) Supervision of contagious diseases as to milk routes. (4) Abolition of street peddling and grocery store dealers. (5) Sterilization at dairy and preparation for ultimate delivery with labels of data. (6) Arbitrary attitude towards dairies supplying cities and over which no jurisdiction exists.

Pierson,[37] Assistant Chief Dairy Division, Department of Agriculture, gives the following as the ordinary conditions that should be found in every well-managed dairy:

(1) A roomy, clean, dry, light and well-ventilated cow stable. This is absolutely necessary to keep cows in the best of health. (2) Healthy and clean cows which appear well fed and contented. (3) Abundance of pure water given to the cows at least twice daily. (4) Feed of good quantity. The food must be free from dirt, decay or a musty condition. (5) A spirit of kindness towards the stock by every one employed about them. (6) Provision for aërating, straining and cooling the milk, in a clean atmosphere free from all stable odors, immediately after being drawn from the cow. (7) Provision for washing and sterilizing all utensils which come in contact with the milk. (8) Facilities for storing the milk and keeping it cold.

To show that these are not simply theoretical and visionary possibilities, the brilliant example of the Royal Danish Veterinary School in reference to the milk supplied to the city of Copenhagen may be cited. At no other place are modern methods in such general use nor are they controlled with such efficiency. In this country New York, Massachusetts, Pennsylvania, Iowa and Minnesota have legislated along these lines, but in all of the laws there is the defect of too much of the feature of money, "protection to the farmer." In our own immediate neighborhood several instances of voluntary improvement have demonstrated that even with the increased cost of production and increased selling price there is still a good chance of success and that in the end the intelligent consumer will appreciate the honest efforts expended in his behalf. Such examples as the work of Dr. Russell of the Wisconsin Experiment Station in supplying milk to Madison and Milwaukee and his development of pasteurized milk for infants and invalids, the work of Gurler of DeKalb, of the Clover Hill Farm, and the Walker-Gordon Laboratory in supplying milk to Chicago, are worthy of the highest commendation. Reviewing these demonstrations, any doubt as to the possibility of supplying cities with milk of a high standard of quality and purity for general distribution must be removed and these examples should be emulated by every dairyman in the business.

To show what may be accomplished by systematic inspection and prosecution, the example of the Department of Health of Chicago may be cited: In August, 1895,[38] the authorities issued instructions ordering the entire force of the municipal laboratory to bend every energy towards improving the milk supply and to vigorously prosecute all dealers selling milk or cream not in accordance with the city ordinance. The number of samples collected and analyzed was at once increased and the prosecution of offenders reduced the number of samples below grade from 60% of all samples collected to 5% in a few weeks. Over 14,000 samples were examined in 1895 and over 25,000 in 1896. Vigorous prosecution and publication of the names of dealers has shown its effect not only on the dealers themselves but on the farmers who supply them. In cases where the milk has been found wanting in any particular, the dealer has stopped taking milk from this farmer and thus the farmer has been forced to supply good milk. It has been repeatedly held in courts that shippers of milk below grade cannot recover in a suit for payment. Every analysis of milk made represents a sanitary inspection of the premises where the sample was taken as well as an examination into the quality of the milk. Moreover, special sanitary inspec-

tions are made whenever the circumstances seem to warrant. I have visited many dairies in the immediate vicinity of the city of Joliet, Ill., but I have yet to find one where proper and adequate hygienic sanitary measures are carried out, and I have yet to find one where there are not abundant avenues for infecting the milk. In almost every quart of milk sold in that city, after standing, a sediment collects which upon macroscopic examination appears to be dirt and microscopic examination and culture experiments prove to be teeming with germs. I have observed this not once but many times and I submit that this is not the kind of food for our babies, our aged and infirm or sick. Are we to allow such conditions to go on unprotested? Or is it not rather our duty to issue a warning to the public and to call things by their right names — to point out in unmistakable terms the enormous danger to public health that arises from mistaken ideas of cleanliness, and the slaughter of innocents caused by the idiotic methods employed in our milk production.

Recently I made some cultural experiments with milk sold in the city of Joliet, and I give you the results according to notes made at the time. The technique of these bacteriologic investigations was carried out in the simplest manner, to test the milk for the presence of germs of the "typhi-colon group" as well as other pathogenic forms. Beyond the colon group, just mentioned, no particular efforts at the identification of separate species were made — that being left for the future. Samples of milk, averaging one pint each, were purchased in the open market from the various dairies supplying milk to the residents of this city, from cows tested with tuberculin and those not so tested. These samples were put into pails provided for that purpose and which had been subjected to steam sterilization. The milk was at once carried to the laboratory and put into tall sedimenting glasses which had also been steam sterilized and allowed to stand for twelve to eighteen hours, being kept at a temperature ranging from 45° to 50° F. during this time. Then 10 cc. of milk were drawn into a sterile pipette and placed in the tube of the centrifuge, which was then whirled at a speed of 3,000 revolutions for five minutes. After the bulk of the milk had been poured off, a small portion of the sediment remaining in the bottom of the tube was taken up with the platinum loop and used to inoculate tubes of sterile glucose gelatin, which were at once put into the incubator and kept at 70° F. for periods varying from one to four weeks. Positive reactions were obtained in nearly every example. Second, and in some cases third, inoculations from the original gelatin cultures were grown in glucose-glycerine agar, on slants, in stabs and in plates. These agar tubes and plates were kept in the incubator at a temperature of 35° to 40° C., and in forty-eight hours showed numerous colonies which continued their growth in such exuberance that in a few days the surfaces of the media were entirely covered. Cover slips prepared from these cultures showed germs with the same morphologic characteristics as the direct smears from the milk. Control tubes of uninoculated media which were always opened with the inoculated tubes and in every way subjected to the same manipulations and conditions have remained absolutely sterile — consequently we can attribute the positive results produced in the samples to the presence of undesirable constituents in the milk examined. Litmus agar slants were prepared from the colonies of the third generation growing upon litmus agar and an acid reaction was shown in twenty-four hours, continuing, with the formation of gas cavities, until in from three to four days the media had entirely changed from blue to red. Glucose bouillon inoculated with these cultures and put in the fermentation tube rapidly developed gas which was easily identified as H and CO_2.

Clinical Department.

A CASE OF MYXEDEMA.

BY ADDISON S. THAYER, M.D., PORTLAND, ME.

This patient was first seen by me Oct. 21, 1902. A severe nosebleed caused hurried search for a doctor, at a time when doctors were making their afternoon calls. An orthopedic surgeon, Dr. E. G. Abbott, after telephoning to several general practitioners, kindly responded in person, plugged the posterior nares, and transferred the case to me.

The classical symptoms of myxedema had been present for years — some symptoms for more

than twelve years. There was waxy pallor of the skin, bagginess of subcutaneous tissues, falling out of hair, constant lachrymation, hemorrhages from mucous membranes, subjective and objective deficiency of body heat, and slowness in thought, speech and motion.

The stumbling gait and its consequences seem especially worthy of note. As the patient herself afterwards expressed it, "I could not get my foot forward fast enough to prevent stumbling, and I could not get my hands in front of me in season to break the fall and save my face from bruises."

This patient is, perhaps, uncommonly susceptible to thyroid medication, which began the same evening. At no time has she been able to take in a single day more than two of Parke, Davis & Co.'s thyroid tablets without intracranial pressure, "nervousness," or tachycardia. After two weeks the dose was reduced to one tablet daily; after three months, to one-half tablet, once daily, — at which time all of the above symptoms had almost wholly disappeared.

The accompanying photograph was taken two weeks after the beginning of treatment, when there was already a noticeable improvement in appearance. The fall which caused the nose-bleed had caused also bruises and distortion of feature; and it was necessary to wait for these swellings to subside, in order that the picture should present no abnormalities except the residue of myxedema.

A CASE OF EPILEPSY AND NEPHRITIS SIMULATING PUERPERAL ECLAMPSIA.

BY PHILIP H. COOK, M.D., WORCESTER, MASS.,

House Obstetrician, City Hospital.

M. H., aged thirty-four, of American birth and parentage, IV-para, entered the Worcester City Hospital on Aug. 13, 1903, at 10.30 P.M., well advanced in first stage labor and was admitted to the Maternity Ward on the service of Dr. Foster H. Cary. Friends who came with her stated that she was of a nervous disposition and subject to epileptic seizures, the last of which had occurred about one month ago. Preceding labors were normal. Last one was six years ago. No particulars of attacks were obtainable. Patient stated that she was about nine months pregnant. Had felt well throughout pregnancy, aside from the convulsion one month since. No headache, nausea and vomiting, or epigastric pain. Said eyes had not troubled her.

On physical examination, pulse 108, good volume and tension. Tongue shows old scars. Heart negative. Marked edema of legs and feet, none of face or hands. Skin moist. Catheterized specimen of urine was pale in color. Nitric acid test showed it to be laden with albumen.

Labor progressed normally and child was born at 12.43 A.M., Aug. 14. Pulse 80 after birth of placenta. Patient soon went to sleep and passed a good night. At 9.50 A.M., Aug. 14, patient asked to have curtain lowered, as light hurt her eyes. Twenty minutes later the nurse's attention was attracted by a sound "like filing a saw," and going into the room she found patient in a convulsion. The head moved quickly from side to side, the eyes rolled and there was frothing at the mouth, without, however, any admixture of blood. The arms were rapidly flexed and extended, while the thumbs were closely flexed across the palms. The jaws were clenched and the teeth gritted continually. The whole body quivered and tossed from side to side. A gag was inserted and a few whiffs of ether given during the convulsion, which lasted about two minutes. The patient now passed into a semi-comatose condition, responding to supra-orbital pressure. Pulse just after the convulsion was 100, good volume and tension. Temperature normal. Respiration noisy and stertorous in character. Skin moist. A hot pack was ordered, to be continued for half an hour. Before the end of this time the patient had recovered consciousness and was talking rationally. She had no recollection of anything which had occurred during the attack. Shortly after recovering she complained of headache and restlessness, which yielded readily to treatment. Milk diet and diuresis were ordered and the pulse taken every twenty minutes through the day. It never rose above 84 and reached that point only twice. During the afternoon considerable edema of the lower lids was noted.

Urinalysis showed: Albumin ¼%+, sugar, 0; color, pale; specific gravity, 1010; reaction, acid; bile, 0.

Sediment: Many hyalin and fine granular casts, considerable squamous and large round epithelium. Rare normal corpuscle, leucocyte and small round cell.

Late in the afternoon the patient's husband called and from him the following facts were obtained. She had been subject to attacks for fifteen years and treated by several physicians without benefit. No aura till two years ago, since when the seizures have been preceded a few minutes by dimness of vision. Following this comes convulsion lasting a few minutes, then stupor lasting about half an hour. Has injured herself during convulsions. Attacks sometimes only twice a year, but have come as often as once in two weeks. The children, the last of whom was born six years ago, are all well, but inclined to be nervous.

The patient now began a perfectly normal convalescence. Her temperature never exceeded 98.6, nor her pulse 90. A urine chart was kept for three days, with results as follows: Aug. 14, 79 oz., urea, 231 gr., albumin ¼%+; Aug. 15, 81 oz., albumin trace; Aug. 16, 84 oz., urea 252 gr., albumin trace. Sediment as before.

On Aug. 24 albumin was reported as slight trace. Sediment. Some pus and blood, no casts seen. Edema had nearly disappeared. Patient was now allowed an increase in diet. At 10 P.M. she had an attack similiar in every respect to the first one, but preceded by a shrill cry.

A gag was inserted, and full consciousness returned in about twenty minutes. Pulse 88, temperature 98.4. From this time on the convalescence was uneventful. The child, which on account of the mother's tendency it was thought unwise to put to the breast, did well on modified milk and on Aug. 27 both patients were discharged well.

Medical Progress.

In general the pursuit of any one-sided diet can lead to the formation of renal calculi particularly if combined with irregularities in drinking. Exclusive meat eaters acquire uric acid calculi, vegetarians oxalic or phosphatic stones. Health lies in a mixed diet. Highly spiced and salted food favor hyperacidity of the stomach and this is harmful in many ways to those disposed to renal stones. The salt of the food goes directly over into the urine, increasing its specific gravity.

The constituents of the stone should be determined. This is far more easily done than sup-

and at regular intervals so that the quantity of urine shall be 1,500 to 2,000 cc. in twenty-four hours. To attain this 2,500 cc. of liquid must be taken in the day, which means 500 cc. (1 pint) at each meal and about the same quantity between meals and before retiring. Water is the best liquid. Klemperer gives a diet table illustrative of this idea and says that patients who pass 250 cc. bright, clear urine every three or four hours during the day can be assured that they are protected from the formation of new calculi.

urine is, the more uric acid can it hold in solution. Over this colloidal property, diet exerts no influence, consequently all energies must be directed toward changing as much of this free acid as possible into combination with a base, sodium acid urate, which is reasonably soluble at body temperature. Acid can exert a great influence in this direction, because a meat diet furnishes acid elements to the urine, a vegetable diet furnishes alkalies. With a preponderance of meat diet and little vegetable food the free uric acid in the urine reaches 80 to 90%, while on a mixed diet the rela-

than twelve years. There was waxy pallor of the skin, bagginess of subcutaneous tissues, falling out of hair, constant lachrymation, hemorrhages from mucous membranes, subjective and objective deficiency of body heat, and slowness in thought, speech and motion.

The stumbling gait and its consequences seem especially worthy of note. As the patient herself afterwards expressed it, "I could not get my foot forward fast enough to prevent stumbling, and I could not get my hands in front of me in season to break the fall and save my face from bruises."

This patient is, perhaps, uncommonly suscen-

headache, nausea and vomiting, or epigastric pain. Said eyes had not troubled her.

On physical examination, pulse 108, good volume and tension. Tongue shows old scars. Heart negative. Marked edema of legs and feet, none of face or hands. Skin moist. Catheterized specimen of urine was pale in color. Nitric acid test showed it to be laden with albumen.

Medical Progress.

RECENT PROGRESS IN THERAPEUTICS.

BY ELLIOTT P. JOSLIN, M.D., BOSTON.

THE TREATMENT OF RENAL CALCULI.

Prophylaxis. — Each stone consists of a crystalline and organic element. The organic element becomes visible when the crystal is carefully dissolved. This ground substance has not been isolated, but the micro-chemical reactions suggest an albuminous substance and Klemperer[1] thinks it the mucin which is present in all normal urines. This is of the greatest importance in prophylaxis, because formerly it was supposed that a catarrh of the mucous membrane must be present before a stone could form and this lithogenous catarrh eluded treatment. Now it is recognized that a calculus can always form, if crystals are precipitated in the urinary passages, and the first aim therefore of prophylactic treatment is to prevent this precipitation. But as neither one nor several crystals form a calculus unless they adhere, the second task of prophylaxis is to remove these smallest aggregations of crystals. This second task is simpler and the same no matter the form of crystal. It is purely mechanical.

A renal calculus will never form if there is a copious flow of fluid through the urinary passages. Crystals are more readily precipitated from a concentrated solution and less thoroughly washed along. Consequently calculi are found in heart disease, in the first few months of life, after acute illnesses, but they are rare in diabetes mellitus unless as a result of energetic treatment, and never found in diabetes insipidus. Women drink notoriously too little fluid, men do not err so much in this direction, but they drink irregularly through the day. One portion of urine will be concentrated, another dilute. The first rule then is that liquids shall be taken freely and at regular intervals so that the quantity of urine shall be 1,500 to 2,000 cc. in twenty-four hours. To attain this 2,500 cc. of liquid must be taken in the day, which means 500 cc. (1 pint) at each meal and about the same quantity between meals and before retiring. Water is the best liquid. Klemperer gives a diet table illustrative of this idea and says that patients who pass 250 cc. bright, clear urine every three or four hours during the day can be assured that they are protected from the formation of new calculi.

[1] Klemperer: Die Therapie der Gegenwart, Sept., 1903.

In general the pursuit of any one-sided diet can lead to the formation of renal calculi particularly if combined with irregularities in drinking. Exclusive meat eaters acquire uric acid calculi, vegetarians oxalic or phosphatic stones. Health lies in a mixed diet. Highly spiced and salted food favor hyperacidity of the stomach and this is harmful in many ways to those disposed to renal stones. The salt of the food goes directly over into the urine, increasing its specific gravity.

The constituents of the stone should be determined. This is far more easily done than supposed, and is summarized in Klemperer's article, but cannot be considered in this review. Having determined the character of the stone, a diet should be planned which takes into consideration the character of food which leads (1) to the formation of the particular stone and (2) influences the solubility of the substances forming the stone.

DIETETIC PROPHYLAXIS AGAINST URIC ACID CALCULI.

The uric acid of the urine comes from the nucleo-proteids which form the essential constituent of the nucleus of the cell. A meat diet therefore favors uric acid, particularly the cellular organs like thymus, liver, kidney, but a milk and egg diet with farinaceous dishes and vegetables[2] causes no uric acid. In general 1 pound of meat produces in twenty-four hours 1.5 gm. uric acid, 1 pound thymus 2 to 3 gm. On a milk and vegetable diet the uric acid falls to 0.4 to 0.6 gm. per day. It never wholly is absent, because cells are constantly breaking up in the body. One half pound meat is a proper quantity to allow and it makes no difference whether it is white or red (light or dark). Fish can be reckoned as meat. Bouillon need not be forbidden since the extractives which it contains increase unessentially the quantity of uric acid. (This is contrary to the usual belief.)

The second and more important question is how to hold in solution so insoluble a substance as uric acid. The uric acid exists in the urine as an easily soluble salt and as an acid which is very insoluble. Only a small part of the latter is really soluble, the greater part being held in a sort of suspension from which by shaking alone it may be precipitated. The urine holds the uric acid in suspension by reason of the colloidal property which is furnished by the normal coloring matter, urochrome. The darker colored a urine is, the more uric acid can it hold in solution. Over this colloidal property, diet exerts no influence, consequently all energies must be directed toward changing as much of this free acid as possible into combination with a base, sodium acid urate, which is reasonably soluble at body temperature. Acid can exert a great influence in this direction, because a meat diet furnishes acid elements to the urine, a vegetable diet furnishes alkalies. With a preponderance of meat diet and little vegetable food the free uric acid in the urine reaches 80 to 90%, while on a mixed diet the rela-

[2] See Hall: Berl. klin. Woch., 1903, Sept. 21, p. 868.

tion between free and dissolved uric acid is about half and half. By an increase of vegetable food the uric acid appears more and more as a salt and is so excreted. If vegetable food is persisted in to the exclusion of other food the urine finally becomes alkaline from calcium phosphate. Practically it is sufficient if the two forms of uric acid are excreted half and half. This is accomplished when large quantities of fruit and vegetables are eaten with moderate quantities of meat, fish and leguminous vegetables. A plateful of vegetables should be taken twice daily and at least a pound of fruit.

The uric acid will be excreted as a salt, when the diet is of a mixed character containing a moderate quantity of meat, if 1 gm. (15 gr.) bicarbonate of soda is given five times daily. The more meat, fish and leguminous vegetables given, the more soda required. The soda is administered to best advantage three or four hours after a meal. It is not required just after a meal, because at that time the acid elements of the blood are being used to form HCl in the stomach. Klemperer suggests giving bicarbonate of soda in the form of a natural mineral water. The CO_2 contained in such also tends to favor the solubility of the uric acid. The necessary quantity of soda bicarbonate to be given can be determined by the reaction of the urine. Any one can convince himself of the effect of a meat or vegetable diet upon the reaction of the urine by living upon one or the other exclusively for a few days and then testing the urine with litmus paper.

[We have not as yet sufficient data to say positively in what condition the uric acid exists in the urine, but at the body temperature there is no reason to believe that uric acid is not all present in the form of a salt. When urine cools and some uric acid crystals form there is a change from the form of a salt to the form of a free acid.

Urochrome has not been satisfactorily proven to hold uric acid in a colloidal condition. Klemperer performed one experiment in which he found that the uric acid was precipitated a little more slowly from a solution of sodium urate, to which uric acid had been added, in the presence of urochrome than in its absence.

The administration of alkalies in the food or the addition of alkalies to a urine cannot influence the solvent power of the urine for uric acid unless enough alkali is given to make the urine actually alkaline. This is true as well of lysidin, piperazin and the other organic bases as of sodium bicarbonate and lithium salts. This should be expected from theoretical reasons and has been shown to be true by experiment.

In an article published by Klemperer in Vol. 5, p. 48, of the *Zeit. für physik. u. diätet. Therapie*, he states that carbonic acid decreases the solubility of uric acid but increases the solubility of the acid urates of sodium and potassium.

We would refer to an article recently published in this JOURNAL by McCrudden, 1903, Aug. 6, p. 149, for a further discussion of this subject. — E. P. J.]

THE PROPHYLAXIS OF OXALIC ACID CALCULI.

The calcic oxalate of the urine is chiefly derived from the food. Considerable quantities occur in spinach, tea, cocoa and smaller amounts in the remaining vegetables, fruit and beer. Meat is poor in oxalic acid except for the connective tissue elements. Oxalic acid occurs most as the insoluble calcium salt in the food, but is set free by the hydrochloric acid of the stomach. The more acid the gastric juice, the more oxalic acid is set free to find its way into the urine. Therefore by the avoidance of spinach, tea, cocoa and the gristle of meat and by the use of an alkali with meals the urine will contain little oxalic acid. It does not become wholly free from it, because of endogenous sources like creatinin and glycocholic acid.

The solubility of oxalic acid is increased in the presence of acid sodium phosphate, but as this is produced through the agency of an excessive meat diet, this method is impracticable. A more favorable resource is open. Calcium oxalate is more readily soluble in solutions of magnesium salts than of calcium salts. The former then are desirable and preponderate in meat, leguminous and farinaceous foods, potatoes and apples, while the latter, the calcium salts, are relatively abundant in milk, eggs and fresh vegetables.

DIETETIC PROPHYLAXIS OF PHOSPHATIC CALCULI.

Calcium phosphate is precipitated in an alkaline urine. This occurs when the urea is broken up by bacterial invasion into carbonic acid and ammonia. This condition is best met by treating the primary condition by lavage of the urinary tract, etc. But the urine is often alkaline because of fixed alkalies, instead of the volatile ammonia. This often occurs coincidently with the secretion of HCl in the stomach and is a normal occurrence, a few hours later the urine returning to an acid reaction. If the gastric juice is removed by vomiting or by washing out the stomach, the urine remains persistently alkaline.

Prophylaxis consists in restoring the general bodily condition to a healthy plane and treating the digestive disturbance. A mixed diet is to be preferred, since experience shows the complete avoidance of vegetables is unavailing. Vegetables and fruit, however, should be taken only in moderate quantities and alkaline waters totally interdicted. Plain water or water charged with carbonic acid is advisable since this passes to a considerable extent into the urine and by increasing the number of acid molecules contributes to the solution of the phosphates.

VEGETABLE FOOD IN GOUT AND NEPHRITIS.

Hall contributes an interesting article upon this subject.[3] It has been the custom to restrict meat as much as possible in gout and nephritis. Formerly it was supposed that white meat was less harmful, but recent investigations have shown that the difference in the content of ex-

[3] Berl. klin. Woch., 1903, Sept. 21, p. 868.

tractives between white meat and red meat is slight. Though much attention has been devoted to the study of the purin derivatives in meat and to their exclusion from the diet, vegetables have been allowed freely and without distinction. How irrational such a course is the following table shows:

Food.	*Purin Nitrogen in per cent of undried food.*
White bread, rice, tapioca, cabbage, cauliflower, lettuce	0.
Potatoes	0.0007
Onions	0.0036
Asparagus, cooked	0.0086
Pea meal	0.0156
Oatmeal	0.0212
Beans	0.0250

From this table it is obvious that though white bread, rice, lettuce and potatoes are wholly or nearly free from purin bases and so belong in a purin-free diet, other vegetables like onions, asparagus, beans and pea meal and oatmeal contain an abundance of extractives. This fact explains an observation of V. Nooden, who obtained about the same quantity of uric acid when a patient was fed with asparagus, beans and sauerkraut as he did when the patient was on an ordinary diet. Douglas also found 0.702 gm. uric acid in the urine of twenty-four hours from a patient whose diet was rich in peas, beans and lentils and only 0.675 gm. uric acid when the same patient was on the customary meat diet. Hall found in three individuals living on a diet free from extractives that the addition of beans caused an increase of uric acid in the same way as meat. The increase in extractives amounted to half the quantity of the extractives contained in the beans given.

The following table shows that various forms of beer contain many purin derivatives:

Substance.	*Purin Nitrogen in per cent.*
Claret, Volnay, Sherry and Port wines	0.
Milk	0.0002
Lager beer (A)	0.0052
(B)	0.0020
Pale ale	0.0058
Porter	0.0061

There is about the same quantity of uric acid forming material in one quart of beer as in three and one third ounces of beef. It is still an open question whether purin bodies in the food exert an influence on the development and course of gout and nephritis, but the close relation between these bodies in the food and the formation of uric acid is no longer uncertain. At present the dietetic treatment of these affections will only follow rational lines when besides meat, the vegetable foods such as peas, beans, onions, asparagus and oatmeal are restricted and beer absolutely forbidden.

TOXIC SYMPTOMS FROM UROTROPINE.

Urotropine is so extensively used that it is well to bear in mind that it is not harmless. Coleman [4] states that toxic symptoms like strangury occur with comparative frequency if the urotropine is not properly diluted. The susceptibility of individuals varies so much that the drug should be constantly controlled by examination of the urine. Signs of renal irritation, frequent and painful micturition, hematuria, hemoglobinuria, irritation of the stomach and bowels, headache, tinnitus aurium all may occur. Withdrawal of the drug is soon followed by a disappearance of symptoms.

FORMALIN INHALATION IN PULMONARY TUBERCULOSIS.

Spengler [5] advises formalin inhalations in pulmonary tuberculosis and fetid bronchitis. He prepares a solution containing ether 75 cc., absolute alcohol, 20 cc.; formalin, 5 cc. Ten drops of this are placed in a tumbler and about ten or twelve inspirations taken, the mouth being removed from the glass for expiration. The first inspirations should be superficial, the latter ones deep. The inhalations are made every other day at bedtime, and intermitted after a fortnight, to be resumed in a few days and continued as before.

TOXIC SYMPTOMS FROM ASPIRIN.

Dr. Franke [6] recounts his experience on taking 1 gm. (15 gr.) of aspirin for pains in the calves of the legs. In fifteen minutes there was swelling of the upper lip which quickly spread over the whole face. This was followed by difficulty in swallowing, frequent respiration and a rise in the pulse rate to 160. These symptoms subsided gradually after twenty minutes, to be replaced in an instant by a rash like urticaria over the whole body, but chiefly upon the backs of the hands, the neck and feet. On the next morning all signs had disappeared save the swelling and tense feeling of the lips and eyes. The writer explains the poisoning by the supposition that by some chemical change in the stomach phenol was set free and rapidly absorbed.

EXPLANATION OF FAVORABLE ACTION OF REST IN BED ON THE FEVER OF PULMONARY TUBERCULOSIS.

Pickert [7] explains the good effects of rest in bed on the fever of phthisical patients by the passive congestion of the lungs which is thereby produced. If this is so, the reverse of this condition, or anemia of the lungs, should be followed by fever. This he was able to show to be the case. If phthisical patients, who have gotten free or nearly free of fever by lying abed for several weeks, are allowed to sit up, the temperature varies considerably according to whether their feet are resting on the floor or are extended horizontally. In the former position there is a venous hyperemia of the legs with consequent diminution of blood in the upper part of the body. Systematic experiments showed differ-

[7] Cit. Zeit. f. diätet. u. phys. Therap., 1903, Oct., p. 410.

ences reaching even 1½° C. on single days. The highest temperatures always occurred on those days during which the legs were at no time in a horizontal position.

DANGER IN DISPENSING TABLETS.

One of my friends recently had the following sad experience. A mother brought to his office a child seventeen months old with convulsions. The baby had found a bottle containing pink tablets. By an unfortunate circumstance a file was near by and before any one was aware the baby had broken the bottle and swallowed all the tablets. The mother at once gave mustard and water, but not a sufficient quantity to induce vomiting. The child at first was not indisposed, but in about one and one-half hours convulsions began. The child was then taken to the doctor, but lived only fifteen minutes in his office.

I understand that one large firm has discontinued coloring its tablets, because they attracted the attention of children and led to several instances of poisoning.

Reports of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

TWENTY-NINTH ANNUAL MEETING, HELD AT WASHINGTON, D. C., MAY 12, 13 AND 14, 1903.

FIRST DAY — TUESDAY, MAY 12.

DR. J. W. PUTNAM of Buffalo, president, in the chair.

ADDRESS OF PRESIDENT.

The Congress of American Physicians was founded because the interdependence of the different branches of medicine was recognized by the master minds of the profession. The time had come when specialists needed to broaden their interests and enlarge their views of the field of medicine. Specialism is so engrossing that its devotees are in danger of becoming narrow in their interests and their activities.

The range of diseases we are called upon to treat is so large and so varied that it would seem impossible for us to become narrow.

The chronic cases of paralysis with deformities from various cerebral spinal and peripheral causes form a large and hitherto hopeless class. For years those afflicted with diplegia, hemiplegia and spastic paraplegia have sought medical aid in vain. Tendon transplantation and the principles which govern the operation should find a place in our chapters on treatment. It should be taught to the student from the neurological standpoint as well as from the surgical. We have long ago made common cause with the surgeon in cerebral and spinal operations; let us extend it to the domain of surgery of the neuromuscle machine. To the surgeon belongs the technique. To us belongs the duty of selecting cases for operation and of enlarging its field of usefulness. The after care of the patient is as important as the surgical. The operation must be followed by an education, both mental and physical, which we must direct. It is only through co-operation that the best results will be obtained.

Hitherto the relation of neurology to obstetrics has not been sufficiently appreciated nor emphasized. The effect of prolonged labor upon the child is being studied, and requires much more careful investigation in order to determine the effect of cranial birth injuries upon the brain. The obligation rests with us to sound the note of warning in season and out of season that epilepsy is in a large number of cases due to cranial birth lesions. The lesson must be so impressed that it will be a rule with accoucheurs to examine the head for fractures or undue depression after severe labor. When this practice has become a rule, and the cranial injuries are treated early and carefully, we may see as a result a diminution in the number of cases of epilepsy, idiocy and cerebral birth palsies.

THE SIGN OF THE ORBICULARIS.

This was the title of a paper by DR. GEORGE W. JACOBY of New York. The sign of the orbicularis is a symptom which consists of the inability of a hemiplegic voluntarily to close the eye upon the paralyzed side except in conjunction with the other eye. Thus in cases of hemiplegia the temporo-facial branch of the facial nerve is often so slightly affected as to lead to doubt whether the upper facial territory is involved at all. If in such a case the hemiplegic be asked to close both eyes together, he is able to do so without difficulty. He is also able to close the eye upon the sound side while keeping the eye upon the affected side open, but he is unable to reverse this procedure and close the eye upon the paralyzed side while keeping that upon the unaffected side open. This sign has hitherto been supposed to occur in central paralysis only. It was claimed by Jacoby that in many cases of peripheral paralysis this sign is present, and can be found if sought for at the proper time. These observations formed the basis for the following conclusions: (1) The statement of Bard that the sign is invariably lacking in peripheral facial paralysis, and is therefore a distinguishing mark of central affection, is incorrect. (2) The presence of the sign in peripheral paralysis is further proof of the existence of commisural fibers between the nuclei of the seventh nerves. (3) The sign is of clinical value in so far as its presence in peripheral paralysis shows that complete recovery has not yet occurred. (4) The secondary over-action in the orbicularis palpebrarum, which is late in appearance, and always coincides with some recovery in power, does not occur in those cases in which the sign having been present has passed away.

DR. G. L. WALTON of Boston thought it important to bear in mind that unilateral control of the lid movements differs on the two sides in health. More individuals can close the left eye alone than can close the right eye alone. This

may be due to the better education of the left cerebral hemisphere, for the education consists in learning to hold one eye open, not to close one eye.

Dr. Jacoby said that the independent closure of each eye was entirely acquired, and that in countries where a great many pursuits are followed which necessitate the independent closure of the eyes, it is much greater than in countries where those pursuits do not exist.

THE ACHILLES REFLEX AND THE FRONT TAP.

This was the title of a conjoint paper by Drs. George L. Walton and W. E. Paul of Boston. It was stated that the Achilles jerk has been extensively studied, but has not taken the place it should as a routine test of equal importance with the knee jerk; the front tap has not been extensively studied. The Achilles jerk is practically of equal constancy with the knee jerk, is more uniform in excursion and requires less skill than the knee jerk. In tabes the writers have found it absent more constantly than the knee jerk. The kneeling posture is preferable in most cases. In 500 cases without central nervous disease this reflex was wanting on both sides in only one instance; on one side, in four. Sluggishness of the tendon reflexes in health may be due to prior toxic affection, as diphtheria. In epilepsy the Achilles reflex and knee jerk are active except during the attack. The Achilles jerk is sometimes absent in osteo-arthritis with sciatic pain. The writers explain the front tap as allied to ankle clonus, though not of its sinister import. The foot being dorsally flexed by the examiner puts the calf muscles on the stretch, and the tap upon the tibialis anticus, by tending to dorsally flex the foot still further, suffices to produce contraction of the calf muscles. This reflex was present in 40% of 500 individuals healthy or suffering from no nervous disease. In epilepsy, hysteria, neurasthenia and other neuroses, it was found present in about 75%. It was never found present in tabes or other hypotonic affections.

THE REFLEXES IN LONG DISTANCE RUNNERS.

This was a paper by Drs. Philip C. Knapp and J. J. Thomas of Boston. They had made a comparative study of the knee jerk and allied reflexes in the participants in the "Marathon" run of twenty-four miles taken before and after the run, showing the influence of severe physical exertion combined with mental excitement upon the reflexes. In some cases the knee jerks were lost; in all, the plantar reflexes were more or less exaggerated.

These two papers were discussed together.

Dr. F. W. Langdon of Cincinnati said he had made it a rule to test the ankle jerk in tabes and other conditions. He had not found it uniformly absent in tabes, but had seen a number of cases of tabes with the knee jerk and ankle jerk preserved. In sciatic neuritis it is either markedly diminished or absent on the affected side.

Dr. Joseph Collins of New York found the ankle jerk more frequently absent in tabes than the knee jerk, the ankle jerk sometimes disappearing earlier than the knee jerk, which is a more constant manifestation. In the depressed or vasomotor type of neurasthenia he had found the "front tap contraction" diminished or absent in a large proportion of cases.

Dr. C. L. Dana of New York said that the ankle jerk was absent in one-half the cases of so-called sciatica. It is not so easy to test the ankle jerk as Dr. Walton has stated. It may also be elicited by re-enforcement.

Dr. H. T. Patrick of Chicago had been in the habit of testing the ankle jerk in every case, and had noted a difference in the two sides more frequently than in the case of the knee jerk. In some cases of tabes the knee jerk disappears first; in others the ankle jerk is the first to disappear.

Dr. Philip Zenner of Cincinnati had observed a number of instances in elderly individuals in whom the ankle jerk was absent. The nervous system appeared to be normal.

Dr. Jacoby said that in cases of tabes when the ankle jerk is present a careful examination will show that the knee jerk is also present, but that we may have the ankle jerk absent and the knee jerk present. The loss of the ankle jerk usually precedes the loss of the knee jerk.

Dr. Knapp agreed with Dr. Walton in his conclusions regarding the ankle jerk. He thought that the front tap contraction seemed more or less associated with ankle clonus. It has considerable significance as an indication of exaggeration of the tendon reflexes.

Dr. Walton in closing the discussion said that probably those cases of sciatica with loss of ankle jerk result from pressure on the nerve trunks by the products of osteo-arthritis of the spine, or possibly from neuritis. He had been surprised to find how persistent the ankle jerk and the knee jerk are in advancing age. There is no invariable rule regarding the priority of disappearance of the knee jerk or ankle jerk in tabes.

(All of the speakers agreed that the best method of obtaining the ankle jerk was to have the patient in a comfortable kneeling position on a chair during the examination.)

PRIMARY SARCOMATOSIS OF THE CENTRAL NERVOUS SYSTEM.

This was the title of a paper and the report of cases by Drs. Wm. G. Spiller and Wm. F. Hendrickson of Philadelphia. In the first case the symptoms were those of brain tumor and of transverse lesion of the thoracic cord. Multiple sarcomata of the brain and spinal cord were found. In the second case the symptoms were those of cerebellar tumor, and operation was done. Many tumors, some large and some small, were found in the membranes and nerve roots of the brain and spinal cord. In the third case the symptoms were those of a transverse lesion of the thoracic cord. A primary sarcoma of the spinal cord substance was found. Attention was called to the comparatively few symptoms

present in Case 2, notwithstanding the extensive sarcomatosis. The resemblance to syphilis of the nervous system was also discussed. The occurrence of a tumor in the cerebello-pontile angle in many of these cases of sarcomatosis was mentioned, and the question of operation was raised. The importance of the recognition of sarcomatosis of the central nervous system was emphasized, especially as regards surgical intervention when the symptoms seem to indicate that only one tumor is present, as in Case 2.

SPINAL CORD TUMOR TREATED BY OPERATION.

DRS. JAMES J. PUTNAM and J. W. ELLIOT of Boston reported three cases of tumor involving the spinal membranes.

The first case was noteworthy because the tumor, which proved to be a sarcoma, involved the axis and atlas and had caused a generalized paralysis, together with marked impairment of the respiration.

The growth was not sharply delimited, but was removed, so far as possible, with the curette.

In spite of the serious nature of the disease the patient has improved so much that he is now keeping a small store.

Three years have now elapsed and there has been no recurrence of the disease.

In the second case, a new growth, which was likewise of sarcomatous character, formed a collar about the spinal cord and dura at the junction of the cervical and dorsal region. The removal was successfully accomplished, but the respiration became much impaired even during the operation. The next day the temperature began to rise and continued to mount rapidly until the patient's death on the second day.

This result recalled one of the rarer effects of spinal injury. No cause could be ascertained for it, unless it were that the dura was punctured slightly at the time of operation.

In the third case, which was one of secondary cancer, involving the vertebral column and membranes in the lower dorsal region, the operation had been undertaken distinctly for the relief of pain. The growth was discovered at the expected point and was removed, so far as possible. The main point of the operation, however, consisted in the cutting of two spinal nerve roots, which were involved in the tumor. As a result of this, the patient's condition was considerably ameliorated for a number of weeks, at the end of which time she was seized with convulsions and other signs of involvement of the brain, and died shortly afterward.

The last two papers were discussed together.

DR. W. A. BULLARD of Boston said that where we have to deal with the dura and the membranes of the spinal cord, laminectomies are not so harmless as one might suppose. In a recent case in which there was anterior dislocation of the fourth cervical vertebra, laminectomy was done for pachymeningitis. The operation was successful surgically, but after forty-eight hours fever developed, and the patient died without apparent cause. He had seen the same result in other cases.

DR. B. SACHS of New York believed that cases of general sarcomatosis are not so very rare. He had seen a case of multiple gliosarcoma in a child which ran a rapid course. In a man forty years of age a tumor appeared on the frontal bone. On account of the multiplicity of symptoms the question was raised whether the disease was of syphilitic origin or sarcomatosis. The case terminated fatally, and proved to be a general sarcomatosis. He did not think special credit was due any one for making a correct localization for spinal cord or brain disease. The question of greater importance is to be able to determine before operation the character of the morbid process. In this connection he cited a case in which all the signs of spinal cord tumor were present, and an accurate localization recorded. Upon operation no growth was discovered. The patient died two weeks later. Macroscopically the cord appeared normal, but on microscopical examination a number of small tubercles were found in the dorsal and sacral roots with tuberculous infiltration of the cord.

DR. H. T. PATRICK of Chicago reported a case in which a tumor apparently sprang from the auditory nerve. The patient had gradually become quite deaf, this having been preceded by rhythmic tinnitus. The tumor was very easily removed, and proved to be an osteo-sarcoma of the petrous portion of the temporal bone, the deafness being due to protrusion of the growth into the internal ear. Death took place shortly after the operation.

DR. WM. C. KRAUSS of Buffalo referred to a successful case of removal of a spinal cord tumor from the cervical region which he reported at last year's meeting of the Association. Five months after the operation the patient died. The tumor was a small round-cell sarcoma.

DR. M. A. STARR of New York asked Dr. Putnam if there had been any respiratory difficulty during the operation for tumor of the axis. In a case of fracture of the third cervical vertebra there were distinct pressure symptoms upon the cord. During etherization he stopped breathing. Artificial respiration was kept up. The second time, chloroform being used, all voluntary respiration ceased. With artificial respiration during the entire operation a considerable amount of bony callus was removed with the relief of pressure. The boy is now in perfect health at the end of five years. He thought Dr. Spiller had done great service in presenting the subject of multiple tumors of the brain and spinal cord. He referred to a case in which a tumor was localized in the motor zone, but at the operation no tumor was discovered. The patient was tuberculous and lived four months. At the autopsy eight tumors were found scattered around in different areas of the brain, none being located in the motor zone. One tumor had absorbed about one-half of one lobe of the cerebellum, for which no symptoms at all had been present. The medullo-pontal junction is a favorite point for tumors. He had seen five cases. In all of these operated upon death resulted. Sudden

death is very common in all brain tumors. He recently had two cases of tumor of the cerebellum. Both patients died suddenly.

Dr. G. J. Preston of Baltimore spoke of malignant cerebral tumor following disease in the breast, and reported a case in which the growth was localized in the parietal region but was found in the ponto-bulbar region.

Dr. Collins referred to a case of sarcoma in the abdomen which terminated fatally. Multiple sarcomata were found in the brain and spinal cord.

Dr. C. L. Dana said that a few years ago he saw a patient in whom a sarcoma was successfully removed from the cervical portion of the cord. Improvement followed. In a case of removal of a tumor from the pontine angle the patient died. He called attention to the fact that cerebral softening from arterial fibrosis sometimes simulates brain tumor exquisitely.

BRAIN TUMOR.

Dr. C. Eugene Riggs of St. Paul reported two cases of brain tumor (endothelioma) with characteristic symptoms of involvement of the left motor area. Both were submitted to operation and terminated fatally.

Dr. Charles K. Mills of Philadelphia spoke at length in regard to operation for brain tumors. He believed that the cause of failure in operation was often due to imperfect methods of procedure. In Philadelphia they had gradually evolved more and more rapid methods of operation. He recommended the large osteoplastic flap made by a combination of the use of the trephine with the dental engine. He considered this method of value on account of the saving of time. In the last operation the skull was opened in eight minutes without shock. He believed strongly in operation for brain tumors in the majority of cases, if they were at all accessible.

Dr. Starr said that the best method to use was Doyen's electrical apparatus, and he considered it as rapid as the method spoken of by Dr. Mills. By this means it was possible to cut through the skull in fifteen seconds. He considered this a great improvement upon the old-fashioned way of cutting with chisel and hammer.

Dr. Dana had seen the instrument mentioned. He thought there was a good deal more in the surgery than there was in the burr. In one of the prominent hospitals in New York, with this burr he had known it to take over an hour to get through the bone. With the best instrument the surgeon must be trained in its use.

Dr. Sachs thought the question of time scarcely entered into the technique. He did not consider the fatal issue in so many cases the result of the modern operation.

Dr. J. W. Putnam of Buffalo was opposed to the statement that slowness makes no difference. He did not believe it possible to settle on one form of operation, because different surgeons will find that their own speed differs with the instrument.

(To be continued.)

Recent Literature.

The Practical Application of the Röntgen Rays in Therapeutics and Diagnosis. By William Allen Pusey, A.M., M.D., Professor of Dermatology in the University of Illinois, and Eugene Wilson Caldwell, B.S., Director of the Edward N. Gibbs X-Ray Laboratory, University and Bellevue Hospital Medical College. New York: W. B. Saunders & Co. pp. 591.

The book is written in collaboration by Dr. Pusey and Mr. Caldwell, the former a dermatologist, the latter a practical scientist. It is divided into two parts, the first of which, by Caldwell, deals with the use of tubes, interrupters, induction coils and static machines and with fluoroscopy and radiography. The several lists of apparatus are very complete and the descriptions detailed. This part is preparatory.

The body of the book deals with the therapeutics of the x-rays, exhaustively considered by Pusey. A description full, interesting and lucid of the effect of the x-rays upon the tissues and upon bacteria is followed by a discussion of the phenomena observed. The bulk of the second part consists of a description of diseases which the author has treated with the x-rays. Numerous illustrative cases are cited, accompanied by a brief discussion and summary of the results obtained. The tone of this part of the book is conspicuously judicial. This observer has used the x-rays in a large number of cases of great variety with the evident intention of determining their efficacy, and throughout he weighs his facts without prejudice. Failures and successes are both recorded. The last chapter gives the general conclusions. Here Dr. Pusey gives his estimate of the relative susceptibility to the x-ray treatment of the various diseases, and states that this method finds its greatest field in malignant disease. It is interesting to note that Dr. Pusey recommends in operable cases a combination of surgical and x-ray treatment.

The book is indispensable to those who use the x-rays as a therapeutic agent, while its illustrations are so numerous, its descriptions of apparatus, of technique and of tissue changes so complete, that it becomes valuable to every one.

Nose and Throat Work for the General Practitioner. By George L. Richards, M.D., Fall River, Fellow of the American Laryngological, Rhinological and Otological Society, etc. New York: International Journal of Surgery Co. 1903.

This is a little book of three hundred and thirty pages, intended as an elementary manual for the general practitioner and the student. Although the author does not mention any such origin, it is just such a book as a lecturer, whose duty it is to cover the field in ten or twelve lectures, might easily produce by writing out his lectures, and inserting such diagrams as happened to come to hand. Of course the lecturer

would describe cases that he had seen, and show instruments that he uses, and draw a better picture of some diseases than of others, also with so little room, subjects of more or less importance would be omitted. Viewed from this standpoint, the book is good. The description of diseases is clear, and the choice of treatment judicious. Going a little more into detail, the abnormalities of the nasal septum, atrophic rhinitis, empyema of the accessory sinuses, tracheotomy, adenoids, are well described. More difficult subjects, such as nasal and laryngeal neuroses, fibroid tumors of the naso-pharynx and chronic ethmoiditis, with polypi and asthma, are somewhat disappointing. No mention is made of the possibility of an infectious origin of acute cold, which is worthy of consideration, at least on account of the number of its advocates. The subject of tuberculosis should include lupus, which is distinct and common enough to be at least mentioned. The inflammatory diseases of the tonsils are a little confusing, and the etiology of pharyngo-mycosis omitted, while its treatment is unnecessarily strenuous. As a whole the book is attractive and trustworthy.

An Atlas of Human Anatomy. For Students and Physicians. By CARL TOLDT, M.D., assisted by ALOIS DALLA ROSA, M.D. Translated from the Third German Edition and adapted to English and American and International Terminology by M. Eden Paul, M.D. (Brux.), M.R.C.S., L.R.C.P. First Section: A — The Regions of the Human Body; B — Osteology. Illustrated. New York: Rebman Company. 1903.

This is the first volume of a translation of Toldt's *Atlas of Human Anatomy*, the translation being from the third German edition and adapted to English, American and International terminology. In the translator's preface it is suggested that, inasmuch as the science of human anatomy is purely descriptive in its methods, and its field not very extensive, it is one of the few sciences in which something approaching finality has been reached. Atlases of anatomy in English have hitherto been fragmentary, and it is said that up to the appearance of this work, no actual pictorial representation of all the data of human anatomy has been available. In this first volume of the series, which deals with, first, the regions of the human body, and, secondly, with osteology, there is a very strict adherence to the atlas plan. Descriptive text is small in amount and closely associated with the very numerous drawings which occupy each page. Various anatomical structures of importance are specifically indicated on each cut. The drawings are carefully made and in very considerable detail, without unnecessary elaboration.

In general, so far as one may determine from a first installment, this atlas when completed will represent an important addition to the means of study of human descriptive anatomy. The difficult matter of nomenclature has been met by the translator as well as could be expected in the present unsettled state of English terminology. The volume is bound not very attractively in art canvas, and is provided with an exhaustive index.

The Work of the Digestive Glands. Lectures by PROF. J. P. PAWLOW, Director of the Physiological Department of the Institute for Experimental Medicine, and Professor in the Imperial Military Academy of Medicine, St. Petersburg, etc. Translated into English by W. H. THOMPSON, M.D., M.CH., F.R.C.S., King's Professor of the Institute of Medicine, Trinity College, Dublin, etc. Illustrated. London: Charles Griffin & Co., Limited. Philadelphia: J. B. Lippincott Co. 1902.

Professor Pawlow's lectures, originally published in Russian, soon appeared in German and French, and now, after the lapse of some five years, have been translated into English in an admirable manner by Professor Thompson. Pawlow's work attracted attention, because he took advantage of the most recent surgical methods in his study of digestive secretions. He was able to separate from the original stomach a fold of mucous membrane, out of which he formed a small stomach which communicated with the surface by a fistula. The technique of the operation was such that the nerve supply of the two stomachs was preserved intact, though the mucous membrane was distinct. The small stomach thus served as a model of the larger, but the juice secreted by it was uncontaminated by food, and so allowed of more accurate observation.

The chief principle Pawlow deduced from his work was the specific excitability of the nervous mechanism of the glands. In accordance with this property the glands furnish a secretion which is adapted in quality and in quantity to the food eaten; for example, a meat diet stimulates an abundant flow of gastric juice, while a fat diet decreases it. Some months ago we commented upon this work of Pawlow in our Department of Progress in Therapeutics, to which we would now refer.[1]

Popielski[2] has recently subjected Pawlow's work to rigid critical analysis. We hope that Professor Pawlow will be able to meet these criticisms.

Radium and Other Radio-Active Substances; Polonium, Actinium and Thorium, with a Consideration of Phosphorescent and Fluorescent Substances, the Properties and Applications of Selenium and the Treatment of Disease by the Ultra-Violet Light. By WILLIAM J. HAMMER, Consulting Electrical Engineer. Illustrated. New York: D. Van Nostrand Company. 1903.

This small book of seventy-two pages discusses matters relating to radium, selenium and ultra-violet rays, together with various collateral topics. The book is a timely one and details many facts, both historical and scientific, which it behooves us to know. It is profusely illustrated.

THE BOSTON

Medical and Surgical Journal

THURSDAY, NOVEMBER 19, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published a Boston, weekly, by the undersigned.

Subscription Terms: $5.00 *per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 Bromfield Street, Boston, Mass.

THE MASTER-WORD IN MEDICINE.

Among other events of interest on the occasion of the opening of the new laboratories of the Medical Faculty of the University of Toronto, recently held, was an address by Dr. William Osler on "The Master-Word in Medicine." Dr. Osler for very obvious reasons has come to be the most sought-for speaker on such occasions in the English-speaking world. Not a year passes that he does not yield to the calls made upon him to address men about beginning their professional life. These addresses never fail in suggestiveness and point the way quite unerringly to the young man about to begin his difficult lifework. This last address delivered at Toronto is not unlike many of its predecessors, and offers food for thought not only to those to whom it was primarily addressed, but also to those of maturer years who are failing or succeeding in the struggle.

We are not surprised to find that Dr. Osler takes as the master-word "Work," which he regards as an essential of success, an opinion with which he will no doubt find few to take issue. Interest in one's work he finds the first step toward success. He lays stress upon the necessity of systematic habits of work; he urges charitableness toward brother practitioners; he insists that we should "cultivate the gift of taciturnity and consume our own smoke with an extra draught of hard work so that those about us may not be annoyed with the dust and soot of our complaints." These certainly are truths often reiterated, but coming from Dr. Osler, with his peculiar charm of statement, they still find lodgment in our minds. It is a source of personal satisfaction to us to find that Dr. Osler in this same address denies the reality of what he calls the "bogie of overwork." Of this he says:

> Much study is not only believed to be a weariness of the flesh, but also an active cause of ill-health of mind in all grades and phases. I deny that work, legitimate work, has anything to do with this. It is that foul fiend Worry who is responsible for a large majority of the cases. The more carefully one looks into the causes of nervous breakdown in students, the less important is work *per se* as a factor. There are a few cases of genuine overwork, but they are not common. Of the causes of worry in the student life there are three of prime importance, to which I may briefly refer.

If students of medicine and practitioners as well could realize the truth of these statements it would be well for the peace of mind of a large element in the profession.

In spite of the fact that Dr. Osler questions the value of introductory addresses, we quite agree with our contemporary, the *British Medical Journal*, when it says, speaking of this address, that his own furnishes an excellent justification for the existence of the custom. We commend it to our readers as a lay sermon of more than ordinary merit.

THE SPRECKELS PHYSIOLOGICAL LABORATORY.

We have already alluded to the establishment of the Rudolph Spreckels Physiological Laboratory at the University of California. It will be remembered that this laboratory was established on a somewhat different basis from others of a similar sort in this country. It was designed primarily to further research in physiological lines, with the understanding that teaching of elementary students should be a somewhat secondary consideration. This laboratory was formally dedicated Aug. 20 of this year.

Apart from the addresses made, the occasion was rendered notable by the presence of Professor Ostwald, who had come from Europe to California for the purpose of assisting in the dedicating of the new laboratory. Prof. Jacques Loeb, to whom in large measure has been due the conception of this laboratory and who is to be its director, delivered at the dedicatory exercises a brief address entitled, "The Limitations of Biological Research." After commenting upon the significance to American research that a laboratory of this character should be established, he outlined in a general way the direction

and tendencies of the work which it is proposed to carry on. He urged the necessity of recognizing physical chemistry as the foundation of biology, and defined as one of the fundamental problems of biology the necessity of answering the question as to whether or not is it possible to making living matter out of dead matter. Regarding this question, which has been a bone of contention for centuries, he felt that it was not too bold to prophesy that through the study of enzymes a solution might be forthcoming. Biologists, he thinks, will either succeed in transforming dead matter into living matter, or they will ultimately find that there is as definite a discontinuity between dead and living matter as between two chemical elements. A second problem facing the modern biologist is the question of transforming one species into another. In this he expresses the belief that we shall either succeed in bringing about a large transformation from the original form or determine the fact that at a certain point the constancy of a species is reached.

In general, Professor Loeb's address, brief as it was, expresses admirably the importance of biological research. Under such leadership as this new laboratory will have, there can be no question that we may in the near future look for results of very positive scientific value. Professor Loeb's preliminary work is a sufficient guarantee of this.

THE ORGANISM OF SMALLPOX.

As announced in our issue of last week, Dr. Gary N. Calkins of New York spoke, Nov. 9, at a meeting of the Biological Section of the New York Academy of Sciences, on "The Life History of the Organism of Smallpox." As is now universally known, Dr. W. T. Councilman and his colleagues have been working for many months past on the etiology of smallpox. Preliminary conclusions were presented at the meeting of the American Association of Pathologists and Bacteriologists, held at Washington in May of this year. At that time Dr. Councilman presented strong evidence to show that the causative agent in smallpox was a parasite of the protozoön type. Certain details in the life history of this parasite were at that time not definitely made out. This work has been prosecuted since by Dr. Calkins at Dr. Councilman's request and, as stated in a report of the meeting, published in the *Medical Record*, the results of this research were presented at Dr. Councilman's suggestion. Dr. Calkins described in detail the various phases of the life history of the organism, illustrated by lantern slides made from actual specimens. So far as one may learn from the report before us, this work is a confirmation of the opinion expressed by Dr. Councilman in May that a protozoön is the actual cause of the disease.

An added interest was given to the meeting by a discussion of certain inoculation experiments made by Dr. Brinckerhoff, whose name from the first has been identified with this research. Dr. Brinckerhoff obtained striking results through the inoculation of apes, in each of which there had been a development of a lesion analogous to the vaccinia lesion. In general he had found that the disease in the monkey was comparable to the disease as observed in man, and, furthermore, his findings regarding time relations between the various stages of the parasite and the evolution of the lesion were quite in accord with results obtained by Dr. Calkins on human lesions. This second published report on the progress of this important work must be regarded with much interest. The final, detailed results of the investigation will now be awaited with even greater expectation than before.

THE GERMAN EMPEROR.

THE penalty of position is admirably exemplified in the experience through which the German Emperor is now passing. Discussion is rife in medical and lay circles throughout the world as to the present character and future possibilities of the affection with which he is afflicted. So far as one may judge from published reports, it is sufficiently clear that the growth which has been removed from the larynx is of benign character and in itself presages no serious outcome. This is the expressed opinion of Professor Schmidt, who performed the operation, and also of Professor Orth, who made the microscopical examination.

Such growths as this are not unusual and certainly are not in themselves inimical to life. It is eminently natural, however, that people should recall the fate of the Emperor's father and also circumstances concerning his mother's death. How justified such apprehensions may be it is quite impossible to prophesy, and we are inclined to think that it is the part of wisdom, as well as of good taste, to await the outcome, whatever it may be, without speculation. In the meantime the world will certainly wish the

Emperor a speedy recovery from his present disability and will sincerely hope that the disease may have been entirely eradicated, as frequently happens in such cases.

MEDICAL NOTES.

Possible Sanatorium at Capri. — It is stated that Professor von Behring has proposed to transform the villa of the late Herr Krupp, which he has purchased, into a laboratory and sanatorium for tuberculosis. The residents of the island have instituted a vigorous protest and hope to thwart the proposed innovation, giving as one reason the dependence of the island upon foreign visitors, which it is maintained would be largely prevented in case a sanatorium were established.

A Correction. — In a statement made in our issue of last week regarding King Edward's Sanatorium for Tuberculosis it was erroneously implied that Sir Edward Cassel, who gave the money for the sanatorium, had died, and that the money had been left in the form of a bequest. The facts are that Sir Edward Cassel is still living and that a gift and not a bequest made possible the King's Sanatorium.

The D. W. Harrington Lectureship, University of Buffalo. — The Medical Faculty of the University of Buffalo has chosen Dr. Samuel J. Meltzer of New York to deliver these lectures for 1903. The subject selected by Dr. Meltzer is "Edema, a Consideration of the Physiological and Pathological Factors Concerned in its Formation." The lectures will be delivered in the Medical College Nov. 30 and Dec. 1, 2 and 3, at 5 P.M. The medical profession is cordially invited to attend.

These are the first lectures given on this foundation. Lectures will be given as often as the income from the fund will warrant.

Professor von Mikulicz on America. — In lecturing recently at Breslau, according to the *Medical News*, Professor von Mikulicz spoke of his recent trip to the United States. He praised American surgeons, and said he found more fruitful ideas among them than among the French or English. Part of the allusion was as follows: "The time is past when we were the givers and the Americans the receivers. The American character has as a fundamental feature unlimited self-confidence. The American believes he can do anything that is wanted, and he wishes to see America regarded as the most beautiful and most preëminent land in the world. Nevertheless, we have no ground for fear, for, in the sharp economic contest, the Germans have some advantages over the Americans. The latter recognize the efficiency of the Germans, calling them the "Yankees of Europe."

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Nov. 18, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 63, scarlatina 38, typhoid fever 22, measles 119, smallpox 0.

Adulteration of Phenacetin. — In the Boston Municipal Court on Monday, Nov. 9, the case of the Commonwealth *v.* Mansfield & Gardner came up for trial. The firm pleaded *nolo contendere* and was fined $100. This was a case of drug adulteration introduced by the State Board of Health, the article in question being phenacetin adulterated with acetanilid.

Bequest to New Haven Hospital. — By will of the late Sarah B. Harrison of Connecticut the New Haven Hospital gets $30,000, to be used for the establishment of free beds.

Harvard Medical School Scholarships. — The Faculty of the Harvard Medical School announces the following awards of scholarships for the ensuing year:

The Edward M. Barringer Scholarship of $500, divided as follows — $300 to G. S. Amsden, 3M., and $200 to H. W. Godfrey, 2M. The Isaac Sweetser Scholarship of $250 — to A. H. Crosbie, 2M. The Claudius M. Jones Scholarship of $250 — to S. J. Beach, 3M. The Hilton Scholarships of $225 each — to C. R. Metcalf, 2M., and W. A. Sawyer, 2M. The Alfred Hosmer Linder Scholarship of $200 — to T. Ordway, 3M. The Eveleth Scholarships of $200 each — to E. H. Place, 4M., L. S. Beals, 4M., and L. G. Beeley, 4M. The Edward Wigglesworth Scholarship of $200 — to C. L. Overlander, 3M. The Charles B. Porter Scholarship of $200 — to R. S. Stearns, 3M. The Faculty Scholarships of $200 each — to L. Arkin, 4M., W. H. Clark, 4M., H. B. C. Riemer, 4M., and W. C. Woodward, 4M. The John Thomson Taylor Scholarship of $200 — to B. E. Sibley, 3M. The Lucius F. Billings Scholarship of $200 — to R. H. Goldthwaite, 2M. The Orlando W. Doe Scholarship of $100 — to W. L. Barnes, 4M. The Charles Pratt Strong Scholarship of $100 — to C. H. Staples, 4M.

NEW YORK.

Accidents from X-Rays. — At a meeting of the Society of Medical Jurisprudence held Nov. 9, Dr. Carl Beck read a paper on the "Medico-Legal Aspect of Accidents Caused by X-

Rays." In it he said that undesirable results frequently attended the use of the x-ray, even when it was applied by the most expert operators. In order to avoid such consequences as far as possible, he advised that a very careful study should be made of each individual patient so as to determine as nearly as might be done the proper duration of an exposure. While some persons may be subjected without harm to long exposures at frequent intervals, others are so sensitive to the effects of the rays that only short exposures, given at long intervals, can be borne without injurious results. At this meeting Theodore Sutro, Esq., was renominated for president and Dr. Carl Beck for vice-president.

OFFICERS OF NEW YORK STATE ASSOCIATION OF RAILWAY SURGEONS. — At the thirteenth annual meeting of the New York State Association of Railway Surgeons, which was held at the New York Academy of Medicine on Nov. 12 and 13, the following officers were elected: president, Dr. Charles G. J. Finn, Hempstead, Long Island; vice-president, Dr. G. T. Conn, Concord; secretary, Dr. George Chaffee, Brooklyn (re-elected); treasurer, Dr. J. K. Stockwell, Oswego. Dr. Henry Flood of Elmira presided, and among the papers read were the following: "Car Sanitation," by Dr. James A. Exton; "The Diagnosis of Injuries to the Head," by Dr. C. B. Herrick; "The Diagnosis of Injuries to the Hip," by Dr. Wisner R. Townsend; "The Modern Treatment of Wounds," by Dr. Walter Lathrop and "Traumatism as a Factor in the Causation of Hernia," by Dr. William B. Coley. In the discussion of the latter Dr. A. J. Gilbert said that hernia had cost the railroad companies more money than any other one cause, and declared that it was "a frightful source of fraud, particularly among employees."

HOSPITAL SATURDAY AND SUNDAY ASSOCIATION. — The board of trustees of the Hospital Saturday and Sunday Association held its first meeting of the season on Nov. 10. The application of the St. Andrew's Convalescent Hospital for admission to the Association was favorably acted upon, and this brings the membership up to forty institutions. The New York Hospital, which is the wealthiest member, formally waived its privilege to receive a share of the annual collection. The general agent reported on the prospects of the coming Hospital Saturday and Sunday. Last year the collection amounted to $83,500, a considerable increase over any previous year.

CONSTITUTIONALITY OF BUILDING LAW. — The constitutionality of certain disputed sections of the building law has been upheld by Justice Freedman of the Supreme Court in his decision on the Moeschen case, which has interested a large number of builders and tenement property owners, the decision sustaining the verdict of a jury in the Municipal Court before which the first trial was held. Some time ago Mrs. Moeschen was ordered to substitute modern closet drains for backyard "school sinks" in a tenement which she owned. She appealed to the courts on the ground that the order was an unreasonable exercise of the state police power, and as such unconstitutional. In view, however, of the importance of the question involved, and the case being a pioneer, Justice Freedman states that the request made by both parties for permission to appeal to the Appellate Division should be granted.

FIVE THOUSAND DOLLARS FOR AN EAR. — The newspapers mention that no less than one hundred and fifty persons willing to part with an ear for $5,000 applied at the office of a physician, a wealthy patient of whom had offered that amount for an ear of the right size and shape to take the place, by means of a grafting operation, of one that he had lost.

DIPHTHERIA AT ELMIRA. — A severe outbreak of diphtheria recently occurred in the New York State Reformatory at Elmira, but by the prompt and free use of antitoxin it appears to have been quickly suppressed, with but a small mortality.

ACCIDENT INSURANCE POLICIES. — An accident insurance policy issued to one Coles of the New York Casualty Company stipulated that it did not cover injuries resulting directly or indirectly from fighting, wrestling, scuffling, altercation, quarrel or assault. Coles, the insured, was employed as a bartender, and while on duty in this capacity had occasion to order a noisy individual from the premises. The disorderly person refused to go, and grappled with Coles, who, while forcibly resisting the assault, or while pushing the aggressor from the room, was injured. On an appeal of the case, which at first was decided against the insured, it has been held by the Second Appellate Division of the Supreme Court that the facts did not operate as matter of law to deprive the insured of all claim against the company, and hence it was an error to dismiss a complaint in an action for

indemnity on the ground that insured violated the policy.

Miscellany.

THE PHYSIOLOGY OF BITTERS.

The custom of taking bitter appetizers immediately before the heavy meals of the day is widespread, both in this country and abroad, the object being, of course, to stimulate the secretion of gastric juice. Latterly it has been suggested that it would be more physiological to make use of a small quantity of alkali instead, as that is known to exercise a favorable influence upon peptic secretion. The chief objections to the use of bitters have been based on researches by Tchelzov, who found that the administration of large doses of quassia hindered rather than helped the digestive process. Reichmann, moreover, showed that in the fasting stomach, the secretory activity of which is normal or diminished, a bitter drink produced less secretion of gastric juice than a draught of distilled water. These experiments take account solely of the specific action of the bitters, and do not regard their reflex effects. These have been particularly studied by Borissov, whose results are analysed in a recent number of *La Semaine Médicale*. He made use of Pawlow's method of sham feeding in a dog in which esophagotomy had been performed and a gastric fistula also established. The bitter substances, therefore, did not pass into the stomach, and the reflex effects of their presence in the mouth could be accurately judged. Borissov found that if a little wad of wool soaked in tincture of gentian was put into the mouth immediately before food was administered, a marked stimulant effect upon gastric secretion resulted; but if the bitter was used fifteen to thirty minutes before the meal it was quite inefficacious. It is concluded, therefore, that these substances have the power of rendering gustatory sensations more acute and of exercising a temporarily stimulant effect upon gastric secretion; for this purpose they should be given immediately before the meal in small doses and in the form of tincture (10 to 20 drops) rather than cachets or pills. We may remark upon this that the habit is obviously susceptible of abuse, particularly, when, as is usually the case, some strong alcoholic liquor is used as the vehicle of the bitter. As a matter of fact, such a stimulant action is the real function which is intended to be subserved by the soup which is taken at the beginning of a meal. There is a tendency — even outside the city of London — to consume this in somewhat large quantity; in such cases it tends to be harmful rather than conducive to digestion; but there can be no doubt, on the other hand, that the use of a tablespoonful or two of a hot and sapid fluid at the beginning of a meal is an excellent means of giving the stomach a fair start in the performance of its functions. — *British Medical Journal.*

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, NOV. 7, 1903.

Cities.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Diseases.	Typhoid fever.

Deaths reported, 2,985; under five years of age, 747; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 687, acute lung diseases 405, consumption 322, scarlet fever 15, whooping cough 11, cerebrospinal meningitis 7, smallpox 18, erysipelas 7, puerperal fever 7, measles 10, typhoid fever 77, diarrheal diseases 114, diphtheria and croup 99.

From whooping cough, New York 5, Chicago 2, Philadelphia 1, Baltimore 1, Boston 1, Fitchburg, 1. From erysipelas, New York 3, Philadelphia 1, Baltimore 1, Providence 1, Boston 1. From smallpox, Philadelphia 4, Pittsburg 14. From measles, New York 5, Philadelphia 1, Boston 3, Worcester 1. From scarlet fever, New York 5, Chicago 3, Baltimore 2, Pittsburg 1, Providence 1, Boston 1, New Bedford 1, North Adams 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Oct. 24, the death-rate was 15.9. Deaths reported, 4,610; acute diseases of the respiratory organs (London) 194, whooping cough 45, diphtheria 58, measles 55, smallpox 1, scarlet fever 36.

The death-rate ranged from 4.0 in Hornsey to 30.8 in Tynemouth, London 15.1, West Ham 17.9, Brighton 13.3, Southampton 9.5, Plymouth 11.6, Bristol 12.5, Birmingham 20.6, Leicester 14.9, Nottingham 13.8, Liverpool 18.8, Bolton 18.0, Manchester 15.9, Salford 24.2, Bradford 17.7, Leeds 15 6, Hull 16.7, Cardiff 11.5, Rhondda 19.6, Merthynr Tydfil 21.8, Middlesbrough 24.1.

METEOROLOGICAL RECORD.

For the week ending Nov. 7, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING NOV. 12, 1903.

PETTUS, W. J., assistant surgeon-general. Detailed as inspector of unserviceable property in the Hygienic Laboratory. Nov. 12, 1903.

GREENE, J. B., passed assistant surgeon. Granted leave of absence for twenty days from Nov. 15. Nov. 9, 1903.

ANDERSON, J. F., passed assistant surgeon. To proceed to Detroit, Mich., for special temporary duty. Nov. 5, 1903.

TRASK, J. W., assistant surgeon. Granted leave of absence for four days from Oct. 17, 1903, under paragraph 191 of the regulations.

SALMON, T. W., assistant surgeon. To proceed to Philadelphia, Pa., and report to medical officer in command for duty. Nov. 7, 1903.

MASON, W. C., acting assistant surgeon. Granted leave of absence for five days from Nov. 19. Nov. 7, 1903.

OWEN, HENRY, acting assistant surgeon. Granted leave of absence for thirty days from Nov. 8. Nov. 9, 1903.

Achenbach, John, pharmacist. Granted leave of absence for seventeen days from Nov. 20. Nov. 7, 1903.

BOARD CONVENED.

Board convened to meet at Chelsea, Mass., Nov. 12, 1903, for physical examination of an officer of the Revenue Cutter Service. Detail for the board — Surgeon R. M. Woodward, Chairman. Assistant Surgeon W. C. Rucker, Recorder.

APPOINTMENTS.

Thomas William Salmon of New York commissioned (recess) as assistant surgeon. Nov. 7, 1903.

George Neves of Oklahoma appointed pharmacist of the third class. Nov. 13, 1903.

RESIGNATION.

Pharmacist Frank Siedenburg resigned, to take effect Oct. 4, 1903.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING NOV. 14, 1903.

D. N. CARPENTER, Surgeon. Detached from the "Chicago" and ordered home to wait orders.

R. B. CHAPMAN, assistant surgeon. Appointed assistant surgeon with rank of lieutenant, junior grade, from Oct. 28, 1903.

O. DIEHL, surgeon. Detached from the "Oregon" and ordered to the "New Orleans."

M. S. GUEST, surgeon. Detached from the "New Orleans" and ordered to the "Oregon."

H. D. WILSON, surgeon. Detached from the Naval Station, Olongapo, P. I., and ordered to the "Vicksburg."

G. M. MAYERS, assistant surgeon. Detached from the "Vicksburg" and ordered to the "El Cano."

J. M. BRISTER, assistant surgeon. Detached from the "El Cano" and ordered to the "Isla de Cuba."

C. BIDDLE, surgeon. Detached from the "Puritan" and ordered to the "Lancaster."

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY. — There will be a special meeting of the Section for Obstetrics and Diseases of Women in Sprague Hall, Boston Medical Library Building, No. 8 The Fenway, Nov. 25, 1903, at 8 P.M., to consider the advisability of holding meetings during the coming winter for the reading and discussion of papers, etc. Dr. Charles S. Bradley will present a paper on "An Account of the Work, including Obstetrical Technique, at the Lying-in Hospital of the City of New York."

W. H. GRANT, M.D.
Secretary.

RECENT DEATHS.

George Julius Engelmann, M.D, M.M.F.S., of Framingham died in Nashua, N. H., Nov. 16, 1903, aged fifty-six years.

Charles Marshall, M.D., a prominent physician of Huntingdon, Province of Quebec, Canada, died suddenly of apoplexy, on November 13, in New York, where he had just arrived on a visit to some relatives. He was a graduate of the medical department of the New York University, and after studying for some time in Europe, settled in Huntingdon, his birthplace. He was a member of the Medical Board of Governors of the Province of Quebec and was prominent in the Masonic order.

BOOKS AND PAMPHLETS RECEIVED.

Textbook of Operative Surgery. By Dr. Theodor Kocher. Authorized translation from the Fourth German Edition. By Harold J. Stiles, M.B., F.R.C.S. Edin. Illustrated. London: Adam and Charles Black. 1903.

Traité de Radiologie Médicale. Publié sous la direction de Ch. Bouchard. Illustrated. Paris: G. Steinheil. 1904.

Traité d'Hygiène. Procédés Rapides de Recherche des Falsifications and Altérations. Par le Dr. P. Smolensky. Traduction du russe par S. Broido et A. Zagulelmann. Annotée par L. Guiraud et A. Gautié. Illustrated. Paris: G. Steinheil. 1904.

Les Nerfs du Coeur Chez les Tabétiques, par le Dr. Jean Heitz. Paris: G. Steinheil. 1903.

Illinois State Board of Health. Report on Medical Education and Official Register of Legally Qualified Physicians. 1903. Mammalian Anatomy with Special Reference to the Cat. By Alvin Davison, Ph.D. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

Clinical Talks on Minor Surgery. By James G. Mumford, M.D. The Old Corner Bookstore, Boston. 1903.

The Medical News Visiting-List. Philadelphia and New York: Lea Brothers & Co. 1904.

Transactions of the Obstetrical Society of London. Vol. XLV. For the year 1903. Part III., for June and July. Edited by Amand Routh, M.D., and Herbert R. Spencer, M.D.

University of California Publications. Physiology. The Limitations of Biological Research. By Jacques Loeb.

University of California Publications. Physiology. The Relations of Biology and the Neighboring Sciences. By Wilhelm Ostwald.

Atlas of the External Diseases of the Eye, including a Brief Treatise on the Pathology and Treatment. By Prof. Dr. O. Haab. Authorized translation from the German. Second Edition, Revised. Edited by G. E. de Schweinitz, A.M., M.D. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Quiz-Compends? No. 7. Compend of Gynecology. By William H. Wells, M.D. Third Edition, Revised, Enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

Transactions of the Association of American Physicians. Eighteenth Session, held at Washington, D.C., May 12, 13 and 14, 1903. Vol. XVIII.

The Medical Epitome Series. Normal Histology. A Manual for Students and Practitioners. By John R. Wathen, A.B., M.D. Series edited by V. C. Pedersen, A.M., M.D. Illustrated. Philadelphia and New York: Lea Brothers & Co.

A Treatise on Orthopedic Surgery. By Royal Whitman, M.D. Second Edition, Revised and Enlarged. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

Infection and Immunity, with Special Reference to the Prevention of Infectious Diseases. By George M. Sternberg, M.D., LL.D. Illustrated. New York and London: G. P. Putnam's Sons. 1903.

The Medical Epitome Series. Anatomy. A Manual for Students and Practitioners. By Henry E. Hale, A.M., M.D. Series edited by V. C. Pedersen, A.M., M.D. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

A Text-Book on the Practice of Medicine. Designed for the Use of Students. By James Magoffin French, M.D. Illustrated. New York: William Wood & Co. 1903.

Original Articles.

THE TREATMENT OF DIFFUSE PERITONITIS.[1]

BY B. F. LUND, M.D., BOSTON.

By diffuse peritonitis is meant that rapidly spreading inflammation of the peritoneum which resulted from perforation of the appendix or other viscus, in which the inflamed area is covered with pus or fibrin, and is not walled off by adhesions from the peritoneal cavity. Such a peritonitis may, if it has invaded all the recesses of the greater peritoneal cavity, be called a general peritonitis. A general peritonitis differs in extent and not in character from a diffuse peritonitis. This condition is one which the surgeon is called upon so often to treat, and one in which his methods and results are of so great importance to his patients, that a thorough discussion of the methods is always of vital interest.

Whatever methods are adopted, a large mortality will always attend the surgeon's efforts in those cases of peritonitis which come to him late, with the greater portion of the abdominal cavity invaded by the process and the system overcome by toxemia. Nevertheless, by intelligent methods of treatment, the mortality, even in extensive, if not entirely general, cases of diffuse peritonitis, has been greatly lowered, and it is to some of the methods which in the writer's experience have seemed to contribute to this lowering of mortality that he wishes to call attention in this paper.

The literature of the treatment of diffuse peritonitis is enormous, and methods of treatment which seem diametrically opposed have or had their ardent advocates. One writer advises irrigation; another condemns it because it distributes infectious products through the peritoneal cavity. One advises drainage, another avoidance of drainage, etc., so that to the uninitiated the matter seems to be in a state of apparent confusion. Even as to the point which seems to the writer the most important point of the treatment, *i. e.*, that the infecting focus should be immediately removed, there is still a difference of opinion among surgeons. It is to this point, which seems to him one of vital importance, that the writer would first invite attention.

There can be no question that the peritoneum will absorb or segregate by adhesion a certain quantity of infectious material. But if an indefinite supply is poured into the cavity by a necrotic perforated appendix or ruptured intestine the peritoneum cannot take care of it. A surgeon in a large hospital who has been called upon to treat cases of general peritonitis which have been poorly observed, neglected and have not sent for surgical aid until the entire abdomen was invaded by the process, the intestines paralyzed, and the patient suffering from septicemia, finds it hard to believe that, without the removal of the infecting viscus, the peritoneum can wall off all septic processes. In perforative peritonitis, early or late, the removal of the infecting focus is imperative, as so well stated by Dr. Joseph A. Blake of New York in a recent article on the treatment of diffuse peritonitis: "The advocates of the treatment by rest will concede that the patient will be much better off with the appendix out if it can be done without operation. We have then simply to weigh the dangers of toxemia and the shock of operation against the danger of continued infection, both systemic and peritoneal from the appendix itself, or the escape of its contents."

With a short anesthesia and quick operation the danger of interference is much less than that of procrastination. Dr. A. J. Ochsner of Chicago, the most eminent advocate of the waiting policy in diffuse peritonitis, states that at no matter what stage a case of diffuse peritonitis comes into the hands of the surgeon, in case the stomach is washed out and nothing administered by it, nourishment being kept up by rectal injections, thus keeping the stomach and small intestines absolutely at rest, in a vast majority of instances the process will become walled off, the acute symptoms subside, and the patient can be safely operated upon at a later date. Dr. Ochsner adduces statistics in proof of his contention.

This policy of waiting in acute perforative peritonitis has been tried at the City Hospital, and the writer has occasionally seen a case which exhibited the symptoms of a diffuse peritonitis wall off and quiet down. A more frequent result of this policy has been the progress of the disease to such an extent that the operation had to be done under conditions much more serious than obtained when the case first presented itself. These cases have afforded a comparison of the value of quick anesthesia and operation with a waiting policy. In the former case the patient suffers no shock, but is relieved from the constant influx of septic material from the infected organ. The current of infectious material is started out of the abdomen instead of into it, and the patient is placed on the road toward recovery.

Ten years ago the writer well remembers the position taken by Dr. Worcester of Waltham, at a memorable discussion in Boston, in which he advocated the early operation or as soon as the diagnosis is made, in all cases of appendicitis. He well remembers the controversy that followed, in which several of Boston's most noted physicians and surgeons advocated the policy of waiting for the formation of the abscess and of adhesions before operating. The courage displayed by Dr. Worcester at that time has been rewarded by the adoption of his opinion by the majority of conservative surgeons throughout the country. Experience has proved that a patient with a perforation draining outside the abdomen is much better than if one enclosed within its impermeable walls and free to distribute poison throughout its cavity.

The writer has observed so many cases of appendicitis apparently "quieting down," with

[1] Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital.

a normal temperature and pulse, in which a sudden rise of temperature and an alarming aggravation of the patient's symptoms have proclaimed a perforation or rupture of an abscess previously limited by adhesions, that he is convinced of the dangers of a waiting policy. The dangers of an early operation in which drainage is employed are not much greater than that of the operation in the interval, and many lives which would have been sacrificed by waiting for the subsidence of the acute attack are unquestionably saved.

Where cases are seen early, as they should be, by the surgeon — within twenty-four or forty-eight hours — all will admit that there should be no question of waiting for the interval with its danger of perforation, but that operation should be done at once. In cases seen later, after the process has had a further start, a waiting policy is indicated still less. After the fire has a better start it is still more dangerous to wait before turning the hose on the flames.

Now in regard to the methods of treatment. Granting the importance of immediate removal of the infecting focus, a complete removal of all necrotic tissue is indicated whenever possible. In the first place a complete removal takes the entire source of infection out of the peritoneal cavity, instead of leaving a smouldering focus behind to prolong the period of suppuration and the necessity of drainage. Where the appendix is the source it should always, where feasible, be removed entire. The writer firmly believes that in a case of salpingitis where, as he so frequently has seen, one badly diseased tube is removed and another, which is only slightly inflamed and contains only a little pus, is left behind, because it is considered improper to sterilize the patient, an absolutely wrong policy has been followed. The tube which has been left behind remains as a smouldering focus of infection, and not infrequently becomes the cause, if not of acute peritonitis, at least a chronic peritonitis causing bands of adhesion between the intestines and the pelvic wall. It often becomes acutely inflamed and necessitates a second operation for its removal, an operation rendered much more difficult by the adhesions resulting from the previous operation, and the chronic inflammation. Further, a chronically inflamed appendix stump may be the cause of fresh fibrinous adhesions throughout the peritoneal cavity resulting in intestinal obstruction requiring operation for its relief. A thorough removal, therefore, of the infected focus is necessary as well for the future as for the immediate welfare of the patient.

The second object to be attained after a removal of the infecting focus is a thorough cleansing of the peritoneal cavity and the placing of it under the most favorable conditions for the subsidence of the infection and return to a normal condition.

For this purpose for several years the practice at this hospital has been in the majority of instances in cases of diffuse peritonitis to thoroughly irrigate the peritoneal cavity with deci-normal salt solution at a temperature of 110°. This process the writer believes to be of great importance and value. Through a long glass nozzle of large caliber pushed into all the recesses of the cavity several quarts or gallons of salt solution are introduced, which comes out of the wound with a violent rush and brings out fragments which otherwise would have remained to prolong suppuration and interfere with convalescence. A warm salt solution soothes instead of irritating the peritoneum, and cleanses every portion of it without rendering necessary the removal of the intestinal coils from the abdominal cavity with the shock which accompanies that procedure. A certain amount of salt solution is left behind, which, being absorbed by the lymphatics, increases the amount of fluid in the vascular system. Another portion of the fluid is immediately taken up by the gauze which is used for drainage, and starts a current from the abdomen out into the dressings and aids in removing any infectious material which may not have been washed out during the operation. From every point of view, then, the process of irrigation seems to be a valuable one. The infectious material is not spread by it from one portion of the peritoneal cavity to another, because through the tubes it is carried to the bottom of the pelvis and other peritoneal recesses, and the current is from there out from the wound, not through the wound into the distant portions of the peritoneal cavity. A certain amount of loose fragments of fibrin are washed out by this irrigation, but attached portions must be left behind. The writer believes it wiser to leave them there than attempt their removal. The occasional washing out of a fecal concretion which otherwise would have been left behind is a valuable result of this procedure.

Only a few years ago Dr. Finney of Baltimore advised removal of the intestines from the abdominal cavity and sponging with gauze to remove adherent flakes of fibrin from them, but this process leaves raw bleeding surfaces with lymphatics open for further infection. It also increases the shock of the operation by evisceration and handling of the coils. The writer believes that it is an unnecessary and usually harmful proceeding.

After removal of the infecting focus and infectious products the next question to claim attention is that of drainage. The writer is an advocate of gauze drainage for the following reasons: In the first place, even if only for a few hours before adhesions are formed about the drainage wicks, these wicks by capillarity remove a large quantity of fluid, some of it presumably septic, from the peritoneal cavity. The irritating effect of the gauze causes, immediately after the drainage of the fluid, the formation of adhesions which wall off the infected area from the general cavity and prevent further reinfection of that cavity, and the subsequent formation of local residual abscesses by any infected material which it may not have been possible to remove

at the operation. For the drainage of the pelvis gauze wicks are used, and among them is placed a glass tube passing to the bottom of the pelvis. The glass tube is not of much direct value as a drain. It is removed at the end of twenty-four hours, and is generally found at that time filled with coagulated fibrin. The writer believes it of value, however, in keeping the gauze in the original position in which it is placed, and preventing its becoming entangled by the movements of the intestines, thus possibly producing obstruction. Gauze drainage alone is employed for the stump of the appendix, and is generally sufficient for drainage of the right flank. The wrapping of gauze wicks in rubber tissue, while it facilitates their removal, prevents, in the writer's opinion, the action of the gauze in the production of adhesions, and is a harmful rather than useful procedure. About such a drain, instead of hard and dry adhesions, as in the case of a gauze drain, there form soft and moist barriers. It does not seem to the writer that ease of removal compensates for the other disadvantages of such drains. The tube, as stated above, is removed at the end of twenty-four hours; the gauze drains, if the cases progress well, are removed in about four or five days, being slightly loosened on the second and third days, and on the fourth day carefully removed. If they are removed carefully and slowly, one at a time, an anesthetic usually is not necessary.[5]

Dr. Blake, in his paper quoted above, advocates the abandonment of the drainage, and supports his contention by a series of cases in which the drains were not carried into the peritoneal cavity, but through the wound; or, in other words, he does not close the wound, but allows the peritoneal fluid to flow out through it, carrying his drain, as far as the writer can make out from the description, to the bottom of the parietal wound, but not into the peritoneal cavity. He advocates the use of drainage only in case it has been impossible to remove the necrotic material, and in cases where there is doubt whether all the infectious material has been removed. It seems to the writer that this doubt does exist in a large majority of cases of diffuse peritonitis, and he therefore advocates the general use of gauze as drainage. Gauze drainage, where properly used and supported by tubes, has not in the cases observed by the writer been the cause of intestinal obstruction.

The assistance of abdominal drainage by gravity has been suggested and tried many times. A few years ago in the Johns Hopkins School, elevation of the foot of the bed was suggested after suture of the abdomen, in order that the abundant lymphatics of the diaphragm might take care of what infectious material had been left in the peritoneal cavity. This procedure was quite extensively tried, but was found uncomfortable and attended by, at least, no decrease of mortality, and has been generally abandoned.

The opposite procedure, namely, the elevation of the head of the bed after drainage of the abdomen in order to permit immediate flow of the fluids left after operation into the pelvis, whence they are quickly sucked out by the capillary action of the gauze and tubes, has *a priori* more to recommend it. It was suggested to the writer by Dr. Murphy of Chicago, who stated that his cases of perforative peritonitis were brought to the hospital sitting up in the ampulance, and were kept sitting up in bed in an almost upright position after the operation. The writer tried this procedure in a severe case of general peritonitis on a little boy in the hospital. The greater part of the cavity of the peritoneum was infected. The boy, after the usual operation and appendectomy, was drained by a large rubber tube brought out at the lower end of the wound and kept sitting up in bed by strapping the legs to a Bradford frame, with his back against a head rest. Although the position was somewhat exhausting, the drainage was very free from the wound, and the boy made an excellent recovery. He was allowed to recline after the fourth day. There were no complications in the way of secondary abscesses. The next case, a little girl in very poor condition, with general peritonitis, in which this plan was tried, proved fatal. The position was very irksome to the child, and, although drainage was free, she grew so weak that she had to be lowered in bed.

Since these experiences the writer has confined himself to the elevation of the head of the bed, about one foot above the level, by placing under the head of the bed the blocks which are ordinarily used to elevate the foot of the bed in fractured femur. One or two pillows are also placed beneath the shoulders. This position gives slant enough to the body to allow the fluid to flow from the flanks into the pelvis, and is not exhausting to the patient as is the more complete upright position. The writer believes that where elevation of the head and shoulders is used the incisions in the flank which were formerly not infrequently practiced by him are unnecessary. The cases in which moderate elevation has been practiced, and these included all the cases which have come under the writer's care since last spring, there have been six cases with four recoveries, certainly a favorable showing, although the number is at present too small to prove of value in forming an estimate of the method. The procedure is one that certainly does no harm, and, it seems to the writer, is probably an aid in the treatment of these cases.

In regard to that grave class of cases of general peritonitis accompanied by distention of the intestines, which frequently, when the surgeon is first called to see them, present the appearance of cases of intestinal obstruction, a few words only should be added here. The subject was fully discussed and elaborated upon by the writer in a paper "On the Value of Enterostomy in Selected Cases of Peritonitis," published in the *Journal of the American Medical Association* for July, 1903. In the treatment of these cases, in addition to the measures given above, an incision

about one inch long is made in the small intestine, and the distended coils drawn outside the abdomen as far as possible, emptied of their contents, and two ounces of a saturated solution of epsom salts injected into the lumen. The opening is then closed with a continuous suture of silk or linen thread. After the operation on these patients early attempts are made to move the bowels by enemata of turpentine, glycerine or saturated solution of epsom salts, and if these efforts prove ineffective, the distention of the abdomen increases, and the patient grows worse, a second enterostomy is done. This procedure consists in opening the abdomen in the median line by a short incision, suturing the first distended coil of small intestine which presents to the transversalis fascia, tying in a glass tube connected with a rubber tube, and thus giving the feces a direct opportunity to escape and allowing the paralyzed intestine to recover itself. This procedure has proved effective in certain desperate cases where death was apparently impending after operation for diffuse peritonitis. For the details of the cases and full discussion of the method the reader is referred to the paper given above.

On looking over the records of hospital and private cases for the last four years the writer finds that he has operated upon thirty-four cases of general peritonitis in which all, or at least four-fifths, of the greater peritoneal cavity was involved in the process. Cases of diffuse peritonitis covering only a slight area have not been included. Twenty-three of these cases were due to perforative appendicitis, of which 10 recovered and 13 died, a mortality of 57%. Most of these cases which died were in very poor condition. Four were moribund, the pulse being so weak that no attempt was made to find the cause of the peritonitis; the abdomen was simply opened and drained by a glass tube in the pelvis; two of these operations were done under local anesthesia, as the patient's condition and constant vomiting precluded a general anesthetic; no cases were refused operation on account of the poor condition of the patient.

Of the remaining 11 cases, 4 were due to salpingitis. Of these cases one recovered and three died; one was due to perforating typhoid ulcer, also died; two to rupture of intestine by external violence, of these one died and one recovered; one to perforated gastric ulcer, which recovered; one fatal case due to perforated duodenal ulcer; and one to perforation of the posterior *cul de sac* by a splinter of wood introduced through the vagina. We have, therefore, a total of general peritonitis from all causes of 34 cases with 20 deaths, or 59%.

The writer's time has not been sufficient to analyze the records of the cases of early diffuse peritonitis which he has operated during that time. The mortality of the early cases, however, has been extremely low. One case of perforated typhoid ulcer, which was fatal; one case of perforated gastric ulcer, which recovered; and one case of ruptured intestine, which recovered, are not included in the above list of 34 cases, because the peritonitis, though diffuse, was not extensive enough to be termed general.

Complications in the way of residual abscess formation, etc., have been rare. Intestinal distention, which could be definitely attributed to the pressure of gauze drains has not occurred in the writer's experience, except in perhaps one case, and in this case the cause of the distention was doubtful. One of the cases of general peritonitis died in ten days after the operation of portal phlebitis, the peritoneal process having subsided. The writer's cases of enterostomy previously published have not been included in these cases, as in none of those cases was the peritonitis general at the time of the primary operation. In three of the fatal cases used as the basis of this paper secondary enterostomy was done unsuccessfully, but the patients died from septicemia, and not from abdominal distention. Although the mortality in the above list may seem high, yet it seems to the writer that the showing is on the whole a favorable one, when one considers the lateness of the operation and the desperate condition of a large number of the cases which are brought to this hospital, and although nothing particularly new has been contributed to the treatment, he has felt that, from time to time, a discussion of the treatment of so important and frequent a class of cases is in order.

In view, also, of the recent advocacy of the rest treatment of peritonitis and of the great conflict of oipnion regarding the propriety of most of the methods which experience has proved in the writer's hands to give the best results, he has felt it his duty to present his reasons for his attitude, and if this paper has any influence in establishing procedure of the early removal of the cause of diffuse peritonitis, he will consider his task well worth while.

A CLINICAL STUDY OF ONE HUNDRED AND TWELVE CASES OF MOVABLE KIDNEY.[1]

BY RALPH C. LARRABEE, M.D., BOSTON.

THIS paper is based principally on two hundred and seventy-two patients examined in the Female Medical Out-Patient Department of the Boston City Hospital during a four months' service in 1902. The cases were chosen at random, without reference to symptoms, appearance or other evidences of movable kidney.

The patients were examined bimanually in the dorsal position, and any tumor of the proper size, shape and consistency, which could be pushed back into the normal position of the kidney, was accepted as a movable kidney. A few cases which were doubtful on the first visit were re-examined after a cathartic, but most of the negative cases were examined but once. A few only were examined in the upright position as well as in the dorsal. One or two were rejected

[1] Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital.

entirely because satisfactory examination was impossible.

One or both kidneys could be felt in 112, or 41½% of the 272 cases studied. High as this figure seems, it was exceeded by that of Godard, Danhieux and Werhoogan,[1] who found 46%, while others have estimated that 60 or even 80% of all women have movable kidney. The figure resulting from this study is probably too low rather than too high. It is, of course, possible that a distended gall bladder, a neoplasm or even a mass of feces may have been occasionally mistaken for a movable kidney, but it is not likely that this was the case to such an extent as to seriously impair the results. On the other hand, the negative cases include a number of women so obese that a tumor the size of the kidney could hardly have been felt. Besides, since it was impractical to examine the negative cases repeatedly and in various postures, it is likely that a number of cases were overlooked, for a movable kidney often slips back into position when the patient lies down, and cannot then be felt. In more than one instance the kidney was felt by an assistant, who, in the course of his manipulations, replaced it so that it could not be palpated again until the patient was directed to cough or to stand up. It is surprising how often movable kidney is found if it is looked for, and how often it is overlooked unless especially sought. Therefore figures based on the number of cases diagnosed in a general clinic where especial attention is not being paid to this point are of no significance. While it is probably true that the class of women making up our outpatients is especially susceptible, yet if regularly sought for in patients of the better class the condition will be found so frequently and so regardless of the symptoms for which relief is asked that one becomes very skeptical as to its importance in causing illness and suffering.

The right kidney alone was affected in 98 of the 112 cases. Both kidneys were palpable in 13, the left alone in but one. In this latter case the patient had a tubercular process in the right lung. This is of interest, as the x-ray has shown that in phthisis the excursion of the diaphragm on the affected side is limited to the upper portion of its normal range.[2] It is possible, therefore, that in this case the right kidney did not get pushed down far enough to be felt in inspiration. Where both kidneys were felt the right was the more movable in all but three cases, the left not being the more movable in any.

We may somewhat arbitrarily class the cases according to the degree of mobility as — first, palpable, where the kidney can be felt only in deep inspiration; second, movable, where the organ can be held down during expiration; and third, floating, where the kidney can be pushed freely about. Thirty-nine cases in this series belong to the first class, 49 to the second and 24 to the third. It is a question in how many of the first group the kidney, though palpable, was not abnormally movable. In three of the 39 only the tip of the organ could be felt. In others the whole kidney could be felt, but could not be held down during expiration. In most cases the lower third to two-thirds could be grasped between the examining hands — a degree of mobility that will doubtless be accepted by most as beyond physiological limits.

The frequency at different ages was as follows:

Below 20		21 cases,	of which	17%	had movable	kidney.
20 to 29, inclusive,	92	"	"	45%	"	"
30 to 39 "	65	"	"	52%	"	"
40 to 49 "	40	"	"	43%	"	"
Over 50 "	36	"	"	42%	"	"

This agrees with the results of others in placing the occurrence as being most frequent in young adult life, but there were 5 cases over sixty years of age and one over seventy. It seems probable that, as Wolkow and Delitzin,[3] Mathieu [4] and others state, movable kidney is not rare in old age. The slight decrease in old people may be due to the leaving off of corsets or to the common increase of flesh after the menopause.

Children were not included in this series. In another series, however, of 37 children, 10 boys and 27 girls, systematically examined in the children's room of the Boston Dispensary, there occurred three cases, of which two were very slight or doubtful (one boy and one girl). The third, a girl of seven, had a right kidney which was easily felt, but which did not appear to be causing symptoms. This is in marked contrast to the work of Rosenthal,[5] who was able to feel the kidney in 50% of the girls examined and in 10% of the boys.

But four nationalities were represented in sufficient numbers to justify mention. Of 93 Americans 37% had movable kidney, of 69 Irish 51%, of 41 natives of the British provinces 49% and of 22 Russian Jews 36%.

The conditions of married life do not seem, according to this study, to favor very notably the occurrence of movable kidney, since it was found in 41% of the single women and in 44% of the married and widowed. Notes as to the number of pregnancies were made in 107 of the positive cases, with the following results:

Never pregnant	51
One pregnancy	6
More than one pregnancy	50

It is unfortunate that no record of the number of pregnancies was kept in the negative cases for comparison, as authorities differ so widely on these points. Some, including Senator,[6] state that women who have borne children are especially susceptible, while others, like Hilbert,[7] Kuttner,[8] and Küster,[9] deny any such influence. According to Mathieu,[4] it is commoner in women who have borne children than in those who have not, but commoner in those who have had but one child than in those who have had several. In 36 of the married women here studied, an effort was made to determine the relation of the lesion to the frequency of pregnancy. It was found that 17 of the 36 had been pregnant four or more times at average intervals of less than two years, and that 14 had given birth to six or more children.

The cases here reported show strikingly the effects of emaciation as a causal factor, for 66% of the patients in whom movable kidney was found said that they had lost weight, though such statements were often not supported by objective evidences. The accompanying table, based on the 166 cases in which the notes mentioned the state of bodily nutrition, shows that the condition is much more common in thin people:

Obese	6	had	movable kidney,	27	did not.
Well nourished	34	,,	,,	43	,,
Fairly nourished	19	,,	,,	13	,,
Poorly nourished or emaciated	19	,,	,,	5	,,

The comparative rarity of the condition in the obese may be due in part to the difficulty of feeling the kidney, even though much lower than normal. It will be observed that, although a much greater proportion of the poorly nourished than of the well-nourished showed movable kidney, yet over a half of the positive cases were of the latter class. Indeed, it was striking how many plump, healthy-looking young women possessed movable kidneys.

Trauma was given as probable cause in but one case, the patient dating her symptoms to a fall four years before. She also had a retroverted uterus. In no case was the movable kidney a consequence of surgical operation, all of the six cases showing laparotomy scars being on the negative list. But 4 out of 14 patients who said that they had had operations on the pelvic organs showed movable kidney. Forty-four of the positive cases complained of cough, often slight.

All but nine patients wore corsets or other constrictive articles of clothing. Efforts to classify them according to the kind of corsets or to determine the effects of tight lacing were unsuccessful.

As to the diseases which brought these patients to the hospital, it was noted that conditions accompanied by wasting or impairment of nutrition presented the largest percentage of movable kidney. Fifteen cases of phthisis out of 27 had it; anemia and chlorosis, 12 out of 25; chronic gastric indigestion, 7 out of 12; cancer, 3 out of 5; neurasthenia, 5 out of 11. Movable kidney appeared to explain the symptoms in but 8 of the 112 cases in which it was found. The diagnosis was "enteroptosis" in 8 others. Thus ptosis of the kidney, alone or with other organs, was considered to be the cause of the symptoms complained of in but 14% of the patients presenting the lesion. This agrees closely with the work of Hilbert,[7] according to whom symptoms arise in 15%.

The study of the symptoms is based on all 112 positive cases and on 150 of the negative ones. Taking the symptoms most commonly attributed to movable kidney, we have the following results: First, pain in the back or lumbar region was present in 11 positive and 14 negative cases. Second, abdominal pain in 21 positive and 31 negative cases. Third, throbbing in the abdomen in one positive case (an aneurism) and in one negative case. Fourth, a sensation of a tumor slipping about in the abdomen in 3 positive cases. Fifth, dragging or undefined discomfort in the abdomen in 2 positive cases and in one negative case. Sixth, dyspepsia in 41 positive and 46 negative cases. Seventh, acute crises of severe abdominal pain in 4 positive and 2 negative cases. Eighth, jaundice in one negative case. Ninth, neurasthenia and kindred neurotic conditions in 17 positive and 18 negative cases. Tenth, none of these symptoms in 40 positive and 53 negative cases. The conditions of the bowels are shown in the following table:

Constipation:	Positive cases, 48%; negative cases, 49%.
Diarrhea:	Positive cases, 2%; negative cases, 4%.
Normal bowels:	Positive cases, 50%; negative cases, 47%.

This study, then, does not indicate that any symptom or class of symptoms is particularly characteristic of movable kidney. The only symptom peculiar to positive cases, viz., a sensation of a lump in the abdomen, was too rare to possess much significance. It should be said that these histories were not obtained by asking "leading questions" after the kidney had been discovered; they were merely the symptoms described to the assistants in taking the histories in the usual routine way.

The condition of the abdominal wall was investigated in 57 of the positive cases. It was lax in 14. Separation of the recti muscles was present in 12, and was occasionally so marked that a large mass of intestine and in one case even the artifically distended stomach protruded. It was not always associated with movable kidney, however, being found in 7 of the negative cases, often well-marked. Hernia was noted 21 times in these 57 positive cases. The umbilical was the commonest form — in 17 cases of such a slight degree as to make its classification as a true hernia doubtful. Two were inguinal, both well-marked and right-sided.

The liver extended below the costal border in 30 of the positive cases. In but two of these was the inferior border also lower than normal. None gave the typical picture of "movable liver," with the extreme right border markedly prolapsed and freely movable. The spleen was palpable in 7 of the positive cases. In but one, a case of secondary syphilis, was there anything in the past or present condition of the patient to account for the position of the organ otherwise than as a ptosis of the viscus.

The stomach was investigated with fairly satisfactory results in 50 cases, 36 of which showed no abnormality in the gastric area. The greater curvature was below the umbilicus in 14. In 3 of these the depression of the organ was well marked, while in two, one a cancer of the stomach, there was dilatation. Four out of 6 cases in which the contents were examined chemically showed decrease or absence of hydrochloric acid and two showed normal acidity.

The pelvis was examined in too few instances and the results were too fragmentary to be of great value, vaginal examination being made but 38 times. Eleven of the 18 positive cases

examined had uterine displacements, while they were present in but 6 of the 20 negative cases.

Albuminuria was present in 8 out of 30 of the cases in which movable kidney was present and in but 3 out of 31 in which it was absent. It has been claimed that after palpation in cases of movable kidney some blood will always be found in the urine.[10] Although many of these patients were freely palpated by several examiners, gross hematuria did not result in any known instance. Microscopical examination of the sediment was not made in enough cases to be of any significance. The hemoglobin was estimated in 64 cases by the Tallqvist method, with the following results:

Above 75% in 21 positive cases and 18 negative cases.
Between 50 and 75% in 8 positive cases and 14 negative cases.
Below 50% in 2 positive cases and 1 negative case.

Thus the association of anemia with movable kidney was not a marked feature.

In none of these cases was there any evidence of hydronephrosis, gangrene, malignant disease, severe hemorrhage or other serious complications. Six cases gave histories of periodical attacks of abdominal pain suggesting strangulation or Dietl's crises. Four of the six showed movable kidney. In 3 of these 4 there did not seem to be any reason to think that the kidney was responsible rather than one of the other numerous and more common causes of abdominal colic. One, in fact, was probably appendicitis, one gave a history of "gravel," and one showed evidences of pelvic inflammation. The fourth case had been subject for four years to acute attacks of severe, incapacitating pain, beginning in the right lower abdomen, extending to the hypogastrium and relieved in a few hours by vomiting. The greater curvature of the stomach was two inches below the umbilicus, and hydrochloric acid was reduced. The right kidney was low in the abdomen, freely movable and not fully returnable to its normal position. A swathe gave complete relief for three weeks, after which she was lost sight of. This was the only case in which there was fair reason for attributing the pain to the movable kidney.

Treatment, in the sense of operative or mechanical fixation or support, was considered unnecessary in 87 of the 112 positive cases. Such patients were not informed of the presence of the anomaly. In one case where this was inadvertently done symptoms promptly appeared, the patient complaining at her next visit of "jumping sensations" in the lumbar region. Two women were advised to wear different corsets. Twenty-five were advised to wear swathes. These included some where the symptoms could hardly be attributed to the kidney, the treatment being adopted rather for enteroptosis or to support lax abdominal walls. Either a somewhat elaborate bandage or a simple binder of canton flannel was used. Surgical treatment was not advised in a single instance.

The immediate results can be stated in but five cases. Three of these showed marked improvement, one obtained no relief, and one, a cancer of the stomach, improved temporarily. None of the cases were observed long enough to show the ultimate results.

Some practical inferences, however, may be drawn. If over two-fifths of the women of certain classes have movable kidney one should be very cautious in attributing to such a common anomaly such indefinite symptoms as backache, dyspepsia or neurasthenia — symptoms which, in these cases at least, were as common where no such condition could be demonstrated. When a movable kidney is found it should be borne in mind in treating the case, but unless there is reasonable ground for attributing to it the symptoms complained of, it is best not to use any appliance for its support and not to direct the patient's attention to its existence. The frequency and innocuousness of the lesion, as shown by this and similar studies, would appear to refute the extreme surgical view according to which a movable kidney should be operated on with the object of preventing serious complications. The mortality of the operation, according to Keen,[11] may be as high as 2 or 3%. Of 137 operated cases collected by Watson,[12] there were 5 deaths, 4 of which were not the result of operation. Surely the mortality of movable kidney itself, direct or indirect, is nothing like this. Considering the great frequency of the lesion, complications are rare, especially the more serious ones. Of hydronephrosis and pyonephrosis, but 15 cases were admitted to the surgical wards of the hospital in three years out of a total of 11,435 admissions, including cases arising from all causes.[15] Cancer is too rare to need serious consideration, and its etiological connection with movable kidney is at least doubtful. The acute abdominal crises due to vascular or ureteral obstruction from twists or kinks of the pedicle are rarely fatal. The same may be said of the renal hemorrhages occasionally seen. The cases of the latter condition, collected by Eshner,[13] appear to have been usually independent of renal mobility, and often recovered after operation, even where nothing had been done other than inspection of the organ.

Two women in this series had been previously operated on for movable kidney. In one a nephrorraphy was done, followed, as the organ was not retained in position, by a nephrectomy. Later she was advised to wear a swathe to support the other kidney. She was markedly neurotic, and stated that the symptoms had not been relieved. During the past year she has been in the hospital at least twice, once to be operated on for appendicitis and once for probable peritonitis. The second patient stated that a sinus had persisted for a year after operation, and that the original symptoms were not relieved. As the notes on this case have unfortunately been misplaced, her statements cannot be verified by reference to the original records. A third case seen in the same clinic since the material for this study was collected had been at the Long Island Hospital for floating kidney, major hysteria, kleptomania and retroversion of the uterus.

Both kidneys were sutured through lumbar incisions without marked benefit. Her chief complaint now is pain in the back. She is extremely neurotic and has a well-marked albuminuria. There is severe hyperesthesia of the abdomen and lumbar regions. Neither kidney can be felt. Thus in none of these three cases was the operation, although in all mechanically successful, attended with marked relief of symptoms, and one at least was injured to the extent of being obliged to take care of a sinus for a year.

Nephrorraphy undoubtedly has its place. Where any of the serious complications, such as hydronephrosis or pyonephrosis or severe crises, are present there can be no hesitation. It is justifiable where there are disabling symptoms that cannot be relieved by simpler means, or even where the patient prefers the risk of operation to the discomfort of a bandage. It should be remembered, however, that the temporary use of the bandage may tide a patient over a period of poor health or debility, during which the symptoms have arisen, and that afterwards, when the patient has returned to a normal state of health or has gained flesh, the kidney may cease to cause trouble. In all cases, however, but particularly where the symptoms are predominantly nervous, one should not advise operation unless he can attribute the symptoms with reasonable certainty to the lesion, and in the words of Fischer,[14] "das ist leicht gesagt aber schwer gethan."

DISEASES OF HOUSE OFFICERS IN HOSPITALS.[1]

BY WILLIAM R. P. EMERSON, M.D., BOSTON.

THE appointment of house officers at the Boston City Hospital is made by competitive examination in which physical as well as medical and personal qualifications are considered. The result is a fairly able-bodied set of men of similar habits and training, well suited to show, both in their general condition and in their physical ailments, the comparative effects of severe and confining work on the three main services of the hospital, namely, medical, surgical and pathological.

The records for the past ten years from July 1, 1893, to July 1, 1903, include two years and one month before the present South Department for contagious diseases was established. During this time two months' contagious service in Wards A and E were a part of each house officer's duty, one month as junior and later one month as house physician or as house surgeon.

Until July, 1896, the appointments were for eighteen months, with no vacation. At this time the service was increased to eighteen months and two weeks, thus allowing a vacation of two weeks before the last six months. At this time also the first pathological house officer was appointed, and the service has so continued unchanged, with two men on duty, one as junior for six months and the other as senior for the same time. In 1898 the medical and surgical services were increased to two years.

The work medical is chiefly records, laboratory and the repeated physical examinations of non-infectious (so-called) fever patients. The work surgical is records, surgical dressings, often septic, and operations; the work pathological is with cultures, especially from the contagious department, the examination of pathological tissues and the making of autopsies.

The following table presents a list of the diseases that have occurred during the house services:

TABLE A.

Diseases of House Officers.

July 1, 1893, to July 1, 1895. During this time each house officer served two months in the contagious service. There was no pathological service.

	Medical.	Surgical.
Influenza	3	..
Tonsilitis	1	..
Diphtheria	2	5
Scarlet fever	3	2
Measles	1	..
Typhoid fever	..	1
Gastro-duodenitis	..	2
Acute gastritis	1	..
Appendicitis	1	..
Furunculosis	..	1

Sept. 1, 1895, to July 1, 1903:

	Medical.	Surgical.	Path. From July, 1896.
Phthisis pulmonalis	..	1	2
Pneumonia	1	..	..
Influenza	4	3	..
Tonsilitis	12	8	3
Typhoid fever	..	1	..
Febriculæ	5	..	..
Scarlet fever	1	..	1
Diphtheria	..	1	..
Vaccinia	..	1	..
Gastro-enteritis	2	1	..
Gastro-duodenitis	2	..	..
Acute gastritis	1	..	..
Acute articular rheumatism	1	..	..
Acute otitis media	2	1	..
Furunculosis	1	4	..
Septic hand	..	1	1
Septic thumb	..	2	1
Septic arm	..	2	1
Teno-synovitis	..	2	..
Acute sinusitis (antrum highmore)	..	1	..
Gas poisoning	..	2	..
Appendicitis	1	2	1

The above table does not include a certain

[1] Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital

number of mild cases, not entered on the records, in which house officers were cared for in their own quarters without being off duty.

The first part of the table shows practically no difference, medical and surgical, when both served on the contagious service.

The small number of entries during this time is accounted for by the fact that there were but two men on each service, therefore a man did not go off duty unless actually obliged to do so, as he would thus leave but one man to do the work. Later with three men on duty, to leave the service for a few days would cause injustice neither to the patients nor to his fellow house officers.

The second part of the table shows a greater number of naso-pharyngeal affections and of affections attended by fever on the medical side, and of local septic infections on the two other services. The proportion of naso-pharyngeal affections and of affections attended by fever, medical as compared with surgical, is two to one.

FEBRICULÆ.

These affections have occurred on the medical exclusively, often of not sufficient severity as to require admission to the service. The following record illustrates these cases:

On Oct. 27, 1899, Dr. A. began to have malaise, slight headache and fever. These symptoms continued five days, increasing somewhat in severity. He kept about work until the fifth day, when his temperature was found to be 104. Upon being put to bed and sponge baths given, his temperature dropped to 100. A four-hourly chart was kept and baths given when his temperature was 102.5 or higher. Six baths in all were required. His temperature subsided by lysis, and was normal on the thirteenth day.

During his illness there were no localized symptoms excepting those attending the fever, namely, slight headache, malaise and loss of appetite. The bowels were somewhat constipated. Urine normal. There was no herpes. The Widal test for typhoid fever was made with five negative results. The blood showed nothing abnormal. The highest leucocyte count was 4,300.

In August of the same year Dr. B. was off duty for ten days with similar symptoms and no physical signs. At the same time Dr. B.'s junior was also affected. The two temperatures ran within one-half a degree of each other daily. The highest in each instance was 103, and the course of each fever was eleven days.

In one of these febricular cases the attack was ushered in by a chill of moderate severity; in another there was slight irritation of the throat, but cultures showed no special organism.

All the cases recorded occurred between the months of August and December, the time of the greatest prevalence of typhoid fever.

The successive illnesses of house officers on the same service within eight months' time of pneumonia, cervical adenitis, several attacks of tonsilitis and of febriculæ, suggested as a possible cause the presence of a patent sewer trap in the room occupied by these men successively. The trap was removed, and in the two years following no more cases have occurred.

The repetition of these febricular attacks on the medical side has not been satisfactorily accounted for. Attenuated typhoid fever bacilli as the cause is excluded by the Widal reaction. An infection by a paratyphoid bacillus is a possible supposition. Tests for such organisms should be made in subsequent cases.

It has been suggested that a toxine may be the cause, or some bacterium, as the pneumococcus, in the blood.

TYPHOID FEVER.

It is worthy of note that of the two cases occurring one was in the South Department and the other on the surgical service, while on the medical service, where the wards are nearly filled with such patients during the autumn months, there has been no case of typhoid fever.

TONSILITIS.

This occurred 13 times medical, 8 surgical and 3 pathological. Half of the 24 cases occurred in January, February and March, 4 cases in each of these months. Tonsilitis did not occur more frequently soon after a return from a vacation, nor near the end of a man's service. The organisms, when reported, were streptococci in all cases, usually in practically pure culture after the first or second examinations.

PHTHISIS PULMONALIS.

There is little evidence that primary infection with tubercle bacilli took place after any one of the three men had come to the hospital.

Dr. X. has a stepfather affected with phthisis. He has a history of overwork, and of being under weight before going on duty, where after two months' service in the out-patient department he had pneumonia, and a few tubercle bacilli were found with the diplococci of pneumonia. Later very slight signs were found in one apex. He went to Saranac Lake for one year, and has returned to his service without subsequent symptoms.

Dr. Y. has one sister affected and one brother died of phthisis. He has a history of at least four exacerbations before entering the pathological service, where after nine months' work he had a sudden hemorrhage, and active signs were found in his left apex. He apparently recovered health, went to the Philippines with the army. An exacerbation, with rapid extension of the process, took place. He is now at Saranac Lake.

Dr. Z. had a chronic tubercular process. However, in spite of his known affection, he was admitted to the army, where he died after some years spent in its service.

LOCAL SEPTIC INFECTION.

This occurred almost exclusively on the surgical and pathological services, apparently due

to the condition of the skin rather than to any other cause. Local inflammatory processes such as dermatitis or fissured hands furnished favorable points for the invasion of organisms. In one case a prick from a needle while sewing up a case of general peritonitis caused a local infection and a septic arm. Free incisions were made. Streptococci were found persisting a month later.

In another instance an infection of streptococci occurred in a dermatitis following a sunburn of the arm. The infection was of so severe a character that the house officer was off duty three months.

The use of rubber gloves, both at surgical operations and in handling septic pathological material, has been found to lessen the number of infections. This has been demonstrated most clearly in the pathological laboratory, where hair-follicle infection was almost constant before the use of gloves.

There has been no evidence of an immunity from such infections occurring. With certain organisms, notably the aureus, repeated re-infections have been the rule.

FURUNCULOSIS.

Five cases surgical and one medical. The medical case was a single furuncle with no recurrence. In the four other cases recurrence was frequent for weeks, seriously interfering with work and with the general health.

SOUTH DEPARTMENT.

There have been seventy house officers in the South Department for Contagious Diseases, each serving three months in the diphtheria and three months in scarlet fever wards. A large number of substitutes have served for varying lengths of time.

The contagious cases among house officers from Aug. 31, 1895, to July 1, 1903, were as follows:

TABLE B.

Year.	Diphtheria.	Scarlet Fever.	Measles.	Mumps.	Varicella.
1895 Aug. to Dec. (inclusive)	1	..	..	..	..
1896	2	2	..	..	..
1897	2	..	1	..	..
1898	2	1	..	1	1
1899	4	2	..	1	..
1900	4	1	..	1	..
1901	5	1	..	..	..
1902	6	2	..	..	..
1903	4	1	..	..	..

Other diseases occurring were:

Follicular tonsilitis	5
Cervical adenitis	1
Gastro-enteritis	1
Facial erysipelas	1
Septicemia	1*
Septic finger	2
Nervous exhaustion	1
Influenza	1
Typhoid fever	1*

* Died December, 1901.

There have been no deaths from any contagious disease during this time. One house officer died of septicemia following a streptococcus infection after a burn. One died of typhoid fever after being transferred to the main hospital.

One house officer had measles, mumps and varicella during his six months' service. Three had both diphtheria and scarlet fever, one had diphtheria twice, one had diphtheria and mumps.

Two house officers immunized themselves by injections every month of 1,000 units of antitoxine, one doing this after having diphtheria during the first two months of his service. He had no reinfection. The other did not have diphtheria.

The objection to such immunization is the danger of urticaria or arthralgia following the use of antitoxine; therefore Dr. McCollom has preferred the early use of antitoxine on the first appearance of a sore throat.

Table B shows an increase in the number of diphtheria cases coincident with an increase in the number of house officers appointed in 1899.

The average duration of diphtheria was fifteen days, that of scarlet fever forty-three days.

In 1894, of 12 men, serving four months each in the contagious wards on two successive services, 8 had either diphtheria or scarlet fever. One of the remaining 4 had typhoid fever.

At one time in the South Department of 6 men on service 5 were sick with either diphtheria or scarlet fever.

Five cases of diphtheria occurred in February, 5 in July, 3 each in January, August, October and November, a less number in the remaining months and none in September.

In a contagious service of six months a house officer's chance of having diphtheria is one in two, of having scarlet fever one in seven.

The following comparative table is made from the time-book of the house officers for the past seven years, and includes the South Department:

TABLE C.

Average Number Times Sick per House Officer.

YEAR.	Medical.	Surgical.	Pathological.	Contagious.
1896	.3	.7	1.0	1.5
1897	.3	.7	1.5	1.2
1898	.7	.2	.5	1.5
1899	1.1	.4	1.0	1.5
1900	1.0	.3	1.5	1.3
1901	.7	.8	.5	1.2
1902	.5	.5	.0	1.5

Average Number Days off Duty per House Officer.

YEAR.	Medical.	Surgical.	Pathological.	Contagious.
1896	4.0	7.0	10.0	
1897	2.0	5.0	72.0	
1898	9.0	1.0	45.0	
1899	21.0	4.0	82.0	
1900	18.0	6.0	18.0	
1901	15.0	10.0	1.0	
1902	6.0	12.0	.0	

Average for seven years per house officer, 15.

Average Number Times Sick per House Officer Yearly for Past Seven Years.

Medical.	Surgical.	Pathological.	Contagious.
.7	.5	.8	1.4

Average Number Days Off Duty per House Officer Yearly for Past Seven Years.

Medical.	Surgical.	Pathological.	Contagious.
10.7	6.0	32.0	18.0

This table, although taken from a different source, shows practically the same results as Table A.

A case of phthisis and of septic reinfection on the pathological service explains its proportionately large number of days off duty.

EXERCISE.

Much interest has been shown, both by the visiting staff and by the hospital authorities, that the house officers, who are so much confined to the wards, and who have a large amount of night work to do (except the pathological service), should have means of obtaining proper exercise on the hospital grounds.

However, little has been accomplished of practical value until the year 1899, when two excellent tennis courts were built; and a year later the trustees, aided by generous contributions from the visiting staff, installed two squash tennis courts and equipped them with adequate electric lighting. Shower baths were also supplied. This has offered an excellent opportunity for obtaining sufficient exercise, practically in the open air, with means for a proper bath and rubdown afterwards.

The relation of systematic exercise and the condition of the men at the end of their services in the main hospital, as stated by at least two men of each delegation for the past seven years, is shown by the following statement:

By systematic exercise is meant the obtaining of exercise at least three times a week sufficient in amount to cause free perspiration and followed by a rubdown.

Medical. — Number of men taking systematic exercise, 13. Condition at end of service: good, 12; fair, 1.

Number of men taking occasional or practically no exercise, 29. Condition at end of service: fair, 16; stale, 13.

Surgical. — Number of men taking systematic exercise, 1. Condition at end of service: good.

Number of men taking occasional or practically no exercise, 41. Condition at end of service: good, 6; fair, 12; stale, 23.

Pathological. — Number of men taking systematic exercise, 6. Condition at end of service: good, 6.

Number of men taking occasional or practically no exercise, 2. Condition at end of service, fair.

The other six men were out of doors afternoons and were in fair physical condition.

By " good " is meant general health excellent, weight normal, and fit to repeat service.

By " fair " is meant tired, but able to do his work well.

By " stale " is meant under weight, appetite poor, having nervous disturbances.

Answer to first conditions were: " Felt fine, never better in my life."

Answer to second conditions were: " Pretty tired, but did my work."

Answers to third conditions were: " I was done." " Fagged out." " Didn't get into good condition for months."

Since the establishment of proper means of exercise and baths, of 18 men serving medical, 9 have taken systematic exercise, and their condition at the end of their service was " good." Of the 18 men preceding them only one took systematic exercise, and but 4 reported their condition as " good."

CONCLUSIONS.

The number of cases has been too few and the time too short to warrant any definite conclusions, especially as regards pathological house officers. The records of medical and surgical services, 60 men each, and contagious, 70 men, would indicate that the danger of house officers having pneumonia, phthisis or typhoid fever is very small, one only of these cases occurring medical, and then in an individual of low resistance.

That naso-pharyngeal and febricular affections occur medical in the ratio of 12 to 1 either surgical or pathological.

That local septic infection is the most frequent disease surgical and pathological.

That the danger of infection in the examination of moist cultures and sputum is very slight, as evidenced by no infection occurring in the staining of thousands of smears for the Klebs-Loeffler and tubercle bacillus and the making of the Widal test with the pure culture of typhoid bacilli.

That there is little evidence in the ten years' records that a house officer's general condition is a marked factor in the question of infection by a contagious disease.

That in a six months' service the chance of diphtheritic infection, including mild cases, is one in two, of scarlet fever infection one in seven.

As regards the influence of improved living quarters and facilities for proper exercise upon the health of house officers, Table C shows a marked decrease in the average times sick yearly per house officer medical, where 50% of the men have taken systematic exercise, from 1.1 in 1899, the year following the increase of service to two years, to .5 in 1902, and in the days off duty for sickness from 21 to 6. The decrease is more marked pathological. On the surgical service, where there has been practically no systematic exercise, the averages are nearly the same.

The generally improved physical condition of house officers is a matter of comment.

It should be urged upon house officers that the sense of fatigue occurs most often in the hospital as the result of nervous tension and indoor

air rather than of muscular exhaustion, and is therefore relieved by proper exercise and baths and the reasons offered for insufficient time for systematic exercise are plausible rather than real.

UNCLEAN MILK, BOVINE TUBERCULOSIS AND THE TUBERCULIN TEST — THEIR RELATION TO THE PUBLIC HEALTH.*

BY E. B. LARNED, M.D., CHICAGO, ILL.,

Professor of Physiology and Physiological Chemistry, Dearborn Medical College.

(Concluded from No. 21, p. 567.)

FROM the drop of milk remaining in the tube after the inoculations were made, direct smears upon cover slips were prepared which showed, upon examination under moderately high power, many germs, both micrococci and bacilli. Although careful search for tubercle bacilli was made in every sample of milk examined, they were found in very few cases only. Right here, it may be well to remark that, contrary to the books, it is no easy matter to demonstrate tubercle bacilli in milk even when we are well satisfied that the milk is infected. Gehrman has reported that thorough search failed to reveal the germs in milk from cows of the herd belonging to the Hospital for Insane at Kankakee, Ill., proven to be tubercular and where culture experiments were successful in cultivating the germs from the milk samples. When I state that all of my samples were taken from popular dairies which supply a large clientele, I think that you will agree that such milk is unfit for food. Bacteria are always present in milk unless it is drawn from the udder under sterile precautions, and milk can be contaminated in various ways, viz., from the udder direct, by the hands of the milker, dirty vessels, hay dust or by the water which is sometimes added by the thrifty milkman. "The transplantation of diseases to new fields is characterized by their aggravation. Microbes, like other vegetables, grow best in virgin soil." From contamination with diseased matters, from affected persons and premises, milk may be the means of carrying and spreading many of the most destructive diseases of man and domesticated animals, such as diphtheria, typhoid, scarlatina, cholera, anthrax, foot and mouth disease, glanders and tuberculosis, and the published results of several investigations have shown that the recognized dangers attending the consumption of raw milk exist in butter and cheese. Bovine tuberculosis is communicable to horses, cattle, sheep, swine, dogs, cats, guinea pigs and rabbits. That the diseases above mentioned may be communicated from lower animals to man and from men to lower animals has been conclusively demonstrated so many times that the bare statement of the fact seems almost superfluous, but there are those, whose statements have weight in some quarters, who will still deny these statements. While, as it seems to me, nothing has been more clearly shown than the practical identity of human and bovine tuberculosis, the infectiousness of milk from tubercular cows, and the efficacy of the tuberculin test as a diagnostic agent, it has remained for Koch [39] to deny the existence of proofs of the infectiousness to humans of milk from tubercular cows, and the infectiousness of human sputum to cattle, etc.

Arrayed against such reactionary statements as this, is the immense amount of published matter from careful, painstaking scientists filling the medical press and accessible to every one — examples of which are incorporated into this article. The science of our forefathers was founded upon empiricism — upon experience alone — and the argument from which there was no appeal, was, "I find, from experience." Then came a new era, wherein science was based upon the laws of chemistry and the demonstrations of physiology. Vague and uncertain methods were changed to clear and positive knowledge and the argument of experience was overthrown by the evidence of the microscope and the test tube. Cipollina [40] reports that a monkey fed with bovine tubercle bacilli cultures contracted tuberculosis with no primary lesions apparent in the gastro-intestinal tract. On the other hand, inoculation of a calf with human bacilli resulted negatively. Although these tests are so limited, yet he thinks that they suggest that Koch's assertions in regard to bovine and human tuberculosis have led to researches which have established that the bovine bacillus is more virulent for both man and animals than the human tubercle bacillus. So in this case, we know that bovine tuberculosis can be transmitted to other animals and vice versa, by the facts produced by the laboratory work of many observers.

The committee on Animal Diseases of the American Public Health Association which met in Buffalo, N. Y., in 1901, presented a report, "The Relation of Bovine Tuberculosis to the Public Health," which was clearly opposed to Koch's principal assertion that the case was not proven and cites [41] twelve cases of human infection with bovine tuberculosis. Many experiments are now in progress in various parts of the world which will bring additional evidence to bear upon the question. In this connection it is reassuring to find that the British Congress on Tuberculosis not only did not accept the doctrine, but declared that "medical officers of health should continue to use all the powers at their disposal and relax no effort to prevent the spread of tuberculosis by milk and meats." In this conclusion I most emphatically concur. As long ago as 1877, before the bacillus of tuberculosis was described, Birch-Hirschfeld called attention to raw cow's milk giving rise to diseases in children corresponding to certain forms of scrofula.[42] In the *British Medical Journal* Rowland has called attention to milk, butter and cheese as carriers of typhoid fever and cholera. Steyer and Konel [43] have reported several cases of typhoid fever which were traced to

* Read at annual meeting of the Illinois State Medical Society, Chicago, Ill., May 1, 1903.

butter as a source. It has been repeatedly shown that when the bacilli of hog cholera are placed in sweet milk they will appear in butter and buttermilk in numbers large enough to destroy experiment animals when inoculated with a very small portion of either. It has also been shown many times that when certain bacteria have made their way into milk or butter they remain alive and virulent for a considerable length of time.

Lafar [44] found tubercle bacilli alive and virulent after they had been in butter one hundred and twenty days. Laser [45] found tubercle bacilli, cholera and typhoid germs in a like condition after a week's stay in butter. Moore and Dawson [46] showed that tubercle bacilli remained virulent in butter for more than ninety days and a guinea pig inoculated with a piece of butter the size of a pea died of tuberculosis ninety-seven days after its infection. Although the number of reported cases of acute infectious diseases in which the contagion was introduced through *butter* is not large, it is enough to show the possibilities, and in view of this evidence, a careful inquiry into the character and management of milk used for this common article of food is of vital importance, and by sterilizing milk in the dairies and creameries one of the channels of infection would be closed.

Ostertag [47] has shown that there is much tuberculosis among swine in certain parts of Germany where they are fed upon material from the creameries. And in certain parts of this country the more enterprising breeders refuse to feed their cattle upon the skimmed milk of the creameries and the slime of the separators unless it has been sterilized by heat. Huesinger has reported anthrax in man produced by drinking the milk of a cow affected by this disease. Nocard has found anthrax bacilli in the udder of a cow examined immediately after death. Klein has stated that in milk cows afflicted with diphtheria the lesions are sometimes located in the milk ducts and then the bacilli are carried directly into the milk. West [48] reported that two children of a man named Bridges died of tuberculosis due to drinking the milk of a cow which was found, when killed, to be the subject of extensive udder tuberculosis. Five more of the Bridges children were suffering from pulmonary tuberculosis. The Royal Commission on Tuberculosis [48] reported experiments in which swine, guinea pigs and rabbits were fed upon uncooked milk and that tuberculosis was thus caused in a very large per cent of the subjects used. Investigations reported from Massachusetts [49] show that milk from tubercular cows may contain the germs of disease even when there is *no* lesion of the udder.

Taylor observed [50] several cases of scarlatina which occurred in the home of a milkman whose wife milked the cows — the milk being supplied to twelve families in the city. In six of these families cases of scarlatina occurred in rapid succession at a time when the disease was not epidemic and without any communication having taken place between those that became infected and the person who brought the milk. Sternberg [51] says that a common mode of tubercular infection, especially in children, is probably by way of the intestinal glands from the indigestion of milk from tubercular cattle, and that such infection will occur has been proven by experimentation upon the lower animals. Von Hessling has published observations concerning the development of moulds in milk which showed that the milk could be so permeated with the germs as to poison the hot coffee to which it was added in small quantities. Wende [52] reports the occurrence of fifty-six cases of scarlatina in children of twenty-seven families upon the route of one milk dealer two of whose family were suffering from the fever. Eyre [53] reports an examination of milk in an epidemic of diphtheria among the inmates of a large school receiving its milk supply from one source and shows that the typical diphtheria germs were found in the milk. Kauthack and Sloden [54] reported a series of observations of the milk from sixteen dairies wherein the milk from nine caused tuberculosis in guinea pigs inoculated with it. Hertwig and Jacob,[55] Bollinger [56] and Schneider [57] have all demonstrated the infectiousness of milk from cows suffering from the foot and mouth disease (Aphthæ epizootica), in a series of experiments upon themselves and others. Dinwiddie,[58] in reporting a long series of experiments as to the relative virulence of human and bovine tuberculosis, finds that, for cattle, bovine tuberculosis seems to be more virulent. For pigs there seems to be no difference, both producing infection. Sheep were highly susceptible to infection from human tuberculosis and the disease was similar to the naturally acquired tuberculosis of cattle. Still,[59] reporting 769 autopsies of children, stated that intestinal tuberculosis existed in 52% of the cases he examined and that 71% of the tubercular cases were under the age of four years and that 43% of the 71% were in children younger than two years of age, the primary lesion in every case being in the digestive tract. Nicolas and Lesieur [60] reported the results they obtained by causing young fish to eat sputum known to contain tubercle bacilli. After seven months the fish were killed and bacilli found in every organ of their bodies. The muscular portions were fed to guinea pigs and in the nodules and abscesses which formed in the bodies of the pigs the tubercle bacilli were readily demonstrated. Brush [61] stated that the annual loss in New York due to deaths from tuberculosis exceeded the whole cost of the government. In this matter of tuberculosis being contracted by human beings from infected milk, I may say that the whole subject of tuberculosis is of such propertions and the menace to public health from this fearful disease of such magnitude that I doubt if more than a few of us realize the actual conditions as they now exist.

That tuberculosis is not decreasing can be readily seen from the following quotations from

the mortality statistics of the Chicago Department of Health.[62] Of the total mortality in 1851 4½% was due to pulmonary tuberculosis, and in 1896 it had risen to 10%, or more than twice as many. The death-rate per 1,000 has increased from 12 in 1851 to 14¼ in 1896. The total number of deaths from tuberculosis of all kinds in 1879 was 977 and had increased to 2,667 in 1896. Of course, during this period the population had increased very rapidly, but the annual death-rate from tuberculosis had also increased from 11.34% of the total mortality to 11.46 of total mortality — and again, while the annual death rate from all causes had dropped from 17.52 per 1,000 of population in 1879 to 14.36 in 1896, the mortality rate of tuberculosis in all forms had actually increased as above shown. The general verdict of the Tuberculosis Congress at Berlin[63] is that "tuberculosis is not hereditary; that the remedy lies in prevention more than cure; and the more healthy the surroundings the more rare the disease." The movement inaugurated by the Congress of Berlin has been carried on by many American cities, and recently, in Chicago, was founded the Illinois Society for the Prevention of Tuberculosis.[64] The fight will not be directly against the bacillus of tuberculosis but the physical conditions of the race. Improvement in sanitary arrangements — relief from overcrowding, and abundant and pure water supply for cattle and swine as well as man, will do more to eliminate this dread disease than tons of antiseptics and serums. In the early stages of tuberculosis of cattle the symptoms are not always plain. A short, dry cough is present and sometimes very noticeable after active exertion. The animal becomes poor, the coat rough, and the eyes sunken. Sometimes tenderness and pain are evinced when the side of the chest is touched and the normal sound of the lungs is changed. In cows, nymphomania frequently accompanies tuberculosis. Medical treatment is useless; the diseased animal should be slaughtered and the stables thoroughly cleansed and disinfected.

Grange[65] states that he has met many cases which have convinced him most emphatically that tuberculosis can invade an animal most extensively and yet the disease cannot be diagnosed by physical examination. He mentions this to impress the value and importance of tuberculin as a test. The description of this remarkable substance was first given to the public about ten years ago, at which time it was thought to be a curative agent for tuberculosis. It did not, however, do what was expected and was abandoned as a cure. Tuberculin is now recognized by competent critics the world over as the most safe, reliable, and practical mode of diagnosing tuberculosis in early and late stages which is in possession of mankind.[66] The application of the tuberculin test has proved so accurate in diagnosing the disease that the United States Veterinary Association in September, 1896,[66] adopted, among others, the following resolutions:

(1) Tuberculosis in cattle and man is identical. (2) Germs of tuberculosis appear in the milk of tubercular cows. (3) Tuberculin furnishes incomparably the best means of recognizing tuberculosis in living animals, and *properly* administered, is harmless to healthy animals and is exceedingly accurate. A series of tests were made in Berlin[67] to ascertain whether, in the absence of symptoms or any external sign, tuberculin could be trusted. The result proved that it was accurate even in animals seemingly perfectly sound. It has been objected that tuberculin decreased the flow of milk in the animals treated, but any temporary decrease is offset by a compensatory increase, and in most cases there is no change.[68]

Tuberculin is a solution in glycerine and water of the products of the growth of the tubercle bacilli upon artificial media and the contents of their cells.[69] The fluid upon which the bacilli are allowed to grow is an extract made with distilled water from perfectly fresh meat. One pound of meat is used to a liter of water, to which is added 1% of peptone, ¼ of 1% of salt and 7% of glycerine. This solution is heated to boiling, filtered and placed in sterilized flasks and subjected to fractional sterilization. The inoculation of the media is accomplished by taking up on the end of a platinum wire a small mass of tubercle bacilli growing on agar and obtained originally from an animal that has died of tuberculosis, and transferring it to the sterile flasks and causing it to float on the surface of the liquid. The inoculated flasks are then placed in the incubator and kept at a constant temperature of about 98° F. After about a week or ten days the growth can be seen spreading in all directions and finally the surface of the liquid will be covered with a layer of tubercle bacilli. When this is noted the flasks are carefully shaken so as to cause most of the growth upon the surface to sink to the bottom of the flask. From a small particle left upon the surface a new growth is developed which should be shaken down as the first was and a third growth allowed to form. This process requires six weeks to two months or more and the contents of the flasks are then in condition for the preparation of the tuberculin. When the cultures have grown sufficiently the flasks and their contents are taken from the incubator and at once placed in the sterilizing oven and kept at a temperature of 125° C. until they begin to boil. In this way the germs are killed and the material may then be filtered without any danger to the workers. After the sterilization, the contents of the flasks are once more boiled and filtered. This filtrate is then evaporated and concentrated to any desired volume, as a rule ½ of the original quantity. Instead of sending out this concentrated tuberculin, it is diluted to such a strength that 2 cc. is a suitable dose for an animal of 1,000 pounds weight; and to accomplish this, there is added to the concentrated solution glycerine equal to 25% of the original culture liquid — this is then diluted with ¼ of 1% carbolic acid so that the

volume of the tuberculin is usually equal to one fourth more than the original quantity. In practice, it has been found that healthy animals do not give reactions with large doses of tuberculin and that tubercular cattle do not show a higher reaction with large doses than with small doses of tuberculin. As will be readily seen from this description of the manner of preparing tuberculin, there is not the slightest possible danger of infecting animals or men with tuberculosis by the use of tuberculin. Again, there is no danger of injuring healthy animals even with quite large doses of tuberculin, as it is apparently very readily eliminated in the faeces and urine. When the tuberculin is to be used upon dairy cattle, a test of the same herd should be made at least once every six months.[68] The regulations prescribed by the Bureau of Animal Industry for the use of tuberculin in testing cattle are as follows: [71]

"To those who have large herds or lack time this shortened course is recommended:

(1) Begin to take the temperature at 8 A.M. and continue every two hours until 10 P.M. (2) Make the injection at 10 P.M. (3) Take the temperature next morning at 6 or 8 o'clock and every two hours thereafter until 6 or 8 P.M. (4) Each adult animal should receive 2 c.c. of the tuberculin as it is sent from the laboratory. Yearlings and two-year-olds should receive 1 to 1½ cc. according to size. Bulls and very large animals may receive 3 cc."

The injection is made beneath the skin of the neck or shoulders and, to guard against complaint and to eliminate possible sources of error, the hair should be closely clipped from the site of the injection and the skin scrubbed with hot water and soap and a 5% alcoholic solution of carbolic acid before the injection is made. The animal should not be turned out, but fed and watered in the stable and the time of watering and feeding noted. There is usually no marked swelling at the seat of injection, but there is, now and then, uneasiness, trembling and the passage of softened dung. There may be also slight acceleration of the pulse and of the breathing. If the animal is diseased, from six to eight hours after the injection is made the temperature begins to rise from the normal, which in cattle varies from 101° to 102° F., and should continue to rise until 105° to 107° has been reached. A rise of 2° above the normal is to be regarded as good evidence that the animal is tubercular and for any rise less than this, a repetition of the injection after three to six weeks is highly desirable. Dairy herds once found free from disease should not be herded with new animals that have not been tested and found sound.

In conclusion, it would seem that the administration of tuberculin should always be conducted under experienced direction. It is an invaluable test, and by its use it is certainly possible to reduce very materially tuberculosis among cattle and, maybe, to eventually exterminate it. So, let us insist that the public be provided with pure, healthful milk of the same high standard of quality, cleanliness and uniformity demanded by discriminating people in other food products.

In closing, I desire to acknowledge the assistance rendered by the references in the appended list and from which I have liberally quoted.

New Instrument.

A TABLE FOR OPERATIONS UPON THE KIDNEY THROUGH THE LUMBAR INCISION.[1]

BY JOHN H. CUNNINGHAM, JR., M.D., BOSTON.

To reach the kidney through the lumbar incision, the patient is placed on one side and canted slightly forward so as to expose the region to be attacked.

Two forces will aid the operator in exposing and delivering the kidney into the loin. The first, and perhaps the most important, is a force directed toward increasing the space between the crest of the ilium and the lower border of the ribs. The second is a force applied from in front at the proper height and level to exert pressure upon the anterior surface of the kidney, and carry it backward and upward against the field of operation.

These two forces are important in kidney operations through the lumbar incision because of the anatomical situation of the organs. In brief, the kidneys are situated in the posterior part of the abdomen, imbedded in areolar tissue. They are post-peritoneal, not firmly fixed, but held in position by the peritoneum, areolar tissue, perirenal fascia and the renal vessels. They lie on a level with the bodies of the last dorsal and first two or three lumbar vertebræ, the right a little lower than the left.

[1] Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital.

From a posterior aspect, the kidneys are under cover of the eleventh and twelfth ribs and the lower border of the diaphragm. About one-fifth of the left and a little more of the right kidney extends below the twelfth rib and the lower border of the ligamentum arcuatum internum of the diaphragm, as it stretches across from the last rib to the transverse processes of the first and second lumbar vertebræ.

Thus a *direct* avenue to the kidney, without cutting away parts of the last two ribs, or without the risk of opening the pleural cavity, is impossible.

The kidney must therefore be attacked through the space between the lower border of the ribs and ligamentum arcuatum internum and the crest of the ilium.

The width of this space is about two fingers' breadth in the male and a little more in the female. Normally, about the lower fifth of the kidney occupies the upper part of this space, but when the organ is freely movable or enlarged it may occupy a greater area.

To increase the width of this space, the patient is usually placed on one side over sandbags or an Edebohl air cushion. Either of these, being placed just above the crest of the ilium, acts as a fulcrum, partially uncovering the kidney and widening the space by lifting the lower border of the ribs upward.

The position, however, is an unsteady one, and usually requires two assistants other than those engaged in the operation.

With the patient in the desired position there is a tendency for the kidney in question to fall forward and toward a median line. Therefore the second force must be applied, that is, pressure from in front on the anterior surface of the kidney, so that the organ is forced upward and backward against the field of operation.

The objections to doing kidney operations upon the Edebohl air cushion or upon sandbags are that too much help is required to maintain the position; that the force exerted upon the anterior surface of the kidney must be manual, and is, therefore, often misdirected and seldom constant; that the full limits of the space are seldom attained, and that the increased number of assistants required to maintain the position multiplies the opportunities for faulty asepsis.

With the view of avoiding the objections to which the methods at present in use are open, as stated above, the writer has devised a table to hold the patient in the desired position and at the same time exert the two necessary forces, thereby doing away with assistants other than those directly connected with the operation.

The table is practically a double inclined plane. It consist of an upright base, 10 inches high by 20 inches wide, and is 2½ inches thick except at the top, where it is a little less, as the edges are rounded. On top of the upright there are two series of three holes, each series 2, 3 and 5 inches respectively from either end. (A, Fig. 1.)

The holes are bored at an angle of 30° and are 3 inches deep by 1¼ inches wide, and into any one of these may be fitted a stake of wood, which rises 7 inches above the surface. (B, Fig. 1.)

There are two inclines, which are fastened to either side of the upright by hooks and rings at a distance of either 3 or 5 inches from the top.

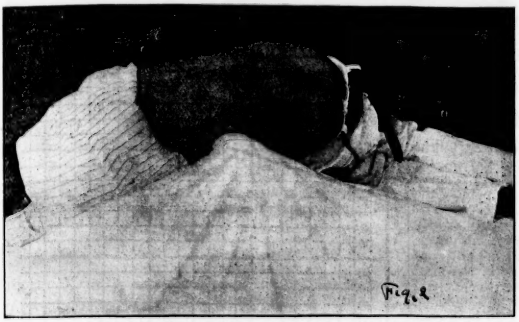
(C, Fig. 1.) The larger incline is 25 inches long by 20 inches wide, and the smaller 18 inches long by 20 inches wide.

The apparatus may be put on any table.

The stake is placed in one of the holes of either series, according to the side to be operated upon. Unless the patient be corpulent it is best placed in one of the holes nearest the center.

In the majority of cases the inclines should be fastened to the upper rings; but there are occasional cases where the patient is so large that the inclines must be suspended from the lower rings in order to open the space to its full extent.

One folded sheet placed on the upright and another partially opened and made to extend from the upright over the stake and inclines will be sufficient padding.



Having arranged the stake, inclines and padding, the patient is placed upon the table so that the upright is just above the iliac crest and the abdomen snug against the stake. That the upright be just above the iliac crest and the patient close against the stake is all-important, because in this lies the success of obtaining the action of the two forces before mentioned.

The legs, which are on the long incline, should be flexed. This forces the patient still more firmly against the stake, increasing the pressure upon the kidney, and forcing it upward and backward against the field of operation. It also makes the position steadier. (Figs. 2 and 3.)

If the patient is properly placed upon the table, the space is opened to its full extent, and the tissues in the field of operation are on the stretch.

After the incision is carried down to the perirenal fascia the kidney and its surrounding tissue tend to bulge into the wound, and the excursion

of the organ is found considerably lessened. After the perirenal fascia is opened, a movable kidney without adhesions is forced out of the wound on to the loin with no other aid than the weight of the patient's body against the stake.

If, as occasionally occurs, the organ is adherent to the surrounding parts, it does not present outside the wound without aid; but is, however, more easily delivered on to the loin because of the properly directed force from in front.

There is no tendency for the kidney to fall back into the wound after being once delivered unless the patient be rolled away from the stake, when it will quickly disappear deep below the surface. It will reappear, however, by allowing the patient to fall back upon the stake.

In most lumbar renal operations it is very desirable to be able to deliver the kidney through the outer wound and to keep it on the loin during some, at least, of the succeeding steps. The present device facilitates inspection and palpation, economizes assistance and simplifies what is at best a somewhat difficult operation.

No post-operative discomfort or lameness of the part has been observed in the limited number of cases in which the table has been employed.

The table affords certain minor points of advantage. In operations upon both kidneys, as, for example, double decapsulation, the patient may be placed face downward with the front of the abdomen resting upon the upright, so padded as to open the lumbar spaces of both sides and force the kidneys back equally well, if not better, than sandbags or the Edebohl air cushion. Also, it does not sink into the whole upper part of the abdomen and press upon the diaphragm as does these other two means. Thus the excursion of the diaphragm is not interfered with and the patient's breathing is therefore more easy.

In gall-bladder operations, and also in laminectomy, the table may prove of considerable service; in the former by affording a means of getting under the ribs, and in the latter by maintaining a firm position and making more prominent the area to be attacked.

Clinical Department.

A CASE OF POST-TYPHOIDAL MYOSITIS OF THE RECTUS ABDOMINIS.[1]

BY DAVID D. SCANNELL, M.D., BOSTON,

Third Assistant Visiting Surgeon, Boston City Hospital; Assistant in Anatomy, Harvard University.

THIS case, which is reported through the courtesy of Drs. M. F. Gavin and J. B. Blake of the Boston City Hospital, is, so far as I can discover, unique in the records of the subject up to the present time. It is unquestionably worthy of being placed on record, not so much, perhaps, for its singularity as for its importance in making one more addition to the already large list of differential possibilities in abdominal diagnosis.

REPORT OF THE CASE.

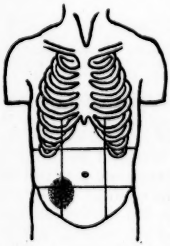
D. C., male, aged nine, Italian, entered the Boston City Hospital May 20, 1901, and was assigned to the medical side with a diagnosis of typhoid fever. (Inasmuch as the main interest of the case lies in its surgical aspect, the medical history will be only briefly considered.)

There was an indefinite history of headache, malaise, loss of appetite, abdominal pain and slight diarrhea for nine days prior to entrance. On physical examination the diagnosis of typhoid fever was readily made, the positive Widal and low white count confirming the clinical opinion. The patient was thought to be entering on the second week of the disease.

The boy's illness was a severe one, being attended in the first week of his stay in the hospital by seven hemorrhages, all of moderate severity. Nine days after entrance there appeared an eruption on his abdomen, legs and but-

[1] Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital.

tocks, passing through the stages of papules, vesicles, pustules and crusts, and occurring in crops. Diagnosis of varicella was made.



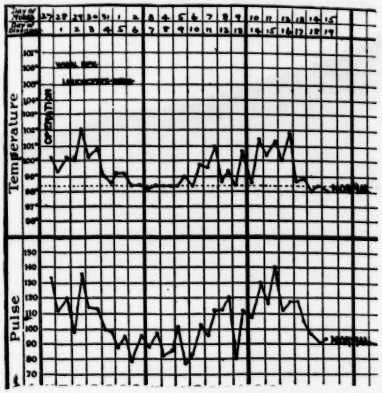
Twenty-seven days from the time of admission another complication in the form of furunculosis occurred, appearing mainly on the anterior abdominal wall, upper thighs and buttocks. Cultures from these showed staphylococcus pyogenes aureus and streptococcus pyogenes; no bacillus typhosus.

Twelve days later there developed a right ischio-rectal inflammation with considerable induration, for which the patient was transferred to the surgical side. Five days later an incision was made and a small amount of pus evacuated. Culture showed mixed infection; no bacillus typhosus. The local inflammation rapidly subsided, and, on July 22, a little over two months from the time of entrance, the boy was discharged well.

Five days later the patient was brought back to the hospital, his interval history having been as follows: On the day after discharge profuse diarrhea, with a small amount of blood in the stools; slight general pain in the abdomen, most marked in umbilical and hypogastric regions; on the day following, several chills and slightly increased hypogastric and right iliac pain; no fever, nausea or vomiting. From this time until his entrance to the hospital there was a steady increase in the local pain; occasional chills and constant fever; occasional nausea and vomiting; slight constipation. It should be noted that during this entire time the boy had been confined to bed; there was no account of heavy straining or sudden forcible movements such as might come from unusual exercise.

Physical examination on entrance: Temperature, 100.2°, pulse, 134 (fair volume and tension); boy looked sick and anxious; tongue coated; dorsal decubitus with thighs flexed on abdomen; chest negative; front of chest and abdomen presented many small crusted areas from previous furuncles.

Abdomen slightly distended; involuntary spasm more or less general but especially marked in lower right abdomen and hypogastrium; tympanitic except in this same area, where it was dull to percussion. Exact palpation because of the spasm and excessive tenderness was impossible, but there was to be felt, notwithstanding, a fairly definite mass occupying area figured in diagram. Movements of the diaphragm and extension of the thighs caused increased local pain. In some respects the sensation on palpating suggested a full bladder, somewhat deviated to the right. No rectal examination was made.



During the making of the physical examination the patient vomited several times; vomitus not significant. Widal negative; urine normal.

Entrance treatment (in the form of a high turpentine enema) effected no change in the abdominal condition, nor in the subjective symptoms of the patient. The diagnosis of acute perforative appendicitis, with abscess formation, seemed a reasonable one, and, in view of the boy's apparently septic condition, immediate operative interference was decided on.

Under ether, with the abdominal muscles relaxed, the question of a full bladder again strongly suggested itself; catheterization resulted in nothing; muscle-splitting incision by Dr. Blake over McBurney's point. The peritoneum showed no injection and the appendix was found to be normal. Exploration of the intra-abdominal surface of the anterior belly wall revealed an ovoidal, indurated, non-fluctuant, extra-peritoneal thickening of the right rectus muscle in its lower third, extending from just below the umbilicus to just above the symphysis pubis. The upper limit of induration was fairly sharply defined by the semilunar fold of Douglas. In the immediate neighborhood of this swelling of the rectus there was apparently a slight involvement of the transversalis and internal oblique muscles. The appendix was removed and the wound closed with layer sutures. No steps were taken at the time to make a second incision into the indurated mass for the purpose of making a histological and bacteriological examination. It is a source of regret that this was not done.

July 29 (second day after operation). No improvement in any respect, the abdominal condition remaining as at time of entrance. Reference to the chart is of interest.

Aug. 2 (sixth day). Operation wound healing perfectly. Despite the drop in pulse and temperature, the spasm, induration and tenderness still persist in lower right abdomen.

Aug. 6 (tenth day). Induration slightly diminished; spasm and tenderness unchanged, however; general condition excellent; wound firmly healed.

Aug. 9 to 12 inclusive (thirteenth to sixteenth day). During this period almost a complete duplication of the clinical picture as presented at the time of admission: acute abdominal pain, involuntary spasm, dullness to percussion and palpable mass in right lower quadrant. There is no obvious cause elsewhere in the patient for the marked rise in temperature and pulse.

From this time on there was a progressive diminution in the parietal induration, until finally by August 20 (twenty-four days after the operation) it had completely disappeared; there was a coincident disappearance of symptoms; on August 23 (twenty-seventh day) the boy was discharged well and has remained so since.

Myositis as a complication or sequela of typhoid fever is a fairly well recognized condition, although its occurrence must be regarded as rare. Reference to the various works on the practice of medicine and surgery throws almost no light on the subject, the great majority omitting even its mention, and the few giving it only a passing comment. Investigation of miscellaneous literature shows an entire absence of recorded cases of involvement of the rectus abdominis. As a fair index of the rarity of post-typhoidal myositis, it is of interest to note that Osler,[3] in a relatively recent compilation of a large number of cases of typhoid fever (829 in all), mentions the occurrence of the condition either as a complication or a sequela only once; in this instance the calf muscles were affected. This must be taken to represent a fairly universal medical experience.

[3] Johns Hopkins Hospital Reports: Studies in Typhoid Fever Nos. I, II, III.

Correlatively with this carefully observed series of cases, we have the extensive surgical observations of Keen,[3] who in over 900 carefully annotated cases has not found the condition occurring once. It would be difficult to find two more significant series, representing in combination nearly 1,800 cases of typhoidal infection.

The report of this particular case does not require any incidental consideration of post-typhoidal lesions occurring by predilection in the rectus abdominis, such as, for example, waxy or granular degenerative changes or hematoma, a condition not uncommon and usually preceded by some form of degeneration.

Reports of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-Ninth Annual Meeting, Held at Washington, D. C., May 12, 13 and 14, 1903.

(Concluded from No. 19, p. 521.)

Second Day, Wednesday, May 13.

CENTRAL NEUROFIBROMATOSIS.

This was a contribution to the study of tumors of the medullo-ponto-cerebellar angle, by Drs. J. Fraenkel and J. R. Hunt of New York. Five cases were reported at length, showing a common origin of the tumor from cranial nerve trunks. The writers concluded that the pathological structure of the growths is of a kindred nature — neurofibromatosis pure, or in various stages of metamorphosis and transformation. The locality is almost identical — the angle formed by the junction of pons medulla and cerebellum. Their symptomatology, because of this localization, is in the essential features analogous.

The certainty of localization, the essentially benign nature of the growths, their loose attachment to the meninges and nerve trunks, distinguish this group of intra-cranial tumors as a most favorable one for surgical intervention.

In view of all this, they find justification for the suggestion to assign a separate place to this syndrome in the group of intra-cranial tumors. The susceptibility of the cranial nerves to neurofibromatosis varies considerably. With the exception of the olfactory and optic, because of genetic peculiarities, any of the cranial nerves may be the seat of neurofibromata.

In general, the sensory nerves are more susceptible and the acoustic pre-eminently so. Primary tumors of the cerebellum or brain stem will often at some stage of the disease simulate closely the syndrome in question. Indeed many of the cases of this type are recorded in literature as cerebellar tumors, pontine tumors, etc.

From a differential diagnostic standpoint particular stress was laid on the appearance of cranial nerve symptoms before the development of symptoms of intra-cranial pressure. Tinnitus, progressive deafness, facial tics, neuralgias and other symptoms referable to the fifth nerve were mentioned as instances in point.

Dr. Mills said he had several similar cases. In two or three instances he had seen operations done for tumors in this locality which were unsuccessful. He thought it was possible to have a growth of a different nature from that described, though the symptoms might be very similar. A very important feature was that the early symptoms were neural.

Dr. Sachs agreed with Dr. Mills and referred to a case of sarcoma of the cerebellum in the ponto-cerebellar angle that he reported several years ago. In tumors occurring in this region, most of the symptoms are unquestionably due to pressure upon the cerebellum. He considered the operation for the removal of growths located in this special angle a very serious one. The angle is barely accessible without serious impairment of important functions.

Dr. Langdon spoke of a case bearing on the question of diagnosis between neurofibroma and sarcoma. Deafness was the only prominent symptom for several years. The subsequent history indicated a slowly developing growth occupying the medullo-ponto-cerebellar angle. There was complete deafness with slight facial sensory and motor symptoms. A year before death, fourth, fifth and sixth nerve symptoms were well developed. At the autopsy eight small tumors were found, some in the pia, but most of them in the dura. He thought the long duration of the symptoms (seven years) might furnish a point in the differential diagnosis between a sarcomatous growth and neurofibromatosis.

Dr. Patrick said it was extremely difficult to determine the nature of the growth from the symptoms.

PROGRESSIVELY DEVELOPING HEMIPLEGIA, LATER BECOMING TRIPLEGIA.

This was the report of a case by Drs. Charles K. Mills and William G. Spiller of Philadelphia.

Hemiplegia gradually developed on the right side, the lower extremity being more markedly and probably earlier affected than the upper, the case therefore belonging to the clinical type of unilateral progressive ascending paralysis. After several years the left lower extremity also became paralyzed, but not to the same extent as the right. The reflexes were all markedly exaggerated, the Babinski response being present. Sensory symptoms were absent. Microscopical examinations showed intense and long-standing degeneration of the right crossed and the left direct pyramidal tracts, the degeneration extending into the pons but not into the left cerebral peduncle; also comparatively recent degeneration of the left crossed and the right direct pyramidal tracts traced by the method of Marchi into the lower part of the right internal capsule. No lesions, degenerative or focal, were found elsewhere; the case therefore was one of

[3] Surgical Complications and Sequels of Typhoid Fever.

uncomplicated primary degeneration of the motor tracts, much greater and older in the right crossed and left direct pyramidal tracts. The case was regarded as a corroboration of the clinical type described by Mills in the *Journal of Nervous and Mental Disease*, April, 1900.

CHRONIC PROGRESSIVE HEMIPLEGIA.

DR. HUGH T. PATRICK of Chicago reported the case of a girl eighteen years of age, who had been perfectly well and normal in every way until her fourteenth year, when the right hand and foot began to grow clumsy and weak. This disability had gradually increased until the present. The entire right side is now paretic, with distinct diminution of muscular volume but no localized atrophy. Although the general appearance and action of the involved extremities suggested flaccidity, the deep reflexes were all greatly exaggerated and Babinski's sign well marked. It seemed easy to exclude all well known diseases, but he was inclined to think that the case might belong to a new clinical type recently described by Mills under the name "Ascending Unilateral paralysis." Concerning this type, however, he had occasion to examine repeatedly one of the two cases published by Mills, and was satisfied that the case was an example not of a new disease, but of unilateral paralysis agitans. This patient would be presented to the Association later, and the symptoms of paralysis agitans demonstrated. Two additional cases of one-sided paralysis agitans without tremor were briefly reported.

PROGRESSIVELY DEVELOPING HEMIPLEGIA.

This was the report of a case and exhibition of the brain by Dr. G. M. HAMMOND of New York. The patient gradually developed hemiplegia on the right side beginning in the leg, extending to the arm, and finally affecting the face, taking four months for the total extension of the paralysis. Later, paralysis began in the left leg and finally embraced the left arm, but not the face. The autopsy disclosed extensive degeneration in the white matter of both hemispheres, more extensive on the left side. This could be traced downward in both motor tracts.

The last three papers were discussed together.

DR. H. M. THOMAS of Baltimore referred to a case recently under observation of a boy in whom there was marked mental change. The autopsy showed degeneration of both pyramidal tracts without any observable lesion.

DR. W. HIRSCH of New York spoke of two patients with progressive hemiplegia, in whom distinct mental symptoms of general paresis developed at the end of two years. Secondary degeneration of the pyramidal tracts in paretics is well known.

DR. STARR, in discussing Dr. Mills' paper, cited the case of a woman presenting at first the symptoms of spastic paralysis in the right leg. Gradually the right arm became involved, but the face escaped. The only diagnosis possible was unilateral sclerosis. About a year later the left side was similarly affected, in addition to atrophy in the muscles of the arm and leg. Soon after, bulbar symptoms developed rapidly, and death took place eighteen months after the onset, with all the signs of well-marked amyotrophic lateral sclerosis. It seemed to him, that in Dr. Mills' case, the differential diagnosis of amyotrophic lateral sclerosis should not be overlooked. He thought these cases should be classified into a large general group exclusively limited to the motor tract of the nervous system.

DR. DANA spoke of a case which seemed to belong to the type described by Dr. Mills. The condition appeared somewhat like a unilateral type of multiple sclerosis. A man forty-five years of age gradually developed descending right hemiplegia associated with the usual accompaniments of spasticity. The diagnosis rested between a sclerotic area in one cerebral hemisphere, or some type of paralysis agitans. A man with unilateral paralysis agitans without tremor at present under observation, at first impressed him as being a case of hemiplegia due to some degeneration of the motor tract. Subsequently he developed the characteristic symptoms of paralysis agitans.

DR. COLLINS reported the case of a man who became gradually hemiplegic on the left side. About a year later he began to have emotional symptoms, such as involuntary laughter without adequate cause. Subsequently, a right hemiplegia developed. The emotional symptoms are now conspicuous, and he thought the lesion therefore involved the thalamus.

DR. SACHS had seen a patient with progressive hemiplegia who gradually became completely paralyzed and demented, and finally succumbed to the disease.

DR. PATRICK then showed a patient (the one referred to in his paper) with unilateral paralysis agitans without tremor, in whom the condition had existed for five years. Tremor could be developed in the affected upper extremity when the patient made an effort to forcibly grasp an object with the opposite hand.

DR. MILLS admitted that there were several things in Dr. Patrick's case which pointed toward the diagnosis of unilateral paralysis agitans, but he did not feel thoroughly convinced that this is the correct diagnosis. He said that in his original paper he had stated that among the affections from which it was to be differentiated was unilateral amytrophic sclerosis. The patient was under observation from 1897 to 1903. The only systemic disease found on microscopical examination was the pyramidal degeneration described by Dr. Spiller. He considered the case referred to by Dr. Collins as one of disseminated sclerosis with bulbar symptoms. He thought the discussion had shown the disease to be much more common than was supposed.

DR. HAMMOND said that his case showed a different type of disease from the one described by Dr. Mills and Dr. Spiller. He thought it would take more than a close observer to tell the

difference at the bedside before a post-mortem examination had been made.

FLACCID PARALYSIS FOLLOWING CEREBROSPINAL MENINGITIS.

Dr. Wm. N. Bullard of Boston read a paper with this title and stated that the ordinary forms of paralysis following cerebrospinal meningitis as described in the textbooks are spastic. There is, however, also a flaccid form which usually appears as paraplegia. This closely resembles in its later stages the conditions which are found in the later stages of anterior poliomyelitis. In the earlier stages it is characterized by the persistence of pain and tenderness to a much greater degree than occurs in poliomyelitis, and also by a tendency to accompanying spastic contracture. He thought it very probable that some of the epidemics which have been described as anterior poliomyelitis were really due to cerebrospinal meningitis, the existence of which in the epidemic form is not uncommon, while the evidence for the existence of true epidemics of anterior poliomyelitis, usually a sporadic affection, is not yet absolute. Several cases of this form of paralysis were reported.

Dr. J. J. Thomas of Boston had seen many of these cases. He thought they were cases of cerebrospinal meningitis. During the acute stage of poliomyelitis it was often difficult to make a diagnosis. He had also noted the presence of tenderness, the early formation of contractures, and the tendency of the paralysis to be bilateral.

Dr. Henry Upson of Cleveland referred to a case of spinal meningitis with multiple neuritis which he reported several years ago. There was diffuse tenderness over the legs. The autopsy revealed both conditions in a marked degree.

Dr. Knapp thought the previous history would enable us to make a distinction between cerebrospinal meningitis and anterior poliomyelitis. In cerebrospinal meningitis the symptoms might be so slight and so little characteristic as to be easily mistaken for the initial fever and malaise of anterior poliomyelitis.

Dr. J. J. Putnam doubted whether it was always possible to make a differential diagnosis or to decide that cerebrospinal meningitis is present. He thought it important to limit the differentiation and to recognize the two types, but it should be noted that the two stood in a certain sort of relationship to each other. He believed what was ordinarily called anterior poliomyelitis occurs in epidemics. He referred to twenty-eight cases occurring in the vicinity of Boston and seen by him.

Dr. E. D. Fisher of New York said there was no difficulty in making a differential diagnosis between cerebrospinal meningitis and poliomyelitis, except during an epidemic when both conditions were found.

Dr. Patrick thought the examination of the cerebrospinal fluid was of value in making the diagnosis.

A CASE OF ALEXIA.

Dr. Philip Zenner of Cincinnati reported the case of a man sixty-three years of age. Forty years ago he had a venereal sore, but without any constitutional manifestations. Eighteen years ago he had acute articular rheumatism. For several years he has had some dyspnea on exertion. The alexia came on in April, 1902, during an attack of dyspnea. It is not improbable that the attack came on during sleep. The only other speech disturbance which he has observed is occasional difficulty of finding a word, or using a wrong word. In addition to the aphasic manifestations and occasional dyspnea, he complained of irregular heart action, precordial pain, and disturbed sleep. The heart was enlarged and the sounds muffled. The urine contained some albumen but was otherwise normal. There was no motor paralysis nor ataxia. The cutaneous sensations, hearing, taste, and smell, pupils, optic disks, and knee jerks were normal. The ankle jerks were absent. There is a right hemianopsia. Central vision is normal. He often repeats himself in conversation, forgets occurrences of the day, and vacillates in his actions, but in general, he manages his business and his own affairs. He fully understands everything said to him, and expresses himself clearly and fluently. He is altogether unable to read, but he can tell single letters, though not always with ease, and often incorrectly. He recognizes capital letters much better than small letters. He can read only so far as he is able to spell the words. Whenever he succeeds in spelling the word correctly he recognizes it at once. During the time he was under observation there was no change in his condition. As to the seat of the lesion, the hemianopsia pointed clearly to the occipital lobe. The relation of the angular gyrus, now generally accepted as the visual speech center, to the lesion can be less definitely outlined. Its destruction would, doubtless, cause more extensive aphasic manifestations than existed in this case. The lesion probably encroaches upon this area and severs its relations with the lower visual centers.

Dr. Smith Baker of Utica said there was a very easy fatigue of accommodation in such cases, and that might possibly give a clue to the difficulty experienced by the patient in recognizing certain figures which differ in form from certain other figures.

Dr. Langdon believed that the lesion was distinctly limited to a visual type of aphasia. He referred to a case of pure alexia he had seen, in which the man was unable to read after a few moments what he had written.

Dr. Knapp mentioned the case of an active, intelligent woman of middle age, who awoke one morning with considerable dizziness. A valvular lesion of the heart was present. There was well-marked alexia with right hemiplegia, and slowness in recognizing objects by sight, although the visual fields were normal. She was able to

write. She recognized her room and household perfectly well, and also the neighborhood in which she had lived for many years, but everything seemed reversed. The house seemed to be on the opposite side of the street, and the relations of the house seemed exactly reversed.

THE PRINCIPLES UNDERLYING PRACTICE IN MENTAL THERAPEUTICS AND LEGAL REGULATION OF ITS PRACTICE.

This was the title of a paper by DR. RICHARD DEWEY of Wauwatosa. He concluded that the practice of mental therapeutics is an important part of the practice of medicine as a whole, and should be taught systematically and so regulated as to prevent fraudulent practices or imposition.

DR. BAKER believed that the time is coming when we shall be forced to give more attention to the mental side of the human constitution in our attempt to restore people to health. He thought such method should play an important part in all the sources of what we now call purely nervous affections, because upon last analysis they prove to be neuro-psychical.

DR. ZENNER said there was nothing of more value than psychic treatment, and that such treatment often produces transitory relief of organic disease. In a great many therapeutic measures the relief comes through the mind.

DR. LANGDON did not think it possible to approach a solution of the problem until we have a better curriculum in the medical schools.

(To be continued.)

Recent Literature.

Protozoa and Disease. By J. JACKSON CLARKE, M.B. (Lond.), Author of "Surgical Pathology and Principles," etc. New York: Wm. Wood & Co. 1903.

In this book it is the author's intent to set forth the important facts which have been definitely established concerning the protozoa as parasites, and in this way to introduce to the medical profession the rôle played by the protozoa in disease. The author proposes in the second part to collect the work that has been done, with reference to protozoa, on those diseases which until recently were considered of doubtful or unknown etiology.

The opening chapter, which consists of general considerations concerning "the unicellular organisms and the cell," is marred by the presentation of the endogenous formation of leucocytes from the giant cells of the bone marrow as an established fact from which to draw an analogy. This interpretation given by Denys to the presence of leucocytes in the giant cells of the marrow has not been generally accepted. The greater number of observers working on the bone marrow have regarded the giant cells in question as phagocytic, and this view is supported by the degeneration of the ingested leucocytes. The use for purposes of analogy of such a questionable process as the endogenous origin of the leucocytes is, of course, unfortunate.

No attempt is made to classify the protozoa, but the various groups and the more important species are set forth in a manner both pleasing and instructive. Although sufficiently elementary to serve the purpose of the beginner, the book contains a store of information which should excite the interest of every student of medicine. Of especial interest is the account of Plasmodiophora brassicæ, an organism causing the tumor masses found on the roots of cabbages, a disease commonly known as "stump root." An account is also given of Ameba coli and its relation to dysentery and liver abscess. Human malaria is discussed in a special chapter introducing the class of parasitic organisms known as Sporozoa. The life cycle of the malaria organism is illustrated by a diagram, so that its various stages are readily followed.

Among the Sporozoa, the Hemosporidia and the Neosporidia concern medicine more especially. The essential facts concerning the life history of Pyrosoma bigeminum, the organisms of Texas fever, are discussed. The subclass "Neosporidia" includes the Myxosporidia (the psorosperme of fishes); the Microsporidia — exemplified by the organism of pébrine, a disease of silkworms; and the Sarcosporidia, organisms found in the muscles of various animals.

Of the Flagellates, the Trypanosoma which infest the blood in the tsé-tsé fly disease of Africa, in the disease known as surra in South Asia and in mal de caderas of South America, — all diseases affecting domestic animals, — are of especial interest. Trypanosoma have also been found in the human blood in certain obscure tropical fevers.

A short chapter is given over to the diseases which affect the protozoa themselves. Although certain portions of the book are somewhat speculative, it, as a whole, is of value in that it presents the protozoa together with the pathological processes which they bring about. Not only are organisms described, but a chapter is given up to technique and specific directions given for the study of the various types.

How to Succeed in the Practice of Medicine. By JOSEPH MCDOWELL MATHEWS, M.D., LL.D. Louisville: John P. Morton & Co.

A book on such a subject as this is always interesting reading, but we are inclined to think may hardly serve as a guide to the physician beginning practice. The author, as a teacher in medicine, tells us in the preface that he has often talked to students about the "business side" of the medical profession. The book is a reduction of these thoughts to words. As a narrative of the methods which have led to the anthor's success we may commend the volume. Its suggestions are many and for the most part useful, but we suspect that success in practice cannot be furthered by the experience of another. It is after all peculiarly a personal matter.

THE BOSTON

Medical and Surgical Journal

THURSDAY, NOVEMBER 26, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: $5.00 *per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

PUBLIC HEALTH PROBLEMS.

IN two recent sanitary papers [1] the author of one of the most practical and useful publications yet issued in this country ("Municipal Sanitation") shows his ability to deal with the philosophical as well as the utilitarian side of the subject.

In "Dirt, Disease and the Health Officer" Dr. Chapin assumes the position, which is undoubtedly correct, that many health officials have blindly expended their strength in attacking mere filth without understanding the true specific causes and conditions under which such filth may prove an injury to the public health. The popular mind is very apt to take very much for granted in the matter of disease prevention, and to believe that such diseases generally have a spontaneous origin in filth. Such was the origin of many of the strict plumbing laws now in existence. A plumber appeared before a legislative committee bringing with him an array of defective pipes and traps, and the astonished committee, without further consideration, recommended a stringent law. The question whether such defects had been a fruitful source of disease, and whether actual proofs of cases of illness from such causes could be cited, was not even asked by the committee.

So, too, with the modern practice of embalming. It is the living, breathing, human being sick with infectious diseases who is a public danger, not the dead corpse sealed in its coffin, and the duty of the health officer is much more concerned with the former than the latter. It is a question whether the law in the one instance and the custom in the other have not largely sprung from the financial interests of certain classes than from the demands of public health.

Dr. Chapin in this brief paper strives to bring out the true principles on which practical sanitary work should be founded. The following quotations show the author's trend of thought:

> When our honored and lamented Reid went to Havana and discovered that yellow fever was transmitted by the bite of a mosquito, and Gorgas, by the most brilliant sanitary experiment ever made, put an end to this disease in its very stronghold, they drove the last nail in the coffin of the filth theory of disease. . . . The majority of even intelligent people to-day believe that Havana was made healthy by municipal engineering, while it was really accompanied by scientific effort specifically directed against certain infections.
>
> An entirely disproportionate amount of time and money is devoted to plumbing regulation and the abatement of minor nuisances which have no relation to public health. Popular misconception as to the relation of dirt and disease is illustrated by the advertising cartoons of "Spotless Town," which is supposed to be so clean that the poor old doctor is dying of starvation. But we can rest assured that however spick and span may be the streets, and however the policeman's badge may be polished, so long as there is found the bore so careless with his expectoration, and the doctor who cannot tell a case of sapolio from one of diphtheria, the latter disease, as well as tuberculosis, will continue to claim their victims.

Again he says:

> I would plead with health officers for a more rational perspective in directing their efforts and to devote more attention to the isolation of infectious diseases, medical inspection, disinfection, vaccination and the control of milk supplies and less to the abatement of nuisances; and in the latter, more attention to those nuisances which clearly and directly menace health, and less attention, or none at all, to those which do not.

These may be deemed radical statements, but they are the opinions of a practical health officer after years of experience and careful observation.

In "Preventive Medicine and Natural Selection" the author takes up the question whether active health measures do not interfere with natural selection so far as human beings are concerned. Darwin says: "There is reason to believe that vaccination has preserved thousands who from a weak constitution would formerly have succumbed to smallpox. . . . It is surprising how soon a want of care, or care wrongly directed, leads to the degeneration of a domestic race." [2] The assumption here is wrong at the outset, since observation shows that smallpox attacks and kills both the weak and the robust

[1] "Dirt, Disease and the Health Officer." "Preventive Medicine and Natural Selection," by Charles V. Chapin, M.D., Superintendent of Health. Providence, R. I. 1900.

[2] The Descent of Man. Part I, Chap. 5.

without discrimination. Dr. Chapin says upon this question:

> The practical point which I am here venturing to consider is whether we are warranted in abandoning our fight against these diseases, and permitting natural selection to have again a free field.

Several reasons are then given for continuing the vigorous campaign against infectious diseases:

> The infectious diseases have been held by some to be an important factor in eliminating the feeble, the poorly nourished and the constitutionally defective. While it is true that such may more readily succumb when attacked by disease, there is no evidence that they are any more susceptible to most of the communicable diseases than are the most robust. The selective action of these diseases cannot therefore be so important a factor in maintaining race stamina as is sometimes assumed.
>
> In conclusion, it appears that natural selection in the relation of man to infection is working for the ultimate good of the race; and while public health measures are in some respects antagonistic to this process, in others they favor it. Furthermore, the immediate results of preventive measures are so marked, and the chances of overcoming these diseases in the future by other means than the immunity due to selection, is so great, that we find no warrant in the principles of organic evolution for abandoning our present warfare.

THE TITLE OF SURGEON.

THE high place which surgery as a branch of medicine has taken in the popular mind is sufficiently evident. The reasons for this are not far to seek. In many respects it is the most exact branch of medicine. It permits the demonstration of immediate results. It has less to do with our somewhat discredited drugs than other lines of practice. All these things, together with the appeal to the popular imagination, not leaving out of account the extraordinary advances made in surgical theory and practice during the last few years, place surgery and the surgeon in a somewhat distinct category. The sharp distinction between medicine and surgery, which has been growing rather than decreasing as specialism has progressed, is likely in the near future to give place to a closer relationship between the two fundamental branches of medicine. This is sufficiently shown by the work of our best and most progressive surgeons, who are more and more investigating problems which have a medical as well as a surgical bearing, and possibly are less intent upon the operative side of their calling. Such a recognition of the interrelations of medicine and surgery is altogether to be encouraged, and no doubt will bear fruit in the immediate future.

In the meantime it is interesting and entertaining to observe the extraordinary hold which the mere name surgeon has upon the professional mind. To be a surgeon is apparently still the chief ambition of the ordinary medical student. If the attainment of his ambition is impossible, he enters upon the more humdrum life of the medical practitioner with lingering regret. That the name surgeon carries with it much authority is shown by the curious fact that this title is apparently retained wherever possible in work which is not distinctively surgical. Men concerned with diseases of the eye, for instance, apparently wish to be known as ophthalmic surgeons rather than as opthalmologists, and are often so designated in their hospital positions. The ophthalmologist clearly deals with many cases which have no relation whatsoever to surgery; in fact, his surgical practice must be but a small part of his general work. Nevertheless, he wishes to be known as a surgeon. Writers of textbooks on ophthalmology are extremely apt, in describing the most ordinary tests, to speak of the person performing these tests as a surgeon. Turning to the army, we see the same tendency prevailing. Although, and this is coming to be more and more the case, a very great proportion of the work of the army medical officer is medical rather than surgical, he still is known as surgeon.

In general, we find this tendency running through the whole profession. If there is the slightest excuse for dubbing a man surgeon, this title is chosen in preference to the time-honored one of physician. We have no fault to find with this attitude of mind. It merely seems to us desirable that in the arrangement of medical titles the word surgeon should be more strictly applied, and the word physician looked upon as a term of equal dignity and desirability. No doubt time will adjust this somewhat anomalous condition, and the physician, when he has attained in the popular mind to the degree of accomplishment which is already the surgeon's, will invest his title with an equal popularity.

A TIMELY REBUKE.

IT is reported from London that the Hon. Stephen Coleridge, well known for his activity in the antivivisection movement, has recently lost a suit in which he was defendant before Baron Alverstone, Lord Chief Justice of England. The circumstances were that Mr. Coleridge in a public address read a statement fur-

nished him by two women, in which Dr. Bayliss, professor of physiology at London University College, was charged with deliberate cruelty in the conduct of a certain physiological experiment. As is generally known, vivisection is permitted by the English law under certain restrictions and limitations, and Dr. Bayliss was one of those licensed to perform experiments. He naturally resented the imputations made by Mr. Coleridge, and began proceedings for libel and slander, with the result that the defendant was adjudged guilty and a verdict, with damages amounting to £2,000, rendered in Dr. Bayliss' favor.

Such a decision coming from such a source cannot fail to have a most salutary influence. The vilification of scientific men by the adherents of the cause of antivivisection has apparently been growing year by year, with but small regard to the facts. English experimenters have been exposed to much defamation, possibly more than men working in similar lines in this country, but so far as we know legal action has not hitherto been taken. It is fortunate for the cause of fairness and decency that so prominent a man socially, and so conspicuous an advocate of the cause of antivivisection, should be brought to account for his malicious utterances. How deep an impression this legal rebuff may have upon the rank and file of the antivivisection agitators it is, of course, impossible to say, but we suspect that in England at least there will hereafter be a certain hesitation in the promulgation of unverified statements which reflect upon the character of highly respected men. It will be difficult also, in this instance, for the defendant to pose as a martyr to the cause, or to elicit popular sympathy on any pretext whatever. Many of the attacks made upon the medical profession in relation to vivisection are too manifestly absurd and wide of the truth to excite any deep resentment, but it is well to have it understood that even such statements may not be made with impunity, and without incurring legal reproof. Freedom of speech has long since reached its limit in this matter.

MEDICAL NOTES.

Pneumonia in Chicago. — According to the Bulletin of the Chicago Health Department, it is announced that for the first fortnight of the month of November 135 deaths from pneumonia have been reported and 82 from consumption, showing an excess of the former disease. Such a prevalence of this common and frequently fatal affection is worthy of careful study As a possible prophylactic measure the Bulletin urges a return to a simpler life.

Gift to Stamford, Conn., Hospital. — It has been announced that the gift of $10,000, made anonymously a year ago to the Stamford, Conn., Hospital, was from Robert M. Bruce, a resident of Greenwich. Some time ago Mr. Bruce also gave to the town of Greenwich an isolation hospital.

A Ruling in Favor of Christian Science. — According to a report from Columbus, Ohio, it is stated that the supreme court has rendered a decision which apparently permits the practice of Christian Science in Ohio. The decision turns upon a case tried some time ago in which a family was acquitted of the charge of manslaughter in the lower court in having refused medical aid to a child. The state carried the case to the supreme court on exceptions, which were overruled. Such decisions we must regard as unfortunate and detrimental to the well-being of the community.

Lecture under Auspices of the Henry Phipps Institute. — Dr. William Osler, on the evening of Dec. 3, will deliver a lecture on "The Home in Relation to the Tuberculosis Problem," in Philadelphia, under the auspices of the Henry Phipps Institute for the study, treatment and prevention of tuberculosis. This is one of a series of lectures to be given on tuberculosis in the course of the winter by men eminent in this branch of medicine.

The Senn Prize Essay for 1904. — The Committee on the Senn Medal begs leave to call attention to the following conditions governing the competition for this medal for 1904:

A gold medal of suitable design is to be conferred on the member of the American Medical Association who shall present the best essay on some surgical subject. The award will be made under the following conditions: (*a*) The name of the author of each competing essay must be enclosed in a sealed envelope bearing a suitable motto or device, the essay itself bearing the same motto or device. (*b*) All successful essays become the property of the Association. (*c*) The medal shall be conferred and honorable mention made of the two other essays considered worthy of this distinction, at a general meeting of the Association. (*d*) The competition is to be confined to those who, at the time of entering the competition, as well as at the time of conferring the medal, shall be members of the American Medical Association. (*e*) The competition for the medal will be closed on and no essays received after March 1, 1904. Communications may be addressed to any member of the committee, which con-

sists of the following: Dr. James H. Dunn, Chairman, Minneapolis; Dr. M. L. Harris, 100 State Street, Chicago; Dr. Floyd McRae, Atlanta, Ga.

IMPROVEMENT OF VITAL STATISTICS. — At the recent meeting of the American Public Health Association held at Washington the committee on vital statistics reported that effective co-operation had been instituted between that Association, the Conference of State Boards of Health, the American Medical Association, the United States Census Bureau and the United States Public Health and Marine Hospital Service for the improvement of the vital statistics of this country. Among the objects sought are the extension of adequate methods of registration, the use of uniform and comparable tables and rates in bulletins and reports, and the improvement of the international classification of causes of death. A pamphlet on "Statistical Treat- of Causes of Death" has been issued by the United States Census Bureau, requests for which should be addressed to Mr. W. A. King, Chief Statistician for Vital Statistics, Census Bureau.

It has special reference to the difficulties encountered in compiling deaths returned from several causes, and asks for the co-operation of the profession in framing a thoroughly satisfactory method of procedure in such cases.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Nov. 24, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 52, scarlatina 35, typhoid fever 22, measles 98, smallpox 0.

CASES OF ANTHRAX. — Owing to the occurrence of cases of anthrax in Lynn, Mass., and Boston, suspicion has been directed to several bundles of skins, recently imported. Both the Lynn and Boston boards of health are investigating the matter.

WOMEN NURSES IN INSANE HOSPITALS. — At the tenth semi-annual conference of the State Board of Insanity, recently held in this city, a subject under discussion was the question of women nurses in wards for insane men. The discussion was an active one, with a general consensus of opinion that women might advantageously be employed in such work more than has hitherto been done. Particularly in the sick wards and in the care of old men women have been found desirable.

A CENTENARIAN. — Patrick Scanlon of Wendell, Mass., died Nov. 21, at the reputed age of one hundred and three years. He was born in Ireland, March 15, 1800.

DEDICATION OF MT. SINAI HOSPITAL. — Exercises in dedication of the new Mt. Sinai Hospital were held Nov. 22, at the new building, 17 Staniford Street, Boston. An out-patient department, as well as wards for house patients, will be maintained. The services of the hospital will not be limited to members of the Jewish race.

WARREN TRIENNIAL PRIZE. — The Warren Triennial Prize was founded by the late Dr. J. Mason Warren in memory of his father, and his will provides that the accumulated interest of the fund shall be awarded every three years to the best dissertation, considered worthy of a premium, on some subject in Physiology, Surgery, or Pathological Anatomy, the arbitrators being the physicians and surgeons of the Massachusetts General Hospital.

The subject for competition for the year 1904 is on some special subject in physiology, surgery, or pathology.

Dissertations must be legibly written, and must be suitably bound, so as to be easily handled. The name of the writer must be enclosed in a sealed envelope, on which must be written a motto corresponding with one on the accompanying dissertation.

Any clew given by the dissertation, or any action on the part of the writer which reveals his name before the award of the prize, will disqualify him from receiving the same.

The amount of the prize for the year 1904 will be $500.

In case no dissertation is considered sufficiently meritorious, no award will be made. Dissertations will be received until April 14th, 1904.

A high value will be placed on original work.

NEW YORK.

DONATIONS TO MONTEFIORE HOME. — At the annual meeting and election of officers of the Montefiore Home and Hospital for Chronic Invalids, which was held on Nov. 1, it was announced that two gifts, aggregating $75,000, had been made to the institution. One was an endowment fund of $50,000, presented by S. R. Guggenheim, and the other a fund of $25,000, to be known as "The Betty Loeb Memorial Fund," instituted and endowed by James Loeb in memory of his mother. A report was also

presented giving the details of the construction of an annex to the hospital which is now in course of erection. This is a four-story building of brick and stone which will cost about $30,000 and is to be used for emergency and isolation purposes.

HEBREW SHELTERING GUARDIAN SOCIETY. — At the annual meeting of the Hebrew Sheltering Guardian Society, held at the home of the society on the Hudson at One Hundred and Fiftieth Street on Nov. 15, it was announced that gifts amounting to $117,500 had been received. It is proposed, as soon as sufficient funds have been raised, to purchase a large plot of ground in Bronx Borough and erect on it some fifty or sixty cottages, each to accommodate twenty children. The general plan of the institution, as reorganized, will be that of Dr. Barnado's in London, and the children will receive manual and technical training. Among the improvements which have been made in connection with the present home are the establishment in the neighborhood of a reception house, where new inmates are kept under supervision for a time to prevent the introduction of contagious diseases among the other children, and of a building especially for the care of the infants.

A CENTENARIAN. — Mrs. Marie Pigrum Harrison, a native of England, died in Brooklyn on Nov. 14 at the age of one hundred years. Her husband, who was an actor, and died about twenty years ago, was for a considerable time a member of P. T. Barnum's company at the old Ann Street Museum, New York, and Mrs. Harrison had a unique collection of shoes and articles of clothing once worn by Tom Thumb, Commodore Nutt and other famous dwarfs, with whom she was a great favorite.

Miscellany.

IN MEMORIAM — GEORGE HAVEN, M.D.

AT a meeting of the Obstetrical Society of Boston, held Nov. 17, 1903, the following resolutions were unanimously adopted:

Resolved, That we, the Obstetrical Society of Boston, do hereby express our sense of the great loss that the profession as well as our society has sustained by the death of our esteemed colleague and fellow member, Dr. George Haven.

" By the brilliancy of his professional career, his devotion to his patients, his unfailing tact and courtesy, he made a name and place for himself that sufficiently attests his value to his professional friends and to the community.

" *Resolved*, That the secretary be directed to forward a copy of these resolutions to his family and to the BOSTON MEDICAL AND SURGICAL JOURNAL."

MALCOLM STORER, M.D., Secretary.

Correspondence.

THE AMERICAN SOCIETY OF CLINICAL SURGERY.

BOSTON, Nov. 17, 1903.

MR. EDITOR: My New England conscience prompts me that I promised to write out for the JOURNAL some sort of report of the meetings of the American Society of Clinical Surgery, held Friday and Saturday, Nov. 13 and 14, in Baltimore and Philadelphia.

The experiment, so far, has proved a success beyond our expectations. Twenty-one men, out of the total membership of thirty-six, gathered at the Johns Hopkins Hospital on Friday. They represented the schools and hospitals of Baltimore, Philadelphia, New York, Boston and Cleveland. The Johns Hopkins Hospital entertained us delightfully with clinics and luncheon. After the organization of the society had been perfected, we spent an hour in Dr. Halsted's surgical clinic where he demonstrated important cases and his method of teaching. At 11 o'clock Dr. Finney showed some interesting results of plastic operations upon the nose and demonstrated his now well-known operation of pyloroplasty. At half-past twelve Dr. Harvey Cushing demonstrated his method of teaching operative surgery to small classes of students, working upon dogs as actual subjects. The procedures were extremely interesting. After a delightful luncheon, given us by the hospital, we listened to Dr. Bloodgood's capital demonstration of his method of teaching surgical pathology, saw Dr. Cushing's exhibition of patients upon whom he had operated for the removal of the Gasserian ganglion and for drainage of hydrocephalus, and to Dr. Young's explanation of his methods in prostatectomy and sundry other genito-urinary surgical conditions.

On Friday evening, at half-past six, the society left on a special car for Philadelphia, where it spent the night. Saturday was passed in Philadelphia. Perhaps the most interesting number for that day was Dr. G. G. Davis' exhibition of methods in the teaching of applied anatomy. Dr. Davis is an accomplished surgeon as well as a thorough anatomist and his collection of anatomical preparations, illustrating surgical lesions, is unique; this exhibition was given in the old Medical Hall of the University of Pennsylvania, at 10 o'clock in the morning. At 11 o'clock we adjourned to the University Hospital, where Dr. Edward Martin gave a series of brief demonstrations illustrating the effect of head positions upon the epiglottis during anesthetization, a mechanical intestinal suture and the value of percussion and auscultation in the diagnosis of fractures. Dr. Charles H. Frazier followed with a demonstration of the practice and results of operations upon the Gasserian ganglion and some further interesting observations upon the technique of intracranial operations. After luncheon at the Rittenhouse Club the society proceeded to the always delightful old Pennsylvania Hospital, where Dr. R. G. LeConte and Dr. John H. Gibbon did the honors. Short demonstrations of results in the treatment of acute osteomyelitis and of perforating gastric ulcer were followed by a pilgrimage to the ancient galleries, wards and library of the hospital. This ended the first series of meetings of the society, an experience which we all look back upon as most valuable and delightful.

You see how impossible it would be formally to report such a program. The society is small, for a large gathering would defeat our purposes. Even the name is still *sub judice* — several members feeling that some such title as Society of Surgical Research would be more appropriate; but that the organization is well set upon its legs and likely to continue is probably established.

Sincerely yours,

J. G. MUMFORD, M.D.

RECORD OF MORTALITY

Deaths reported, 3,050; under five years of age, 743; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 693, acute lung diseases 512, consumption 334, scarlet fever 12, whooping cough 15, cerebrospinal meningitis 8, smallpox 6, erysipelas 8, puerperal fever 12, measles 14, typhoid fever 56, diarrheal diseases 104, diphtheria and croup 123.

From whooping cough, New York 5, Chicago 4, Philadelphia 2, Baltimore 1, Providence 1, Salem 1, Chicopee 1. From erysipelas, New York 1, Chicago 2, Philadelphia 1, Providence 1, Boston 2, Salem, 1. From smallpox, Philadelphia 1, Pittsburg 5. From measles, New York 9, Chicago 1, Providence 1, Boston 3. From scarlet fever, New York 5, Chicago 2, Philadelphia 2, Baltimore 1, Lowell 1, Cambridge 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Oct. 31, the death-rate was 16.3. Deaths reported, 4,718; acute diseases of the respiratory organs (London) 260, whooping cough 41, diphtheria 61, measles 74, smallpox 4, scarlet fever 40.

The death-rate ranged from 4.7 in Hornsey to 29.9 in Warrington, London 15.8, West Ham 18.9, Brighton 10.8, Southampton 9.9, Plymouth 16.3, Bristol 13.5, Birmingham 18.3, Leicester 15.2, Nottingham 17.2, Liverpool 19.3, Bolton 11.4, Manchester 17.4, Salford 20.0, Bradford 14.7, Leeds 18.7, Hull 16.3, Cardiff 15.7, Rhondda 13.9, Merthyr Tydfil 18.2, Middlesbrough 19.8, Tynemouth, 19.9

METEOROLOGICAL RECORD.

For the week ending Nov. 14, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING NOV. 19, 1903.

WILLIAMS, L. L., assistant surgeon-general. To proceed to New York, N. Y., for special temporary duty; and as inspector of the Purveying Depot. Nov. 14, 1903.

CARMICHAEL, D. A., surgeon. Bureau letter of Oct. 5, granting Surgeon Carmichael leave of absence for thirty days from Oct. 16, amended so as to read twenty-four days from Oct. 16. Nov. 14, 1903.

WASDIN, EUGENE, surgeon. Granted leave of absence for one month from Dec. 7. Nov. 13, 1903.

MAGRUDER, G. M., surgeon. Granted leave of absence for two days from Nov. 17. Nov. 14, 1903.

ROSENAU, M. J., passed assistant surgeon. Relieved from duty at Vera Cruz, Mexico, and directed to rejoin his station in Washington, D. C. Nov. 16, 1903.

PARKER, H. B., passed assistant surgeon. Relieved from duty at Vera Cruz, Mexico, and directed to return to the Bureau at Washington, D. C. Nov. 16, 1903.

LUMSDEN, L. L., passed assistant surgeon. Granted leave of absence for ten days from Nov. 15. Nov. 14, 1903.

RAMUS, CARL, assistant surgeon. Granted leave of absence, on account of sickness, for nine days from Oct. 28. Nov. 14, 1903.

STANSFIELD, H. A., assistant surgeon. To report to Director of the Hygienic Laboratory for duty. Nov. 16, 1903.

GOLDBERGER, JOSEPH, assistant surgeon. To proceed to Laredo, Texas, for special temporary duty. Nov. 17, 1903.

BERRY, T. D., assistant surgeon. To proceed to Cleveland, Ohio, and assume temporary command of the service at that port during absence of medical officer in command; upon completion of which to rejoin his station. Nov. 13, 1903.

BOGGESS, J. S., assistant surgeon. Granted leave of absence for one month from Dec. 15. Nov. 16, 1903.

APPOINTMENT.

Francis Asbury Ashford, of the District of Columbia, commissioned (recess) as assistant surgeon in the Public Health and Marine Hospital Service. Oct. 29, 1903.

RECENT DEATHS.

ALLEN HAZEN, M.D., of New York, died in Jericho Centre, Vermont, on Nov. 17, after an operation for appendicitis. He was thirty-six years of age and was graduated from the College of Physicians and Surgeons, New York, in 1895. He served as an interne in the City Hospital on Blackwell's Island, and for the past five years had been on the board of medical examiners of the Mutual Life Insurance Company.

SAMUEL TALMAGE, M.D., of Brooklyn, N. Y., died on Nov. 20, aged seventy-two years. He was graduated from the Medical Department of the University of the City of New York in 1870.

HERBERT A. STARKEY, M.D., of Sloatsburgh, N. Y., died suddenly on Nov. 21. He was the son of Dr. David Starkey of Philadelphia, and was formerly surgeon for the Pullman Car Company at Pullman, Ill.

Original Articles.

HYPERNEPHROMA.*

BY PAUL THORNDIKE, M.D., AND JOHN H. CUNNINGHAM, JR., M.D., BOSTON.

AT the present time pathologists are forced to classify a certain class of renal tumors from a genetic as well as from a simply morphological point of view. The first steps in this direction resulted from the work of Grawitz (1883), who described a group of tumors (which had up to that time been classed most usually as renal lipomata) as *strumæ lipomatodes aberatæ renis*, and claimed for them a suprarenal origin. In the years immediately following, and in fact up to the present time, other writers have claimed a renal origin for these tumors, some asserting that they arise from the epithelium of renal tubules, while others claim the endothelium of the perivascular lymph spaces as their starting point. It has, however, seemed clear to all that these growths cannot be collected into any one morphological group, and are by no means to be classified simply as sarcomata, carcinomata or adenomata. They have, during the last few years, received the name of hypernephroma, the term signifying any tumor having its origin from adrenal cells, whether the growth be adenoma, carcinoma or sarcoma in type. This term seems a peculiarly fortunate one at this stage of our knowledge, as it definitely indicates the adrenal and not the renal origin of the growths in question, and yet makes no claim for any purely histological basis of classification, and commits us to no one of the many points of view still held by histologists regarding such growths. At the present time the proofs of the existence of this class of growths and of the propriety of using this name for them are about as follows:

(1) The situation of the growth just beneath the kidney capsule — the most common seat of aberrant suprarenal tissue.

(2) The similarity of malignant tumors of the adrenal gland and these malignant growths of aberrant suprarenal origin.

(3) The absence of any transition structure between the growth and the renal tissues surrounding it.

(4) The tendency of the tumor to extend along and to involve venous rather than lymphatic channels.

(5) The resemblance of the tumor cells to those of the suprarenal cortex.

(6) The presence of fat drops and glycogen in the protoplasm of the cells — substances which are by no means universally or even commonly found in the adrenal tissues, and yet which are always present in tumors of this gland so far as they are known.

(7) The property of the nucleolus of staining differently from the nucleus, a fact rarely if ever observed in cells of renal adenomata.

(8) The presence of giant cells like those in the small hyperplastic growths of the suprarenal gland of which we have a knowledge.

(9) The existence of an abundant capillary network as seen in the suprarenal cortex.

(10) The presence of lecithin in amounts closely approximating those characteristic of suprarenal tissue.

The proper classification of hypernephromata will doubtless depend upon a combination of histological and genetic methods, and recent work upon glycogen and lecithin indicates that some progress will be made along chemical lines. It also seems proper to tabulate what few clinical facts we can already offer from the cases already described by Grawitz and his followers since 1883. These facts are briefly as follows:

(1) The tumor occurs most frequently in the adult male.

(2) It is usually large and has a nodular surface.

(3) It is entirely within the kidney substance or it is partially subcapsular.

(4) The function of the kidney which contains it is interfered with either by destruction of renal substance or by its compression from the tumor mass, or by both these factors acting together.

(5) The tumor grows rapidly, is usually malignant, but may probably be benign in some instances.

(6) It usually involves the renal vein and sometimes the vena cava, and metastases are formed along the blood current, especially in the lungs, liver and bones, but do not involve the lymphatic channels.

Of the three cases which are here described, one occurred on the service of Dr. F. S. Watson, to whose kindness the writers are indebted for its use in this paper. They are also indebted to Dr. W. F. Whitney of the Harvard Medical School, and to Drs. F. B. Mallory and E. E. Southard of the Pathological Department of the Boston City Hospital, for assistance in the preparation of the material for illustrations.

CASE I. Man, forty-eight years old, entered the service of Dr. Paul Thorndike, Jan. 21, 1903. Family history good, except for one sister, who had a cervical adenitis. Thirty-five years ago patient had typhoid, and, four years ago, lead poisoning. Eight years ago had an attack of pain in the right kidney, and thinks he passed a small calculus at that time. Three years ago he began to notice blood in his urine. Bleeding was almost constant for six months, but occasionally disappeared for one or two days, and coincident with the disappearance of the hematuria he usually developed considerable pain in his right lumbar region, which was relieved by the reappearance of the blood in the urine. At the end of this six months he had more bleeding than usual for one week, and then the blood disappeared and the urine became clear. During the next six months he had attacks of hematuria occurring every one or two weeks and lasting about twenty-four hours. Between these attacks he had considerable pain of a dull, aching character in the right kidney region. This renal pain was relieved by the reappearance of hematuria, coincident with which the patient developed a pain referred to the corona glandis. He thinks that he passed clotted blood occasionally. At this time he was beginning to lose strength, gave up his work, but as the hematuria subsided temporarily, no operation was performed. He continued his mild attacks of hematuria until May, 1901, when he had a severe attack lasting one week.

*Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital.

This hematuria continued periodically until two months before entrance to the hospital, at which time the blood disappeared entirely from the urine. One week before entrance he again began to pass blood, and noticed a long clot of small diameter just before entering the hospital. At this time the tumor was discovered and the patient advised to come to the hospital for operation. During the three years he lost about fifty pounds in weight and failed considerably in strength.

Physical examination at time of entrance. — Large, well-developed man, emaciated and anemic. Pulses equal, regular and of fair volume and tension; rate, 100. Temperature, 99.6. Heart area normal, action regular, sounds not strong, but clear. Soft systolic murmur at apex not transmitted. Lungs normal. Extremities and reflexes normal. Abdomen symmetrical, full, lax and tympanitic, except in the right hypochondrium, where there is dullness continuous with that of the liver, the upper border of which begins at the fourth intercostal space and extends 9 cm. below the costal margin in the mammary line. Palpation reveals a hard, nodular, slightly tender mass which does not pulsate, but descends with deep inspiration. The lower border is ovoid in shape, with the convexity downward. Urine at entrance bloody, alkaline, specific gravity 1,026; urea, 30 gm.; albumin, a very slight trace. Much normal and abnormal blood and a few large, squamous epithelial cells. White count: 6,500. Hemoglobin, 60%.

The blood in the urine disappeared the day after entrance. Twenty-four hours' amount for the three days following entrance varied between 14 and 21 ounces. Temperature gradually climbed to 101.2 without apparent cause or change in the patient's condition. Urea remained at 30 gm. Operation on the fourth day after entrance; Dr. Paul Thorndike. Incision was six inches long, beginning just below the costal margin in the mammary line and extending downward over the tumor mass. Tumor was found covered with a network of large dilated vessels. Tumor region packed off from the general cavity and the peritoneum over the mass divided and clamped. The tumor, which was firmly bound by adhesions to the surrounding tissues, was freed and delivered. The mass continued down along the renal vessels and ureter. These were clamped *en masse* and the tumor removed. The ureter, which was much thickened by infiltrated new growth, was isolated and tied four inches from its upper end. The vessels were transfixed and tied with silk, but all the tumor could not be removed from them. The patient's condition became very poor, requiring considerable stimulation. The wound was closed with deep silkworm-gut sutures, except for two inches at its lower end, which was left open for the removal of gauze packing left in place to control the remaining hemorrhage. Duration of operation, thirty minutes. Subcutaneous injections, 1,000 c.c. salt solution. Packing removed on the third and fifth days. Daily dressings were made on account of some sloughing from the depths of the wound. The wound, with the exception of the sinus down to the stump of the pedicle, was healed by first intention and stitches were removed on the eighth day. Sinus persisted, but the patient improved rapidly, and was up on the seventeenth day and discharged on the thirtieth day after operation. At that time he had gained much in weight and general appearance. Sinus still persisted. From the time of operation the twenty-fours' amount of urine increased steadily, without the use of diuretics, and up to the time of discharge varied from 40 to 50 ounces. Urea remained about 30 gm. The specific gravity fell, and during the last week of his hospital stay was about 1,017. Nine months after operation patient was well, doing a fair day's work, and stated that he had gained over forty pounds in weight. A very small sinus still persisted.

Pathological report. — The mass retains roughly the general outline of the kidney. It measures 16 cm. by 14 cm. by 12 cm., and weighs 1,500 gm. The surface is everywhere nodular and covered by the kidney capsule. The larger of these nodules is about one-fifth of the whole mass and is near the upper pole of the organ. The capsule, which is much thickened by dense, white, fibrous tissue, strips with difficulty, and is so generally adherent as to bring away tissue with it. On section the kidney cortex is evident only in a few places, it being mostly replaced by nodules of various sizes, discrete and confluent, dark red or yellowish in color, with a yellowish white trabeculation, and firm to the touch. The area of the pyramids is occupied by a mass of pale yellow elastic tissue which is distinctly trabeculated and limited in outline, and contains many small areas of hemorrhage and a few areas of degeneration. The pelvis is enlarged and brilliantly injected. The calices are not distinct, but are occupied by bulging tissues due to the pressure of the tumor mass. Scattered over the inner surface of the pelvis are a few yellowish green areas of necrosis about the size of peas. Histological diagnosis: hypernephroma.

CASE II. Woman, fifty-two years of age, entered the medical side of the Boston City Hospital April 14, 1903, on the service of Dr. George G. Sears. Her father died of yellow fever, her mother of intestinal obstruction. She has one sister and one brother living and well, and one child now living and well at the age of twenty-six years. She has never suffered from uterine disorders, and passed her climacteric at forty-six years of age. She has always been well, and has had no illnesses during her adult life. On Dec. 15, 1902, she stumbled and fell, striking the lower part of her back. She felt lame for a few days, but was about and received no treatment for the injury. On Jan. 15, 1903, she began to have an indefinite attack of nausea, which lasted several days. She did not vomit and had no fever. She was up and about, but did not eat so much as usual. Feb. 1, 1903, she suddenly had a severe attack of sharp pain in the right side, which radiated toward the bladder. She immediately passed much bloody urine, followed by a continuance of a dull, aching pain in the right lumbar region. She passed considerable bloody urine several times during that night, and this hematuria continued for twenty-four hours. With the disappearance of the hematuria the pain in the back passed away. During the following six weeks the patient had several attacks of pain in the right lumbar region, radiating toward the bladder, but had no further attacks of hematuria. She lost twenty-five pounds in weight, and failed considerably in strength. A slight frequency and pain on urination caused her to consult Dr. C. M. Green, who recommended her admission to the hospital.

Physical examination. — A well-developed, fairly well-nourished woman, nervous temperament, with dark skin. Eyes and mouth negative. Pulses equal, regular, of good volume and tension. Heart area normal, action regular, sounds clear, with a soft systolic murmur at the apex transmitted into the axilla. Lungs negative. Abdomen symmetrical, full, lax and tympanitic, except in the right hypochondrium, where there was dullness, continuous with liver dullness, which extended to the level of the umbilicus in the mammary line. The lower border of the dull area was easily felt, was smooth and convex downward and descended with deep inspiration. There was no pulsation or tenderness over this area. The upper border of the liver dullness was at the sixth rib, and the left lobe of the liver did not appear enlarged. Neither spleen nor left kidney could be felt. Vaginal examination negative. Urine was pale, strongly acid, 1,016, a trace of albumin, much pus, and many squamous and neck-of-bladder cells; no blood. Blood: white count, 6,200; reds, 2,770,000. Hemoglobin, 25%. Patient was put to bed and received general tonic treatment. Many examinations for tubercle bacilli in the urine were negative, and differential blood counts showed nothing but moderate anemia. The patient improved only slightly under tonic treatment, and the general conditions remained the same. Although the tumor mass in the hypochondrium did not give acute symptoms, an exploratory operation was advised and finally accepted. The patient was transferred to the service of Dr. F. S. Watson, May 25, 1903. Operation, May 27, 1903; Dr. F. S. Watson. Incision seven inches long, beginning just below ribs, was extended downward over the tumor mass. Wound was later enlarged by an incision four inches long at right angles to the center of the first incision, outward between the ribs and the iliac crest. The peritoneum covering the kidney was filled with a network of dilated vessels. It was divided over the full length of the tumor, the bleeding points secured, and the cut edges sewed to the cut edges of the parietal peritoneum along the edge of the

wound, thus shutting off the general peritoneal cavity and forming a pocket in which the tumor lay. It was firmly bound by adhesions at its upper pole. These were broken, the pedicle was clamped, and the vessels tied separately. There was much thickened tissue along their course, but as the kidney could not be delivered through the wound its character was uncertain. The ureter was much dilated, very friable, and broke several times while being tied. About eight inches of it was removed, but the remaining portion of it seemed undoubtedly affected. The patient's condition was poor and would not allow of further procedure. The wound was closed with deep silkworm-gut sutures without drainage. During the operation the patient required stimulation by strychnine and 2,000 cc. of salt solution subcutaneously. Time of operation, one hour and twenty minutes.

During the first forty-eight hours after operation the patient's condition was poor, but gradually improved. For the first twenty-four hours after operation the amount of urine was only 13 ounces. This gradually increased, and four days later reached 35 ounces without the use of diuretics. The urea at this time was 1.3%, and there was no macroscopic and but little microscopic blood. Six days after operation there was evidence of acute suppuration in the center of the wound, and about 2 drachms of pus were evacuated. The patient's general condition steadily improved, and the wound, except for a sinus, which led down to the renal pedicle, healed by first intention, and the stitches were removed on the eighth day. Patient up on the twenty-eighth day. Urine remained constant in amount at 35 ounces, and the urea averaged 1.5%. There was at all times a slight trace of albumen with a specific gravity of about 1,012, and a few hyaline casts and small round cells. After getting up the patient gained rapidly in weight and strength, but a small sinus persisted in the wound in spite of frequent dressings. She was discharged seven weeks after operation. Sinus healed at the end of the sixth week. Her general condition at this time was excellent, and she felt as well as at any time during the past ten years. Urea at this time was 1.9%.

SECTION OF TUMOR, CASE II. Note encapsulation; stroma causing nodular appearance; areas of hemorrhage and necrosis; destruction of and encroachment upon renal tissue.

CASE II. By courtesy of Dr. F. S. Watson. Two-thirds actual size. Note the general reniform shape and nodular surface.

Pathological report. — (See plates I and II.) The mass retains the general outline of the kidney. It measures 12 by 9 by 8 cm.³ The external surface is generally nodular, with many points of injection from adhesions. The nodules vary in size from 3 to 6 cm. in diameter, and compose practically the whole upper half of the kidney. The capsule is thickened and firmly adherent over the nodular area. On section the whole upper half of the organ is occupied by a new growth, except for a small bit of renal tissue at the very tip. There is one large calyx in the lower half from which pyramidal tissue radiates. This area presents small, yellowish discrete nodules a few mm. in diameter scattered through it, and the cortex is poorly defined. The tumor mass, which occupies the whole upper half of the kidney, extends from just beneath the capsule into the pelvis of the kidney. It possesses a distinct capsule of its own. The tumor is generally yellowish in color, with areas of hemorrhage scattered through it. There is an irregular trabeculation of a firm lighter-colored tissue making many small compartments of yellowish or reddish yellow tissue. Some of these areas have degenerated and are soft, but for the most part the growth is firm and elastic. Histological diagnosis: hypernephroma.

CASE III. Man, fifty-two years old, entered the service of Dr. Paul Thorndike, Boston City Hospital, on Jan. 17, 1903. Father died of tumor of the abdomen, about which patient knows nothing. Mother died of cancer of the breast. Two brothers living and well. Patient has always been well. Habits always good. Present illness dates back fifteen weeks, at which time he began to have a dull aching pain across the lower back. Pain was constant and did not radiate. One week later the urine became bloody for forty-eight hours, during which time he passed a good deal of blood and several clots. These clots occasionally stopped the flow of urine and caused considerable pain, referred to the corona glandis. At the end of forty-eight hours the urine again became clear and remained so for three days, at the end of which time he had another attack of hematuria lasting thirty-six hours. Urine then remained clear for eight days and again became bloody for twenty-four hours. After this third attack the urine remained clear for fifteen days, when the present attack began; but this present attack had already existed for four days when the patient entered the hospital. During these attacks of hematuria there was frequency of urination (every ten or twenty minutes), and the passage of clots often stopped the stream of urine momentarily and caused considerable pain, referred to the corona glandis.

Between the attacks there was no frequency of urination, and there was no difficulty in starting the stream, the caliber and force of which were unchanged. The pain in the back usually disappeared with the onset of an attack of hematuria. Patient has never passed any stones or gravel and has none of the usual symptoms of vesical calculus. Has lost ten pounds in weight and considerable in strength during the past four months.

Physical examination shows a well-developed and nourished man with a dark but anemic skin, and a nervous temperament. Eyes, mouth, neck and thorax normal. Pulses equal, regular and of good volume and tension. Abdomen full, symmetrical, soft, tympanitic, not tender. Nothing abnormal found. Neither kidney could be felt; no tenderness nor spasm on deep palpation on either side. Urine at entrance was bloody, neutral, 1,008; albumen, a large trace; no sugar; urea, 2.02%. Much normal and abnormal blood and a few large squamous cells. White count, 12,000. Soft rubber catheter, 18 French, could be easily passed into the bladder, and bladder washed clear from blood, which showed that if the bleeding was from the bladder it was slight. The bladder capacity was about 11 ounces. The stone searcher revealed no stone and was followed by no increase of hemorrhage. The hematuria continued for four days after entrance, and he passed many clots, which were worm-like in shape, of small caliber, and varying in length from 1 to 5 cm., and were believed to be ureteral casts. During these four days of hematuria the twenty-four hours' amount of urine varied between 20 and 30 ounces, and was voided in small amounts about every hour. During the twenty-four hours after the disappearance of blood from the urine the patient experienced no lumbar pain, and the amount of urine jumped to 44 ounces and the urea 3.3. During the next twenty-four hours the urine again dropped back to 26 ounces and the pain returned to the back, but no blood appeared in the urine.

At this time the cystoscope showed a normal bladder wall with no areas of hemorrhage, no evidence of new growth, and no foreign body in the bladder. From the left ureteral orifice there projected a worm-like piece of blood clot about 2 cm. in length. The right ureteral orifice ejaculated a normal-colored urine at the usual rate. About six hours after the cystoscopy the urine became bloody, and contained an ureteral cast about 5 cm. long. Bleeding continued for about ten hours, and then ceased. The following twenty-four hours' amount was 20 ounces. Another cystoscopic examination five days after the first showed the same general features. There was no urine being ejaculated from the left ureteral orifice, and the right ureteral orifice was normal in appearance and ejaculated a clear urine. At this examination a segregator was introduced into the bladder and no urine obtained from the left side. That obtained from the right side was only tinged with blood, which was probably due to the previous examination.

Operation, Dr. Paul Thorndike. Left lumbar incision. Kidney found moderately adherent to the surrounding fat, from which it was separated and delivered into the wound. It was not enlarged, but presented several small nodules on its surface. One of these was cut across and a diagnosis of new growth was made. The pedicle of the kidney was clamped and the vessels tied separately and *en masse*, and the organ removed. External wound closed with interrupted chronic gut sutures, except for a an opening at the lower end of the wound, through which an iodoform wick was carried down to the stump of the renal pedicle. Time of operation, thirty-five minutes. Salt solution 1,000 c.c. subcutaneously immediately after operation. Wick removed two days later. No further blood in the urine. Urea twenty-four hours after operation was 2.9%. Twenty-four hours' amount of urine, from 20 to 37 ounces. Patient felt from the first that he was going to die, made no effort to rally, took his nourishment badly or not at all, gradually grew weaker, and died a week after operation. No obvious reason for death could be discovered.

Pathological report. — (See Plate III.) Gross specimen retains the general, normal shape of the kidney. The mass measures 12 by 6 by 5 cm. and weighs 142 gm. The surface is smooth and brownish in color. In the upper pole is a conical elevation 1 cm. above the surface and 3 cm. in diameter. It is covered with kidney capsule and is firm to the feel. The capsule strips easily, leaving a smooth surface everywhere except over this elevated area, where it is closely adherent, and when torn away leaves a firm, white, fibrous tissue beneath. On section the cortex is distinct and is slightly thicker than normal. In the upper pole, in the region occupied by a new growth, it is destroyed.

The pyramids are distinct, but those in the upper pole are destroyed by an area of new growth. This area is

CASE III. Four-fifths actual size. Note sub-capsular site; definite encapsulation; areas of hemorrhage and degeneration.

5 cm. in diameter, almost spherical in shape, generally yellow in color, and is definitely encapsulated by fibrous tissue 3 mm. in thickness. Throughout this area runs a thick stroma with areas of hemorrhages varying from .5 to 1 cm. in diameter, and with other smaller areas of necrosis scattered through it. The pelvis of the kidney is somewhat enlarged, and has thinned walls. Histological diagnosis: hypernephroma.

Since Grawitz' articles in 1883 and 1884, numbers of these and similar cases have been reported by French and German writers, but most of them have served as examples illustrating points in a varied controversy of a histological character, and although many of the cases have been reported with great care and detail, the literature of the subject up to date remains distinctly histological in character, and no efforts have apparently been made to indicate and formulate a clinical picture which may perhaps prove of diagnostic value. It seems proper, therefore, to make a brief résumé of such symptoms in this paper, and to base it upon the histories of reported cases as well as upon the three instances included in these pages. The symptoms which at once call themselves to our attention in these

cases are, recurrent attacks of hemorrhage associated with frequency of urination, and often profuse enough to lead to the passage of clots, which in their journey down to the bladder sometimes get caught, stop the stream of urine (often for hours or days, as shown by diminishing amount of urine) and cause pretty severe pain, usually referred to the corona glandis. Between these periods of hemorrhage are periods characterized by no frequency of urination, but by a diminished amount of urine and urea, and a marked pain in the back, persisting continuously and disappearing only with the onset of a new attack of hematuria. This condition is in marked contrast to the pain in cases of renal calculus. Calculus pain is, of course, coincident with the blood which the irritation of the calculus causes. This alternation of periods of hemorrhage and frequency with periods of no hemorrhage and no frequency, but of marked pain in the back, have seemed both distinct and constant enough to merit mention and emphasis; and these alternating periods had a beautiful illustration by the cystoscopic views obtained in Case III, where the clot obstructing the mouth of the left ureter could be readily seen, coincident with the sudden cessation of hematuria, marked drop in the twenty-four hours' amount of urine, marked diminution in the amount of urea and a return of the lumbar pain. Then a few hours later there was an equally sudden return of the hematuria and the passage of a ureteral cast of blood clot.

Stained with methylene blue and eosin. X 25 diam. Note thin capsule with lymphoid cell infiltration below; wide vascular spaces; general tubular or adenomatous appearance; areas of degeneration above (pale staining).

Stained with methylene blue and eosin. X 80 diam. Note vascular stalks; tubular appearance emphasized by lighter spaces (in part due to cell degeneration) lying outside well-nourished cells immediately facing capillaries.

Stained with methylene blue and eosin. X 200 diam. Note oval or polygonal shape of cells; preservation of their rim of cytoplasm; deeply staining nuclei sometimes lying upon cytoplasm threads; the perinuclear, lightly staining spaces, often filling the whole cell, and somewhat characteristic of hypernephroma.

The accompanying plates illustrate beautifully characteristic points of both the gross and microscopic pathology of these growths. These points, already mentioned in the text, are briefly as follows:

(1) An affected kidney may not be much increased in size, but is generally very large.

(2) The general outline of the organ is usually retained, and the surface is almost always nodular, although occasionally there is no external evidence of the growth.

(3) The new growth is either encapsulated within the kidney substance or just below the kidney capsule.

(4) On section the tumor tissue is generally yellowish, with a firm and distinct stroma, which gives the growth a nodular appearance. Some of these nodules usually show areas of hemorrhage and degeneration.

(5) The kidney tissue is either destroyed or pressed upon and distorted by the new growth.

PAPILLARY ADENOCYSTOMA OF THE THYROID AND ACCESSORY THYROID GLANDS.*

BY HARRY C. LOW, M.D., BOSTON,

From the Pathological Laboratory of the Boston City Hospital.

THE papillary tumors of the neck are of great importance to the surgeon, on account of their tendency to rapid local recurrence. Their histological development and their point of origin have been the source of much discussion. The six cases reported here are interesting in showing a true papillary adenocystomatous growth originating in the thyroid tissue from three different sources, namely, the thyroid gland itself, lobules of thyroid tissue directly connected with the gland, and accessory thyroids entirely separate from the thyroid itself.

The name accessory thyroid is used to designate those small isolated masses of true thyroid tissue which often occur in the neck near the thyroid gland. They are apparently similar to the accessory spleens found in the neighborhood of that organ.

These bits of thyroid tissue are liable to occur, as the diagram shows, either running up from the isthmus, representing persistent bits of the pyramid of Lalouette, or as the remains of extensions from the inferior or superior horns, or just posterior to the lateral lobes, lying alongside the pharynx and esophagus. Occasionally they may occur at the root of the tongue, within the larynx or even further from the main gland. In the examination of five hundred cases Gruber [3] found that the occurrence of accessory thyroids was approximately as follows — the superior was present in one out of twelve individuals, the inferior in one out of ten, and the posterior in one out of five. The accessory thyroids are histologically like the thyroid gland, and are not to be confused with the parathyroids, which are of very different structure. We must also distinguish the true congenital accessory thyroids from lobules of thyroid tissue, which may be the seat of encapsulated tumors analogous to the pedunculated tumors of the ovary. Berry [1] thinks that most of the so-called tumors of an accessory thyroid have, in reality, developed in the thyroid gland itself, and are connected with the main organ by a more or less well-defined pedicle. The anatomical studies of Paltauf [4] and Gruber [3] seem to support this view.

The accessory thyroids have been recognized as possible points of origin for all the different varieties of tumors, which may affect the thyroid gland itself, at least since Schlütter [5] in 1857

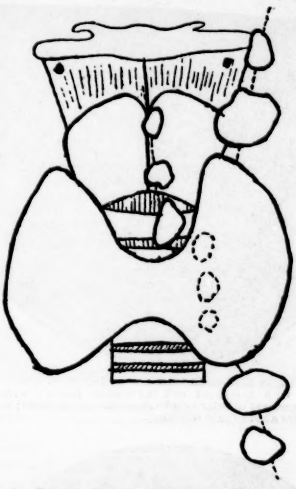

FIG. 1 (after Berry). Larynx, trachea and thyroid gland, showing (on the left side only) the most common position in which the accessory thyroids are found.

wrote "De Struma Cystica Accessoria." Virchow,[6] Schnitzler,[7] Braun,[8] Hinterstoisser,[9] Madelung [2] and others have also reported cases of tumors of the accessory thyroids.

The thyroid tissue may be the seat of neoplasms, which differ widely in histological structure. Hinterstoisser [10] recognized 17 kinds of malignant goiter in 50 cases. We must distinguish those cystic goiters, resulting from softening or hemorrhage in a simple adenoma, followed by secondary papillary ingrowths from the cyst wall, which only occupy a small part of the cyst cavity, from the true papillary adenocystoma of the thyroid. Some of the forms of fetal adenomata, which show only a very slight tendency to papillary formation in small areas, cannot be considered as truly belonging to this type of tumor.

Although I have reported this first case before,[11] it is included here to show the relation of this series of cases to the thyroid gland.

* Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital.

Case I. S. 01.340, female, forty-nine years old. Admitted to hospital May 28, 1901. Patient had much trouble from sore throat about twenty-five years ago, and since then her neck has remained swollen. Year after year the tumor gradually grew in size, but more rapidly in the last two years, until it now occupies the whole front of the neck. During the last seven years she has had more or less discomfort at night, with stiffness of neck, and has had some palpitation, no headache or dizziness, no loss of weight, no difficulty in breathing or swallowing.

Operation by Dr. F. B. Lund. After peeling back the skin and platysma, and ligating the superior and inferior thyroid arteries on the right, the capsule of the cyst, which was covered with numerous large veins, was incised and the tumor quickly and easily enucleated. It formed nearly the whole right lobe of the thyroid. The patient made a rapid recovery.

Pathological report. The specimen, which has been cut in halves, consists of a tumor mass weighing 680 grams. It measures 11 x 12 x 9 cm. It is covered with a firm fibrous capsule. There is no apparent point of attachment. On section a moderate amount of thin, colorless fluid escapes. There are a great many cystic spaces separated with white fibrous walls. These spaces in many places contain clear fluid. The cut surface is divided by broader fibrous bands into rounded areas, which are subdivided by thin fibrous walls. A greater part of these small alveoli are filled with soft yellowish material, which stands above the surface like small plugs. In the center the cysts are large and filled with fluid. The papillary structure is very evident.

Microscopical examination. The capsule is formed of dense fibrous tissue. The growth consists entirely of large and small cystic spaces filled with papillary ingrowths and occasional small areas of simple adenomatous structure.

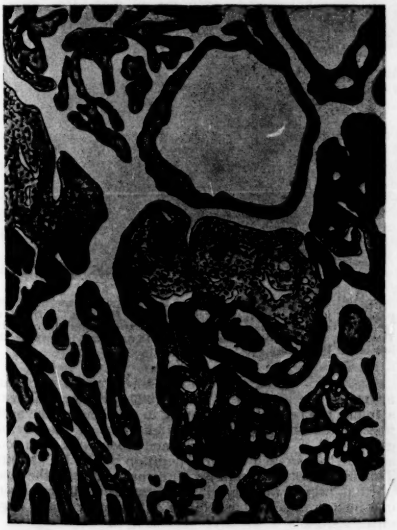

Fig. 2. Typical papillary growth in Case I. Cells mostly like those of normal thyroid. Occasional colloid follicles. In the center are seen some of the large cylindrical cells developing next to the low cuboidal epithelium.

These cystic spaces are only separated from one another by a very thin wall, and intercommunicate to form larger, irregularly lobulated spaces, much more than is evident in the cross section. Most of these spaces and follicles are empty, having been filled with clear mucoid fluid. Very rarely there is seen a follicle lined with flat, poorly developed epithelium, and containing eosin-staining homogeneous material, which is colloid.

The cystic spaces, the papillary ingrowths and the simple follicles are all lined with a single layer of epithelium. This is in most places normal, healthy looking thyroid epithelium of the cuboidal type. There are however, numerous places throughout the growth where the lining of the papillæ suddenly changes in type, and next to the cuboidal epithelium we see a profuse growth of cylindrical epithelial cells (see Fig. 3). Instead of the smaller cell, with its round nucleus, we find a cell three times the size, rich in protoplasm, and containing a single large oval vesicular nucleus, in which there are numerous chromatin granules. There are some small follicles, showing the same size of epithelium, and between them occasionally there is a small solid group of large epithelial cells. Mitotic figures are not numerous in these cells. The illustrations of this tumor show both these types of growth.

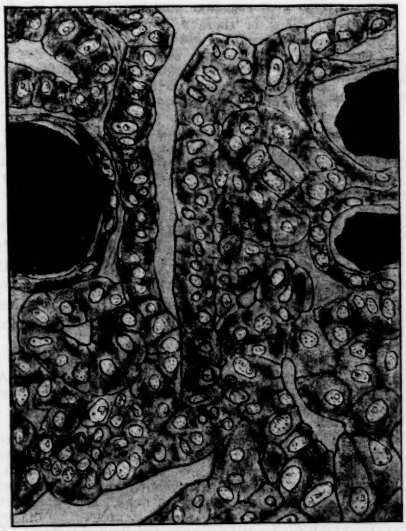

Fig. 3. Part of Fig. 2 more highly magnified. Characteristic proliferating cells of Case I, having large vesicular nuclei and much cytoplasm. Some colloid follicles distended and lined with the very low epithelium typical of the "colloid goiter," and other smaller follicles lined with normal cuboidal epithelium.

There is very little stroma throughout the growth, and it shows only in places slight hyaline and myxomatous degenerations, though it is often considerably distended with fluid to form edematous tissue in large areas of the tumor. The blood vessels are fairly numerous and their walls show very little change.

The second case is similar to the first, but not nearly as extensive.

Case II. S. 02.309, female, forty years old. In the hospital in May, 1902. Eighteen years ago noticed slight swelling in her neck, which has increased very slowly, but has caused no especial inconvenience until the last six weeks. At this time she had a sudden attack of suffocation. For an hour she had great difficulty in breathing. No trouble since. No exophthalmos, nor tachycardia.

Some hard nodules could be felt in the region of the isthmus, and in the right lobe were other hard nodules.

Both lobes seemed to be enlarged to twice their normal size. Operation by Dr. J. C. Munro. Ether at first produced marked strangulation, so chloroform was used, with the patient in erect posture. Upper and outer portion of right lobe was partly freed and the apex left behind. Isthmus firmly attached to the trachea, which was found to be pinched to a narrow triangle by the gland, and after freeing it, respiration improved much. Upper portion of left lobe was not removed.

The specimen removed consists of three portions of grayish-red tissue of rather soft, gelatinous consistency, measuring respectively (1) 7 x 5 x 4 cm.; (2) 5 x 4 x 2 cm.; (3) 6 x 3 x 2 cm. On section grayish nodules are revealed, averaging from 1 to 3 cm. in diameter and being somewhat more firm than the rest of the tissue.

Microscopical examination. There are various nodules separated from one another and the surrounding glandular tissue by broad connective-tissue septa. The follicles of the thyroid gland are apparently normal, moderately dilated and filled with colloid. Most of the nodules consist of an adenomatous growth. The follicles vary in size, some being filled with colloid, many having little or no central spaces, and being lined with rich epithelial cells, having large oval vesicular nuclei. There are in places small collections of these cells forming an apparently true adenocarcinomatous growth.

One of the larger nodules, separated from the rest by a wall of fibrous tissue, is almost completely filled with closely packed papillary ingrowths and a few single follicles. These papillæ branch very complexly, and are covered by a single layer of high epithelial cells. There is an occasional follicle containing colloid. The stroma of the capsule and papillary masses is infiltrated with plasma and round cells. This part of the tumor shows a similar and nearly as complex papillary growth as was seen in the first case.

In the third and fourth cases the tumors probably developed either from a lobule of thyroid tissue, or having developed in the gland itself have become pedunculated as they increased in size and pushed out from the gland. At least in these two cases the growths were in direct connection with the main organ.

CASE III. S. 02.359, male, forty-six years old. Admitted to hospital in June, 1902. Tumor has been growing gradually for nine months. It has caused no subjective symptoms.

On the right side of the neck, just opposite the cricoid cartilage, between the anterior edge of the sterno-mastoid muscle and the median line, is a swelling one inch in diameter. It moves distinctly with deglutition. Operation by Dr H. W. Cushing. A dense, firm tumor very adherent to the thyroid gland was exposed. With considerable difficulty it was separated from the gland. The specimen consists of a mass measuring 3.5 x 3.5 x 2 cm. It is firm, nodular, and deep red on the surface. On cross section it is yellowish gray, soft, granular, and pulpy. There are many fibrous bands throughout the growth.

Microscopical examination. The growth consists of many large and small cyst spaces separated with broad bands of connective tissue. These spaces are filled with very numerous, irregular papillary ingrowths, and occasional scattered follicles containing colloid. The epithelial cells of the growth form a single layer covering the papillæ and lining the cyst spaces and follicles, but they are mostly two to four times as high as the normal thyroid epithelium, are richer in protoplasm and have large oval nuclei. Some places, however, are covered with low cuboidal epithelial cells. At the border the growth seems to be invading the thyroid tissue, which a short distance away appears normal. There are many small alveoli filled with the papillary tumor growth, pushing out into the surrounding tissue. These alveoli have a considerable connective tissue wall, from which there are bands radiating into the adjacent thyroid tissue. There is some infiltration of round and plasma cells into this stroma and in places it shows extensive hyaline degeneration. Throughout the growth there are all kinds of epithelial cells forming a gradual transition between the lowest cuboidal and high columnar cell.

The character of the extensive papillary growth in this case is shown in the illustration, which also well represents the structure of the small papillary development in the previous case. The facts that the growth in this third case began as a small nodule at one side of the thyroid gland, and that at operation it was found to be very adherent to the thyroid, make it possible that it may have developed from an accessory thyroid, and later, through some chronic inflammatory process, have become adherent to the main organ; or that it originated in a bit of thyroid tissue that formed a small lobulation of the thyroid. The latter hypothesis seems the most probable.

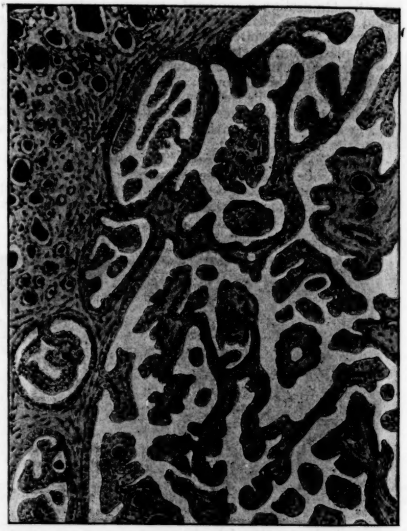

FIG. 4. Case III, showing part of large cystic space filled with papillary growth and scattered colloid follicles, surrounded by much connective tissue infiltrated with round and plasma cells. There are also smaller spaces filled with papillary growth in the border of the tumor.

CASE IV. S. 02.246, female, thirty years old. Admitted to the hospital in April, 1902. For several years a tumor has been slowly growing in the front of the neck, just to the outer side of the right lobe of the thyroid gland. It is freely movable, and about one inch long and one-half an inch wide. Operation by Dr. J. C. Munro. Tumor enucleated except for a narrow pedicle at the inner portion, which was ligated with catgut. A cyst about one inch in diameter developed at the inner lower angle of the right lobe of the thyroid close to the isthmus.

The specimen removed was a mass of soft red tissue, the size and shape of a pecan nut. Surface dark red, dotted with small black areas, size of a millet seed. Cut section is pale gray, soft and moist. Bands of fibrous tissue run in various directions, but otherwise the cut surface is for the most part homogeneous. There are several areas of soft, granular, yellowish white material.

Microscopical examination. There is a definite connective tissue capsule surrounding the growth. The periph-

ery is a simple adenoma with a small amount of stroma, in which are numerous small blood vessels. The adenomatous structure shows various types: a few moderately large follicles containing colloid, many smaller follicles with small lumen and no colloid. Between these are all gradations. These spaces are all lined with a single layer

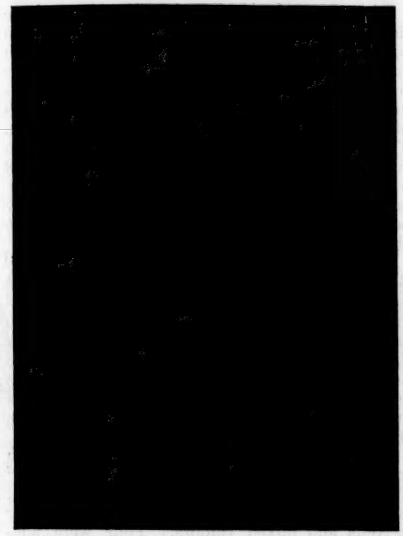

FIG. 5. Case IV, showing the simple adenomatous structure of the periphery, with its small follicles and irregular spaces, and a part of the papillary growths of the center.

of columnar epithelium, which is slightly higher than the ordinary epithelium of the thyroid. Throughout this edematous portion there are long slits or spaces, with a similar epithelial lining, which divide the tissue up into irregular lobes. Near the center these spaces become larger and more irregular, the simple edematous structure becomes less evident and in a major part of the tumor we find an extensive papillary development. The cells covering these papillary masses are very similar to those of the rest of the growth, being only a little larger. They do not show as many variations as were present in the first case reported. There is no stroma in the papillary portion. It contains numerous vessels distended with blood, and is in places edematous. In some of the spaces extensive hemorrhage has taken place. The cyst removed from the right lobe of the thyroid shows several spaces lined with cuboidal epithelium. This was in no way connected with the rest of the tumor.

This tumor, being freely movable and to one side of the thyroid, was found at operation to be connected by a narrow pedicle to the main organ, and has probably developed from lobule of the thyroid gland.

The other two cases are tumors arising entirely separate from the thyroid gland, both of which show a papillary growth almost exactly like that of the first case and occasional colloid follicles.

CASE V. S. 02.680, female, eighteen years old. Admitted to hospital Oct. 10, 1902. First noticed a small lump on the right side of her neck two years ago. This increased in size and became tender and painful. About a year ago it was operated on. Shortly after the wound closed the tumor began to grow again. At present it is tender and painful. On the neck, just behind and below the right ear, is a tumor about the size of an English walnut, which is firm but slightly fluctuant. It is not adherent to the skin, though firmly connected with the deeper structures. Operation by Dr. Paul Thorndike. As the tumor was thought to contain fluid a small incision was made over the mass. On deeper incision considerable hemorrhage occurred. The swelling was found to be a very vascular new growth, with no evidence of suppuration. A very vascular tumor with a definite capsule was then readily freed from the surrounding tissues.

The pathological examination states that it is a firm, oval tumor, measuring 5 x 3.5 x 2.5 cm. There is a distinct capsule closely associated with muscle at one side. On section it is gray with a few small yellowish areas, and one large red area. It is granular and pulpy.

The patient returned to the hospital two weeks later on account of pain in the swelling of her neck. The record says that there is considerable fullness in the right side of her neck, extending from almost the median line to back of the sterno-mastoid muscle. On palpation a smooth elastic mass is felt, made up of several nodules. It does not seem to be in any way connected with the thyroid, trachea or skin. Thyroid gland is apparently not enlarged. Several enlarged glands are felt in the left neck. A further operation attended by considerable hemorrhage resulted in the removal of two very vascular encapsulated tumors. They each measured 4 x 3.5 x 2 cm., and were similar in structure to the one previously removed.

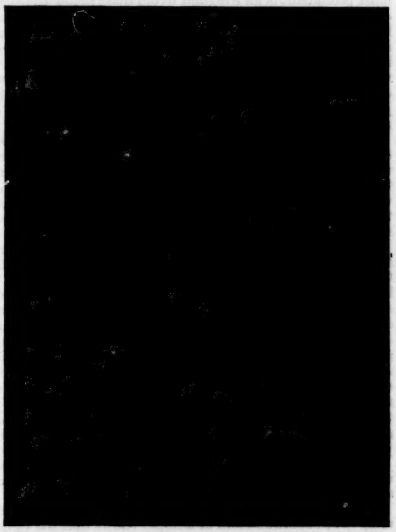

FIG. 6. Case V. Rich papillary growth in numerous small spaces. Cells rapidly multiplying. Many colloid follicles. In upper right corner is part of one of the small areas simulating carcinoma.

Microscopical examination. The tumor is made up of small irregular spaces lined with a single layer of columnar epithelium. Owing to the fact that these spaces are encroached upon by very numerous and intricately branched papillary ingrowths from the walls, they vary infinitely in size and shape. The spaces are either empty or partly filled with mucoid material, and many of the smaller ones contain colloid. In very many places there is considerable proliferation of the epithelial cells between the spaces. These cells are quite large and have large

vesicular nuclei, which occasionally show evidences of mitoses. In some places the lumina of the follicles have become small and are filled with proliferating epithelium, and the growth resembles a true carcinoma with very little stroma (see Fig. 6). The tumor is rich in blood vessels, and shows no evidence of degeneration. Some of the papillary growths in the larger cyst spaces are distended with edema.

Although none of the nodules removed in this case showed lymphoid tissue, it seems probable that at least some of the growth developed by extension to the adjacent lymph nodes, as is evident in the following case. It is rather hard to believe that there were several separate accessory thyroids as points of origin. Gruber [3] in his anatomical notes states that only once in twenty times where the accessory thyroids were found present was there more than one, and he did not in any case find more than two present, these being on opposite sides.

CASE VI. S. 99.470, male, fifty-eight years. Admitted to hospital in August, 1899, in the service of Dr. Paul Thorndike. Two years before noticed a small swelling in the right neck, which has rapidly increased in the last ten months. Larynx and trachea are pushed apout half an inch to the left side. Entire side of neck is now occupied by four definite and distinct tumor masses. The most prominent is an irregular ovoid mass below the angle of the jaw. Next largest is below and towards the median line and less movable. Two other smaller ones are just above the anterior third of the clavicle. In the left neck is an indefinite tumor the size of a cherry. The skin is not adherent to these growths. The general enlargement of the axillary, epitrochlear and inguinal lymph nodes justified the clinical diagnosis of Hodgkin's disease or malignant lymphoma.

At operation an ovoid nodular mass of fairly firm consistency, measuring 9 x 5 x 3 cm., was removed. There were certain nodules that had a firmer consistency than the rest of the mass. The cut surface was dark red, somewhat soft and granular. The patient failed rapidly during the operation, which was stopped, and he died in a very short time.

At post-mortem examination the right side of the larynx showed a shallow depression from pressure of the growth. On the right side of the trachea and closely adherent to it is an enlarged gland extending from the cricoid 6 cm. downwards. The trachea is not distorted. Below this and anterior to the trachea, not closely adherent to it, and not invading the surrounding tissues, are two other glands, one measuring 3 x 2.5 x 2 cm. and the other slightly smaller. They are symmetrically enlarged, firm and non-fluctuating. On section the surface is pinkish gray, granular and very friable, and the soft material is easily scraped off with a knife. There are two more glands about the size of the others beneath the sutured wound. One is firm and the other hemorrhagic and pulpy. The examination of the viscera shows nothing of unusual interest. The inguinal lymph nodes are the seat of an acute inflammatory process.

The microscopical examination of the new growth removed at operation and at autopsy shows that the tumor is made up of several very large cystic spaces surrounded by thick vascular connective tissue bands, in which there is considerable infiltration of lymphoid and plasma cells. These spaces are completely filled with a very intricately developed papillary growth. There is a moderate amount of stroma. The lining of the spaces is made up mostly of high columnar epithelium, but in places there is a low, flat epithelial layer. Very rarely there is seen in a section a few small round spaces surrounded by a thin layer of protoplasm. In one section was seen a group of 8 or 10 of these spaces lined with a definite cuboidal epithelium, and apparently filled with colloid. In the surrounding connective tissue capsule there are small spaces with papillary ingrowths and other alveoli filled with large epithelial cells.

Some of the lymph nodes removed at the autopsy are invaded by a new growth of similar nature consisting of cysts filled with a delicate branching papillary growth. The cysts and papillæ are lined with cylindrical epithelial cells, which have large oval nuclei and finely reticulated cytoplasm. This growth is almost exactly like that in the third case.

There is no doubt that these six tumors have developed either from the thyroid gland or from bits of thyroid tissue. In every one of them true thyroid follicles containing colloid were present, and the growth was made up of cells varying gradually from the typical cuboidal cells of the thyroid to a true cylinder epithelium. The only other tissues in the neck from which such a histological structure could be expected to develop are the remains of branchial ducts, and in that case the epithelium would probably be ciliated and at least would not show the character of the thyroid epithelium.

Gutmann, [12] Koch, [13] Volkmann, [14] Bruns, [15] Berger [16] and others have reported cases that were supposed to be developed from branchial ducts, and some of them showed tendency to papillary formation. Berger and Bruns think that most of them are developed from thyroid tissues, and Gutmann, in writing on the development of the so-called carcinoma of the branchial duct, says it develops from the accessory thyroids, and calls it a struma carcinomatosa accessoria.

It hardly seems possible that this type of growth could develop from the salivary glands. Nasse [17] collects fifty-eight tumors of the parotid gland, mostly endothelioma, angiosarcoma, alveolar sarcoma and mixed tumors. Four were adenoma, but the cells were typical of the parotid and portions of the salivary gland were seen within the capsule of the tumor.

I have found reported in literature only nine other cases which can possibly be called true papillary adenocystoma of the thyroid or accessory thyroid glands. Wolfler [18] in 1883 first described this type of tumor in the thyroid gland. The first case that he reported was operated on by Billroth in 1873, by Wölfler in 1878, 1881 and 1900, and two years ago Smoler [19] wrote the clinical history of the case during the preceding twenty-seven years. It was treated by iodine injections for several years and when first extirpated it was a cyst of the left lobe of the thyroid, one-third of which was filled with papillary ingrowths. It is possible that previous aspiration and hemorrhage had destroyed a much more extensive papillary growth, which may have been originally present. There were recurrences with great papillary proliferation but no metastases. It showed all the three types that he thinks are present in these tumors; namely, normal thyroid tissue, papillary cystadenoma and malignant adenoma, *i. e.*, adenocarcinoma. The chief part was papillary; the epithelial proliferation was in the stroma.

Wölfler's [18] second case was a tumor the size of a man's fist, showing papillary formation in the central part. The periphery was made up of solid cell masses, long cell strands, and some adenomatous structure. There was no recurrence

in this case, as it was probably wholly removed.

Zahn [20, 21] reports two cases; one, in a dog, is uncertain, as the thyroid of the dog normally shows some papillary structure. The other, in a man, fifty-five years old, was of four years' duration and attained the size of an apple. It developed just between the angle of the jaw and the left sterno-mastoid muscle. He describes it with three other cases as developing from a branchial duct, but it undoubtedly originated from a bit of thyroid tissue. Plauth [23] and Smoler both agree with this idea. Both lobes of the thyroid were very much enlarged, causing considerable dyspnea. The adjacent lymph nodes were not affected. The structure was a true papillary adenocystoma.

Jores [22] reports an accessory thyroid tumor of four years' growth, in a man twenty-eight years old. There were four small nodules, two on each side of the sterno-mastoid muscle. They consisted in the periphery of very cellular spaces filled with cylindrical epithelium, separated by a hyaline degenerated stroma. The whole center was made up of rich papillary vegetations covered with cylindrical epithelial cells. There were some follicles containing colloid.

Plauth [23] reports a case in a farmer seventy-two years old, which in three years' duration reached the size of a walnut. The small growth under the chin was treated with iodine injections, and in 1894 was extirpated. It was thought at first to be benign, but on further examination was called a sarcoma or at least a malignant growth. The cyst wall was probably not wholly removed, and it refilled with blood in two months. In January, July and December of 1895 there were further operations for other small nodules. The several nodules removed were each surrounded by capsules of connective tissue infiltrated with round cells. Cross section showed papillary ingrowths into the large cysts and in the walls numerous small cysts filled with papillary vegetations. So he considers it a multilocular cyst, the large cysts being formed by the confluence of the smaller ones and distended by hemorrhage. He thinks this tumor has developed from thyroid tissue and Smoler also includes it in that class, though he says one cannot state positively that the starting point was not in a branchial duct.

Kapsammer [24] reports a case of true papillary adenocystoma, probably originating from an accessory thyroid, as the main gland was found to be normal. His illustrations show a growth almost exactly like that in the third case reported in this article. It occurred in a man fifty-eight years old, was of six years' duration and beginning as a small node at the inner end of the clavicle became as large as three men's fists.

Ehrhardt [25] says he has seen two cases of tumors of the thyroid in which the whole growth has become a conduit of intercommunicating cysts filled with papillæ. He called them cystocarcinoma papilliferum. Both developed in cases of goiter of long standing, and attained large size. They were malignant adenomata showing some papillary structure. One of these cases recurred and showed invasion of the lymph nodes.

Günzler [26] reported recently a case of papillary cystadenoma of the thyroid with metastases in the glands. It is the case of a man twenty-nine years old, who had noticed for two years in his left neck close to the anterior border of the sterno-mastoid muscle a tumor about the size of a goose's egg. Two months after the operation other tumor masses were removed posterior to the sterno-mastoid. These were lymph nodes showing a similar papillary growth. No recurrence had taken place in the following nine months. He calls it a tumor of the thyroid itself, but its situation suggests an accessory thyroid as the point of origin.

Of these nine cases, the first one of Wölfler, and those of Zahn, Plauth and Kapsammer, Jores and Günzler represent perfectly typical papillary adenocystomata, similar to five of the cases reported here.

The cases of Ehrhardt are apparently the same type as our fourth case in which the adenomatous growth is more prominent. The second case of Wölfler is much like a specimen sent me by Mr. James Berry and is really not an adenocystoma. It is true it has a central space or spaces filled with papillary growth, but the structure is more that of an alveolar carcinoma than the adenocarcinoma of this type of tumor. Smoler does not include it in this group. Though it does not fully conform to the type, in showing the three kinds of tissue that Wolfler recognizes as typical of the papillary adenocystoma of the thyroid, I have seen fit to consider it here, as it may represent some stage in the development of these papillary growths.

Several cases have been reported that must be considered doubtful. Pollard's [27] case probably belongs to this group, though he thinks that the papillary ingrowths developed secondarily in the cystic cavity. The cyst was the size of an orange, and the several villous growths only projected in from its lower part. There was, however, another nodule consisting of smaller spaces filled with a branching stroma covered with a single layer of epithelium, and there were occasional follicles containing colloid. Very likely this was a true papillary adenocystoma and in the larger cyst the papillary growth had been destroyed by previous aspiration and hemorrhage, as may have been true in Wölfler's case.

Other cases have been observed and only partially reported by Hinterstoisser,[9] Carranza,[28] Cornil,[29] Sulzer,[30] Barker,[31] Berry [1] and Jackson Clarke.[32] The cases of Hinterstoisser, Barker and Clarke very probably belong in this group but cannot be positively included.

Thus there are on record only 9 cases which can be included in this class: 4 of the thyroid and 5 of an accessory thyroid. The 6 cases reported here make 15 in all. Even considering the rarity of this type of tumor in thyroid tissue and the few cases here collected, there are several points which

we can point out quite clearly as characteristic of all these cases. The slow development and long duration is noticeable in all the cases; those of only two or three years' growth were invariably very small nodules. In none of the cases was there any cachexia. The great rarity of metastases and the tendency to rapid recurrence is very evident.

The question of how in the thyroid, an organ in which during development and post-fetal life there is no cylinder epithelium, a cylinder cell adenocarcinoma develops, is only explained by the supposition that there is a metaplasia of the cuboidal into the cylinder cells. The different kinds of cells shown by these tumors represent all gradations between these two types.

The papillary development in these tumors probably is due to the same conditions as occur in similar tumors of the kidney and ovary. According to Ziegler [33] we may consider the papillary cystic growths in general as tubules or spaces sacculated outwards, leaving thin bands extending into the central space.

Ribbert,[34] however, offers the clearest explanation of the development of papillary growths by showing that this is the only way in which an extensive proliferation of an epithelium can be spread over a large surface so as to receive sufficient blood supply.

Thus we have here a rapid multiplication of the epithelial cells, which receive better nourishment if they do not pile up in several layers, and so this single epithelial layer is folded in and the capillary vessels and surrounding stroma follow these folds to bring nourishment.

After studying these tissues microscopically it seems most probable that Wölfler is right in saying that this hypothesis, that the proliferation of the epithelium takes place first, and the stroma follows it into the papillæ, is true in the papillary adenocystoma of the thyroid. Ehrhardt says he is unable to confirm this view, and that he must conceive the origin of the papillæ as the performance of the stroma. In most of these cases, however, the proliferation of the epithelium is the chief and primary part of the growth and the stroma is very poorly developed.

In the fourth case (Fig. 5) we have a growth which perhaps may be said to be becoming papillary, showing as it does all the gradations, from the simple round follicles of the adenoma to the long slits, and the very irregular cystic spaces. The structure of this tumor would suggest that the papillary development was here the result of a rapid proliferation of the epithelium, together with some distension of the follicular spaces with serous fluid; this taking place within a firm capsule necessarily causes the lining membrane of epithelium to be infolded in order to increase the surface which the single layer of cells may cover and still be well supplied with blood vessels. It is true that in all of our cases these conditions were present, and that there is only in places more than a single layer of epithelial cells lining the cyst spaces. If the cells, while rapidly increasing in number, do not pile up in several layers, the surface must be increased to accommodate them and this may possibly explain the development of this system of spaces filled completely by the infolding of the lining membrane, which offers the greatest increase in area possible.

In Figure 4 we see how this infolding is taking place in the small spaces. Their walls may later break down, if there is not too much stroma, adding to the size of the larger spaces. In Figure 6 we have a case where there are many small spaces instead of one large one, and if our hypothesis is correct, this may be due to the greater amount of stroma which is extremely well supplied with blood vessels and has not become destroyed.

The tendency to cyst formation is much increased by this papillary development. The stroma of these tumors is not often the seat of hyaline degeneration; but it is sometimes myxomatous, though not as commonly as in similar growths of the ovary.

It is an open question whether to consider these papillary adenocystomata as typical malignant growths or not. Hansemann [35] only recognizes these growths in the ovary, kidney and testicle, and classes them as malignant.

The malignant tumors of the thyroid are not yet well classified, and between the types of benign and malignant adenoma we find manifold transitions. It is not uncommon in literature to see cases of "Benign metastasis forming goiter" or "Metastasis from normal thyroid." Honsell [36] has collected eleven similar cases. The papillary adenoma of the thyroid belongs between the benign adenoma and the adenocarcinoma. Pratt [37] classes it among the benign growths, calling it mildly malignant. If we compare it with the true carcinoma and sarcoma of the thyroid it is surely mildly malignant. In 94 autopsies collected by Ehrhardt in which there was either carcinoma or sarcoma of the thyroid, there were only 14 cases in which there were no metastases.

There seems, however, to be no histological reason, except their thick capsule, why these papillary growths should not be very malignant. Wölfler [19] expressed much surprise that in the twenty-seven years' duration of his case there had been no metastases. Only three of the cases, however, show metastases: those of Günzler and Ehrhardt, and the last case reported in this article. It may be true that the recurrence in the fifth case reported here and that of Jores, which is similar, were not separate nodules in one or several accessory thyroids but were lymph metastases. As there was no lymphoid tissue present in any of the nodules we cannot say positively that they were metastases. The metastases in this group of tumors were invasions through the lymph channels, and not the blood infections which are by far the most common in malignant thyroid growths. Thus we have a relatively benign tumor which occasionally at some future time may become dangerous, though never leading to cachexia.

The papillary adenocystomata show a certain malignity, in that they tend to recur easily and

very rapidly if they are extirpated and there is even a small bit left behind. Similarly this class of tumors in the ovary, if ruptured within the peritoneal cavity, is liable to scatter the bits of tissue which will lead to a number of new growths on the peritoneum. In operation these tumors should be thoroughly and completely removed, if possible without incising the capsule surrounding the growth. Every precaution should be taken to prevent scattering in the wound bits of tissue which may become the germs of recurrence. Generally the operation is difficult, as the vessels and deep structures of the neck may be involved, and it may be impossible to remove all the new growth. In those cases in which the operation was incomplete, almost every time there has been recurrence. In many cases where a complete enucleation of the growth was supposed to have been done, there has been no recurrence.

INTESTINAL PARASITES IN APPENDICITIS.[1]

BY J. C. HUBBARD, M.D., BOSTON,

Assistant in Surgery, Harvard Medical School; Third Assistant Visiting Surgeon, Boston City Hospital; Assistant Surgeon to Out-patients Free Hospital for Women.

Case I. C. V. C., entered the Boston City Hospital in the service of Dr. Bolles, who permits me to report the case, on Dec. 28, 1902. She was born in Boston and still lived there. She was nine years old. The family history and the previous history were both of no importance. The present illness began five days earlier with a chill, vomiting and abdominal pain, cramp-like in character, localized about the umbilicus. For the previous two days the pain had been less severe but has become localized in the right inguinal region. The physical examination in brief was as follows: Well developed and nourished. Pulse 124. Temperature normal. Apathetic. Facies slightly peritoneal. Heart and lungs normal. Abdomen symmetrical, slightly distended. An area of dullness near the right anterior spine and in the right flank. All the abdominal muscles in a state of spasm. Tenderness slight in the epigastrium and marked in the right lower quadrant but not general.

An immediate operation was decided on and under ether a muscle-splitting incision was made at McBurney's point. As soon as the peritoneal cavity was opened several ounces of creamy pus welled up. Pus wiped away and the pus cavity found not well walled off from the general abdominal cavity. The mesentery of the appendix, which was easily found, was tied off with chromicized gut. The appendix was tied off at its base and cut away. The stump was touched with carbolic acid. The peritoneal cavity was then washed out with many bottles of salt solution. The pus was found to come from the peritoneal cavity generally. Wicks were placed in various directions and the wound was partially closed. The appendix was red, swollen, gangrenous and perforated at one point. It contained two small worms identified by the pathologist as pin worms. The bacteriologist reported staphylococcus pyogenes aureus and bacillus subtilis in the pus.

At the close of the operation the patient was moribund, but rallied under stimulation and lived till the evening of the next day.

Case II. C. H. B., entered the Boston City Hospital March 5, 1903. He entered the service of Dr. Bolles, but came under my care. He was sixteen years old, a painter by occupation. The family and previous histories were unimportant except that he had never been troubled by indigestion. March 1 had an attack of abdominal pain and took some medicine to cause vomiting. The next day he went to the Boston Dispensary complaining of constipation, colicy pain and tenesmus. The examination was negative except for general tenderness over the abdomen. March 3 the condition was the same. Temperature 97 and pulse 120. March 4 about the house all the day till afternoon, when he went to bed feeling worse. Restless and delirious through the night. Abdominal pain more intense. March 5 seen by Dr. Colburn, to whom I am indebted for a large part of the history, and was sent to the hospital immediately. Pulse 130 and temperature 95. On his arrival at the hospital his condition was very critical. There was general cyanosis. The extremities were cold and the abdomen distended. There was general spasm of the abdominal muscles. He was suffering evidently from general peritonitis and although the boy was moribund it seemed best to give him even a forlorn chance, so under very light anesthesia incisions were made quickly through the abdominal wall in several places. As soon as the peritoneal cavity was opened a large amount of purulent material of the consistency of pea soup gushed out. Drainage tubes and gauze wicks were rapidly put in place and an intravenous injection of salt solution given. The patient lived several hours and then died in spite of stimulation. At a partial post-mortem examination a dead lumbricoid worm was found free in the general peritoneal cavity and another half way through a perforation in the appendix.

[1] Read before the Boston Obstetrical Society, Nov. 17, 1903.

While cases of appendicitis are occasionally reported where pin worms (oxyuris vermicularis) are found in the appendix, those with lumbricoid worms (ascaris lumbricoides) are less numerous. The interest in these cases centers about the etiological importance of the parasites, whether they have any direct influence on the inflammation of the appendix or whether their presence is simply a coincidence. They may have the same relationship to appendicitis as any foreign body. A foreign body lying in the appendix may cause appendicular colic due to the muscular contractions in the appendix in the attempts to expel it, or an actual inflammation may be brought about in the following manner: the foreign body irritates the mucous membrane which becoming swollen throws out an increased amount of secretion. As this cannot escape from the appendix, the lumen being blocked by the swelling of the mucous membrane about the foreign body, it distends the organ. The circulation is thus altered and an opportunity offered for the entrance into its walls of any bacteria, with a resulting inflammation. In such cases the inflammation is due to the presence in the appendix of something foreign to the normal contents, a fecal concretion, a worm, etc., and is in no way dependent on the characteristics of that particular form of foreign body. Does the inflammation of the appendix containing an intestinal parasite have any direct relation to that parasite because it is a worm and not a mass of hardened feces and because it has certain definite characteristics and manner of life? While the question is still open for some of the intestinal worms, for others it seems to have been fairly well settled both by the clinician and the pathologist.

Clinically the importance of intestinal worms has been shown by Metchnikoff,[1] who reports the histories of four cases of appendicitis. Most of the four had several recurring attacks of apparently typical appendicitis. Metchnikoff, finding in the stools of the patients either the eggs of intestinal worms or the worms themselves, gave to his cases vermifuge medicines. The cases all recovered, there were no more recurrences and when the series was reported the patients had been free from any suggestive symptoms for some length of time. He feels so strongly the importance of these worms as an etiological actor in appendicitis that he advises the examination of the stools in doubtful cases of appendicitis and as a routine practice in children, that the worms may be destroyed in time to prevent an attack.

The parasites most commonly found in cases of appendicitis and general peritonitis are trichocephalus dispar, ascaris lumbricoides and oxyuris vermicularis. While the first form of worm is not as common as the other two it was found in 23 soldiers out of 59 who were returned from the Philippines to the United States government hospital for the insane and examined for intestinal parasites.[2]

[1] Bull. Acad. d. Med., Paris, 1901, 3 s, xlv, 301.
[2] Med. Record, Aug. 8, 1903.

The proof of the definite relationship of cause and effect between trichocephalus dispar and appendicitis has been shown by the work of Askanazy.[3] He published in 1896 an article on the source of the food supply for this worm. Examining the worms microscopically, he found in them a substance which reacted to the test for iron and which originated he felt sure in the hemoglobin of the host. To get this food the worm must necessarily suck the blood of the host. He noticed that often at autopsy a worm was so firmly adherent to the mucous membrane that attempts to dislodge it resulted in either tearing the mucous membrane or breaking the worm. Hardened specimens showed that a greater of less part of the worm disappeared into the mucous membrane. Microscopic examination of sections showed that the worm had bored its way into the mucous membrane and had not simply entered a pre-existing opening. These wounds of the mucous membrane then may allow the entrance of bacteria. Girard[4] has demonstrated this very prettily. The case was that of a child of eight years who developed symptoms of peritonitis, the localizing signs being on the left side. The peritoneal cavity was opened, allowing the discharge of a sero-purulent fluid. The appendix appeared normal, but was removed as a precautionary measure. It was hardened and then cut into sections. By this two trichocephali were found. Girard describes the sections as follows: " The appendix is absolutely healthy in appearance. There is no trace of either old or recent inflammation anywhere except at the point where the extremity of the trichocephalus has penetrated into the mucosa. At this point there is a zone of inflammation. A large number of mono and polynuclear leucocytes are seen, some among them showing destruction of nuclei. In the midst of cellular detritus are bacteria, streptococci and colon bacilli. The inflammation around the tricocephalus is then due to the introduction of the intestinal microbes by means of the nematode." In this case an active inflammation was set up about the parasite due directly to it as a living worm leading its own individual life. It follows therefore that a trichocephalus may furnish the primary and direct cause for an attack of appendicitis.

The proof that ascaris lumbricoides ever causes an inflammation of the appendix as a result of its life struggle is less clear than in the case of trichocephalus. Ascaris is known to often force its way into narrow channels like the appendix and gall duct. When it clogs the lumen of the appendix it acts as I have already shown as a foreign body. I believe that it may do more than this, as it is not an inactive mass. It is very easy to conceive that by its struggles it may perforate a diseased appendix which if it contained a lifeless foreign body would have remained intact. This worm may thus change a comparatively simple case of appendicitis into a very complicated one. The question whether

[3] Deutsch. Arch. f. klin. Med., Bd. lvii, S. 104.
[4] Annals de l'Instit. Pasteur, 1901, xv, 440.

it can perforate a healthy intestine is still under discussion, though a case recently reported [5] seems to show that it may. Askanazy attempted to show the same relationship true between ascaris and appendicitis as between trichocephalus and appendicitis. He found in the intestinal epithelium of the ascaris a substance which reacted to the test for iron as did that in the trichocephalus. He felt, therefore, that this iron came from the blood of the host and that it was fair to assume that the ascaris obtained it by sucking. To suck the blood the mucous membrane must necessarily be wounded and entrance given to bacteria.

When we come to oxyuris vermicularis the proof of its etiological value as a cause of appendicitis other than through its presence as a foreign body is lacking. The pin worm is generally considered an inhabitant of the rectum and lower bowel. That this is not true is shown by the frequency of its occurrence in the appendix in a series of 200 autopsies done by Still [6] on children under twelve years of age. He found pin worms in the intestine in 38 cases, in 25 of which they were in the appendix. In 6 they were in the appendix and nowhere else in the large intestine or cecum. Sometimes they were in the extreme tip of the appendix, as in the case of a boy who died of pleurisy and pericarditis. Before death he complained of pain in the right iliac fossa. At the autopsy the appendix was found thickened and in a condition of catarrhal inflammation. In the distal 2½ inches 111 worms were found. No others were found anywhere in the intestine. Some have thought that oxyuris might wound the mucous membrane of the appendix by its wriggling and thus by furnishing a place of entrance to bacteria cause an attack of appendicitis. This theory as far as I know has not been substantiated by any definite proof and remains therefore simply as an attempt to carry the relation that exists between the other two parasites and appendicitis to oxyuris vermicularis.

Conclusions. — An intestinal parasite causes appendicitis through its presence as a foreign body; and by its struggles may bring about a perforation and peritonitis where otherwise none would have occurred.

Trichocephalus dispar has been proved to cause an inflammation of the appendix by injuring the mucous membrane while sucking the blood of the host.

Ascaris lumbricoides has been found with a material similar to that in trichocephalus in its intestinal epithelium and therefore is supposed to attach itself to the mucosa of the host and thus start the processes which result in appendicitis.

Oxyuris vermicularis. No proof has been found that this worm causes an appendicitis except in its rôle of foreign body.

Clinical Department.

A CASE OF SARCOMA OF THE LOWER JAW.[1]

BY F. B. LUND, M.D., BOSTON.

THE accompanying case is reported in order to illustrate the slight amount of deformity which results from subperiosteal excision of the body of the lower jaw, from the lateral incisor tooth to the angle. The patient, a young girl of thirteen, was operated upon on the 16th of July, 1903, for a sarcoma of the lower jaw, which began in the medulla, had caused a fusiform swelling of the lower jaw, had forced its way upward through the alveolar process and grown up into the mouth

[1] Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital.

Case of Sarcoma of the Lower Jaw.

Case of Sarcoma of the Lower Jaw.

as a papillary growth which had been considered an epulis. The anterior molars and rear bicuspids had been pushed inward and loosened by the growth. The patient was etherized, and the portion of the tumor projecting into the mouth removed with scissors, and examined by the microscope, proving to be a giant-celled sarcoma. An external incision was then made along the body and angle of the jaw, the facial artery divided, the periosteum peeled from the entire body of the jaw and the jaw divided by a saw and cutting forceps just anterior to the socket of the canine tooth in front and at a point on the ramus of the jaw level with the alveolar process behind; the submaxillary gland was removed; the lingual and hypoglossal nerves were exposed during the operation and the latter, having been partially divided, was sutured with fine silk; all suspicious bits of tissue were cut away, divided muscles and deep tissues sewn with catgut, and the skin incisions with a subcutaneous horsehair suture; the mucous membrane was sewn inside the mouth with catgut. The patient made an excellent recovery from the operation, but the wound suppurated, undoubtedly owing to the infection from the mouth, and had to be drained. It finally healed well, however, and the periosteum has evidently replaced the lost bone to a very considerable extent, as a firm, bony bar can be felt in the place of the bone which was removed. The photograph shows that the deformity on front view is very slight; the scar on lateral view is rather deep and conspicuous, but will fade out considerably in time, after which the deformity on side will be much less marked.

CHRONIC CYANOSIS FROM ACETANILID POISONING.

BY J. N. HALL, M.D., AND H. R. MCGRAW, M.D., DENVER, COL.

IN view of the cases of "Chronic Cyanotic Polycythemia" reported by Hall in *American Medicine*, June 27, and of Chronic Cyanosis with Polycythemia and Enlarged Spleen," by Osler, in the August number of the *American Journal of the Medical Sciences*, these cases of cyanosis of drug origin are of especial interest. Dr. Osler has informed me that he has recently seen such a case from the use of bromo-seltzer, well known to contain acetanilid, which was mistaken for the newly described disease.

The patient was a professional man from a western state, fifty years of age. He stated that he had had bleeding piles for thirty years, during which time three ischio-rectal abscesses had been opened. He had been generally constipated. Although decidedly sallow at times he has had no real jaundice. He stated that his present trouble dated from the use of large doses of acetanilid for headache, begun six months or more ago. It is probably safe to estimate that he had taken 30 to 40 gr. daily for this period. There was no history of alcoholism. His weight had fallen from 160 to 140 pounds. He felt weak, and suffered from dyspnea, and from palpitation on exertion. Digestion was poor, with occasional vomiting of mucus. His face was slaty in color, and much darker than the cyanosis of advanced emphysema. The mucous membranes were similarly discolored, and the skin of the body to a lesser extent. There was no increased pigmentation over the joints and bony prominences, as in Addison's disease. The color lessened upon pressure, but immediately returned. The temperature rose to about 102° daily. The physical examination was negative so far as the chest and abdomen were concerned. Pulse moderately increased in frequency, and of fair quality. The pupils were somewhat contracted. Several bleeding hemorrhoids and a blind rectal fistula were found by Dr. Sherman T. Brown.

The blood was very dark, with 3,038,000 reds and 18,000 whites. Moderate poikilocytosis existed. The increase in the whites was in the polymorphonuclear leucocytes, doubtless explained by the rectal trouble. The reds were pale, and had a "brittle" appearance. The test with Fleischl's hemoglobinometer gave 30% of coloring matter, though this was chiefly methemoglobin, probably. No spectroscopic examination was made.

The urine had a specific gravity of 1,022, no sugar nor albumen. Its color was dark, and the patient stated

that it was always darker when he used much acetanilid than at other times, evidently from excess of coloring matter from the destruction of blood cells. Its odor was strong. No pathological sediment was found excepting a few bacteria at a single examination.

Iron, arsenic and strychnine were ordered, with nutritious diet and rest. The acetanilid was stopped. The operation upon the hemorrhoids, which the patient desired immediately, was forbidden until the blood condition became more favorable.

The improvement was continuous and rapid, doubtless helped as much by the cessation of use of the drug as by the other treatment. The fever subsided within two weeks. We believe it to have been due chiefly to the rectal condition, although doubtless the damage to the heat-regulating mechanism by the antipyretic played a part in the production of the fever. On the fourteenth day the hemoglobinometer registered 70, on the twenty-seventh day increasing to 93. The red cells numbered 5,600,000, and were of normal appearance. On the next day Dr. Leonard Freeman operated upon the hemorrhoids and the fistula. The patient went home entirely well a fortnight later, and has remained well since.

Reports of Societies.

CONFERENCE OF STATE AND PROVINCIAL BOARDS OF HEALTH OF NORTH AMERICA.

EIGHTEENTH ANNUAL MEETING, HELD AT BALTIMORE, MD., OCT. 23 AND 24, 1903.

FIRST DAY, MORNING SESSION.

THE Conference met in the hall of the Medical and Chirurgical Faculty of Maryland, and was called to order by the first vice-president, DR. JOHN GUITERAS, Havana, Cuba, in the absence of the president.

An address of welcome on behalf of the Faculty of the University of Maryland was delivered by DR. JOHN F. CORDELL, who in referring to the early medical history of Maryland stated that the Medical and Chirurgical Faculty, organized in 1802, was the first to give its formal endorsement of vaccination. As a matter of equal importance, he mentioned that papers were written in 1807 by John Crawford advocating and favoring the animalcular theory of disease. These papers were published in a non-medical journal, for the reason that no editor of a medical journal at that time would accept them. Crawford was erratic, but considered far ahead of his time. He was the first in any English-speaking country, so far as the speaker knew, to advocate the germ theory of disease. Crawford antedated Lister at least fifty years, as a perusal of Crawford's writings would show.

DR. WM. H. WELCH of Baltimore followed with an address of welcome on behalf of the State Board of Health of Maryland. He said, among other things, there was another name which should be mentioned in connection with the medical history of Maryland — John K. Mitchell, father of Weir Mitchell, whose book on the "Cryptogamic Origin of Malarial Fever" was really a classic. He thought Mitchell's name should be coupled with that of Henle, who forecasted the doctrine of contagium vivum.

The first vice-president responded briefly to these addresses of welcome.

THE ETIOLOGY AND PREVENTION OF INFANTILE DIARRHEA.

DR. JOHN H. MASON KNOX of Baltimore read a paper on this subject. He said no single organism was considered to be the cause of infantile diarrhea until the experimental work of Duval and Basset. Following Shiga's work in 1898 the organism was found to have wide distribution. From year to year the organism had been found to be more general.

Reference was made to the investigations of Flexner in the Philippines in relation to dysentery among soldiers and the Shiga bacillus as a cause of it. Subsequent investigations made by bacteriologists in Germany, China, Constantinople, etc., disclosed the existence and prevalence of this bacillus in epidemic dysentery, so that its pathogenicity was now well established.

At the suggestion of Flexner, the speaker and others undertook a series of investigations at the Wilson Sanitarium, and of 53 cases carefully examined, the Shiga organism was found in 42 in greater or less numbers. Careful clinical examination, however, showed definitely that no one type of the disease could be associated with this organism; that all types of intestinal diseases, common among children in summer, were caused by the same organism. Laboratory investigation had shown two or three types of organism very closely related. Thus far the great majority of cases in babies had been the acid Harris type. At the Wilson Sanitarium the speaker and his colleagues had a series of upwards of 40 cases of infantile diarrhea which were found to have been produced by the same organism, and conference with those who had charge of the cases clinically led him to believe that the conclusions of the clinicians were the same as theirs. It was found that not only during the summer, but in the winter, sporadic cases of infantile diarrhea were associated with this organism. Wolfstein had reported 37 sporadic cases of infantile diarrhea as having occurred in winter, and Basset four cases as having been seen in the Johns Hopkins Dispensary, due to this organism.

Shiga, by the serum treatment, had reduced the former mortality of this affection from 20 to 30% to 10 and even 7%. Of 25 cases treated by injections of serum at the Wilson Sanitarium, some betterment was noticed after the injection in the cases that were seen early, but the improvement was not brilliant or startling. In eight cases the serum had a beneficial action. In connection with the serum there were changes made in diet, and medication was used, so that the results obtained were confusing in their interpretation. In cases of long standing, associated with an inflammatory condition of the intestinal tract, in which there was probably ulceration, blood in the stools, etc., the serum was of no avail. Although the serum treatment was not very beneficial, it was harmless, as no dele-

terious effect was observed in any of the cases. He emphasized the importance of supplying the children of our large cities with pure milk and uncontaminated water.

ARE THE LABORATORY METHODS OF DIAGNOSIS IN INFANTILE DIARRHEA APPLICABLE IN PUBLIC HEALTH WORK?

MR. EDWIN G. SCHORER of Baltimore in a paper on this subject, in referring to methods of diagnosis, said that with the establishment of the etiology of infantile diarrhea, a great step in advance had been made, yet under the present conditions they were not available for or applicable to public health work. This last statement might, however, be limited, inasmuch as a bacteriological diagnosis would undoubtedly be of value in the limited number of persistent cases of diarrhea, and in those in which the antidysenteric serum was to be given. For this purpose the mailing case of Dr. Parks was to be recommended. The fact that, at the present time, the methods were not available for general diagnostic purposes, ought not to discourage any one from complying with any request boards of health might make. Much was still to be learned in regard to the dysentery organism and infantile diarrhea, a good share of which could be furnished by statistics obtained and facts learned from local boards of health.

DR. WILLIAM H. WELCH of Baltimore referred to a point of historical interest; namely, that these scientific investigations in regard to the causal relation of the Shiga bacillus to infantile diarrhea received its initiative and support from the Rockefeller Institute of Medical Research. If one did not see for a moment how the discovery was to be utilized practically, it did not lessen the scientific interest in this great addition to our knowledge.

It was a surprise to him that Dr. Knox had found the organism, which had been proven to be the cause of a prevalent group of cases of dysentery, to be the cause of summer diarrheas of children. One did not think of the ordinary summer diarrhea of children as belonging to the same group of cases as adult dysentery. The organism, Dr. Welch said, must be found in other localities than Maryland in order to demonstrate that it had any causal relation to summer diarrhea of children. Some bacteriologists had found the Shiga bacillus in 90%, others in 60 to 70% of the cases of infantile diarrhea. These various percentages in finding the bacillus might be due to variations in skill or a more careful selection of cases on the part of the observers.

The serum treatment of this disease, according to Flexner, was disappointing. The best results had been obtained in the treatment of adult dysenteries. Instances had been reported by Holt, Thayer and others in private practice where the serum seemed to have had a marvelous effect. The evidence showed, however, that conditions in hospital and dispensary practice were unfavorable for obtaining satisfactory results with serum.

DR. HENRY M. BRACKEN, Minneapolis, Minn., referred to the milk question, saying in the larger cities it was difficult to get a pure milk supply. What was generally known as certified milk was one of the best articles of artificial diet for children. At present much attention was being paid in some cities to securing a pure milk supply by excluding tuberculous cows from dairies. Even this would not insure a pure milk supply by any means. The testing of dairy herds for tuberculosis might be satisfactory to the dairymen and seemingly protect the people, but there were more infants that died every year from impure milk than from tuberculous milk. More attention should be given to the sanitary aspects of the dairy than to the diseased animal. Certified milk and pasteurized milk were as satisfactory articles of diet as could be obtained at the present time.

DR. JOHN N. HURTY, Indianapolis, Ind., cited an instance showing that typhoid fever and dysentery (epidemic) could be conveyed by flies as well as by polluted water.

DR. CHARLES O. PROBST, Columbus, Ohio, considered it very important to disinfect the stools in cases of infantile diarrhea, although Dr. Knox had not referred to it.

He understood Dr. Knox to say that the Shiga bacillus inhabited the healthy intestinal canal, and that under certain conditions of environment it might take on pathogenic properties. He asked whether this was so or not.

DR. GARDNER T. SWARTS, Providence, R. I., understood that the Shiga organism was easily killed in the presence of other bacteria, as the colon bacillus, which was a common inhabitant of the intestinal canal. If the Shiga organism was so easily killed in the presence of other bacteria, why did it prevail so extensively?

DR. S. R. TOWN, Omaha, Neb., concurred in the remarks of Dr. Hurty relative to intestinal disorders being contracted and disseminated by polluted water supplies. He cited an epidemic of diarrhea which occurred in Chicago in the winter, years ago, which was caused apparently by the discharge of a large quantity of surface material into Lake Michigan, producing a large death-rate. The Chicago Board of Health prevented the development of a large number of cases of diarrhea, and typhoid fever secondarily, by shutting off the taps at the public schools, and exclaiming "Boil the water!"

DR. JOHN N. HURTY cited a similar epidemic which occurred in Michigan City, Ind. There were no less than 3,000 cases of diarrhea from polluted water.

DR. HENRY D. HOLTON, Brattleboro, Vermont, thought that infantile diarrheas were considered gastro-intestinal diseases, and that dysentery simply applied to bloody flux, which was not common in infants, but was sometimes seen. He quoted an old practitioner as saying that typhoid fever was the result of drinking low ground water.

MR. FRANK WELLS, Lansing, Mich., said the Michigan State Board of Health had published

a leaflet on the subject of infantile diarrhea as the result of a report made by Prof. Victor C. Vaughan. This leaflet, which had been given wide circulation, advised that all cow's milk given to infants shall be pasteurized. The leaflet was furnished to all of the teachers of public schools in Michigan. It was the duty of boards of health, he thought, to furnish such information to the people.

Dr. Henry Mitchell, Asbury Park, N. J., urged repeated inspections of cases of diarrhea in children and adults, as in cases of typhoid fever. The New Jersey legislature had given the State Board of Health authority to make such inspections. A law had also been enacted that no milk should be sold from premises on which there was an impure water supply. He pointed out how this law could be so interpreted as not to be effectual in its administration.

Dr. Knox, in closing the discussion, emphasized the importance of good milk and pure water for children as well as adults. Common house flies were carriers of disease; they were a source of contamination in many instances. Proofs of this were abundant.

Replying to Dr. Probst, he said the disinfection of stools in cases of infantile diarrhea was as essential as in typhoid fever.

In speaking of dysentery, it was not to be confounded with bloody flux, as intimated by Dr. Holton. He used the term "dysentery" to include those cases in which the Shiga bacillus was found to be present.

He could not answer satisfactorily the question of Dr. Probst relative to the Shiga organism inhabiting the healthy intestinal canal, but hoped Professor Welch would do so.

Dr. Welch said the Shiga organism was not present in normal stools. If it were, it was in such small numbers that it required the most painstaking investigation to find it.

Mr. Schorer cited an instance explaining why the colon bacillus killed the Shiga organism. The organism of dysentery was found in the mucous coat of the intestine, while the colon bacillus might be found in any part of the fecal matter.

(*To be continued.*)

AMERICAN NEUROLOGICAL ASSOCIATION.]

Twenty-Ninth Annual Meeting, Held at Washington, D. C., May 12, 13 and 14, 1903.

(Concluded from No. 22, p. 602.)

Third Day — Thursday, May 14.

THE NEURASTHENIC NEURALGIAS.

This was the title of a paper by Dr. Frank K. Hallock of Cromwell and was based on a study of forty-five cases, with the following conclusions:

Clinically two varieties exist: one is non-objective, the pain existing with very slight or no concomitant physical symptoms; the other is objective, the pain being accompanied by localized symptoms, sensory, motor, vasomotor, secretory, trophic. The non-objective neuralgias may be subdivided into a paresthesic type (distinct from the paresthesic of hysteria, etc.), a spontaneous form with or without an appreciable cause, and a habit form due to an antecedent neuritis. The term "neurasthenic" should, perhaps, be limited to the neuralgias which are non-objective, that is without marked concomitant physical signs. It is often very difficult to distinguish between a neuritis of the sensory nerves and a neuralgia with pronounced local symptoms. The motor disturbance, direct or indirect, is generally more marked in genuine neuritis. Another diagnostic point is the fact that decided variations in the general physical state, as well as psychical influences, produce fluctuations in the pain relatively greater in neuralgia than in neuritis. The pathology of neurasthenic neuralgia is necessarily obscure. The extent to which excitability of the sensory nerves is of central or peripheral origin is hard to determine. Cases with marked local symptoms can best be explained by the supposition of a mild grade of peri-neuritis rather than a neuritis, interstitial or parenchymatous. The pathology of the non-objective neuralgias, if it is to be interpreted *peripherally* and not centrally, is most likely of the nature of chemical stimuli due to localized nutritional and metabolic defects. The neuralgia being considered merely a symptom, the prognosis depends chiefly upon the general physical rallying power plus the type of individual. The treatment consists largely in the regulation of the patient's life, and attending to the underlying neurasthenic state. In the management of the local condition the first requisite is rest, partial or complete, according to the severity of the attack. Later, localized applications of massage, hydrotherapy, electricity, dry hot air, etc., are of varying utility in different cases. Inasmuch as the neuralgia is apt to be obstinate and of prolonged duration it is advisable to teach the patient how to bear pain in the most philosophic manner. Hypnotic suggestion is of great value in certain cases.

Dr. Baker had been accustomed to look upon these cases, especially the non-objective variety of neurasthenic, as being best explained in a general way by nerve starvation and by adding to that the newer concept of nerve poison.

Dr. Langdon considered the differential diagnosis in cases of neurasthenic neuralgia as of very great importance. In his experience, any sensation that can be called a true neuralgia is a comparatively rare symptom in neurasthenia. Pain, and even tenderness of the nerve trunks, often occur in neurasthenia, but such cases belonged to the paresthesias, and some other cause than neurasthenia should be looked for.

Dr. Leonard Weber of New York believed it necessary in every case of chronic neuralgia to investigate as to previous syphilitic infection. In his opinion, no disease was more likely to be associated with neurasthenia in the course of

years than old syphilis, in which neurasthenic neuralgias might occur. As a rule, surgical intervention is not followed by good results.

DR. ANGELL thought it very easy for nervous patients to exaggerate unintentionally the significance of symptoms, especially regarding pain. He agreed with Dr. Langdon that many pain cases are cases of paresthesia.

MODERN THEORIES OF THE EMOTIONS AND THEIR BEARING ON MENTAL DERANGEMENTS.

This was the title of a paper by DR. HENRY UPSON of Cleveland. He concluded that in different forms of sensation the emotional element varies. The special senses and tactile sensibility set up intellectual mental conditions. The pain sense and visceral sensibility have a slight localizing value and an emotional content that varies from moderate pleasure or discomfort to the more marked and definite emotional states; either of these elements may be present without the other, especially in the case of visceral sensibility, which often fills the emotional field of consciousness without percepts of localizing value. The modern view of the emotions as perceptions of altered visceral conditions, at some times due to psychic causes, at others dependent on physical disease of the viscera, functional or organic, is derived in part from medical observations and in turn illumines the field of psychiatry. The viscera constitute the instrument played upon by psychic stimuli, and the brain centers are receiving stations for resulting sensations, present in consciousness as emotions. Certain relations between disease and resulting emotions were briefly considered.

DR. H. T. PERSHING of Denver had recently given attention to this subject with special reference to the treatment of emotional disturbances in neurasthenia and hysteria. It was obvious that the first thing to do is to remove the idea exciting an undesirable emotion. In many cases he found great advantage in teaching the patient to voluntarily suppress the motor reaction peculiar to the depressed emotion, and to voluntarily imitate the reaction of the opposite emotion. He thought many emotional disturbances were due to physical causes.

DR. KNAPP said that in patients who have exhausted themselves in struggling against an insistent idea, it was better to suggest to them to let the whole thing go, and to endeavor to divert the patient's attention, and let the idea come on unrestrained.

DR. BAKER thought it should be a matter of routine to inquire whether the patient has been subjected to shock within recent months, or whether he is under prolonged intense emotional excitement of any kind. The result of the latter condition is direct interference with nutrition.

DR. EDWARD B. ANGELL of Rochester said it was much wiser to get at the obstruction indirectly rather than directly, as it was impossible to argue with a person's morbid notion without emphasizing it.

PARALYSIS AGITANS COMPLICATED WITH DELUSIONAL MANIA.

This was the report of a case by DR. JOHN PUNTON of Kansas City. A man sixty-one years of age, with good family history, was well until four years ago, when he suffered from an attack of grippe from which he recovered a few weeks later. About two years ago he gradually became very nervous, and there was marked muscular rigidity and a fine tremor. He also assumed the attitude and gait common to paralysis agitans, together with the characteristic fancies. These symptoms, together with vasomotor disturbances, continued to develop and grow worse in spite of treatment, which caused him to become quite despondent, and later he presented all the symptoms of true melancholia. Subsequently there was acute mania with mental exaltation, delusions and hallucinations. In April, 1901, he was admitted to the hospital with the typical picture of paralysis agitans complicated with delusional mania. At the end of eighteen weeks he recovered his mental health, but the paralysis agitans had not improved.

GENERAL PARALYSIS WITH FOCAL SYMPTOMS AND ATROPHY.

This was the report of a case by DR. ADOLF MEYER of New York. In a man forty-two years of age, difficulty in the use of the left arm developed slowly, together with inefficiency in work, which finally passed into slight expansiveness, characteristic for general paralysis. Under observation, the difficulty was found to be an anesthesia of the left arm of central origin, leading to deficient use when the eyes were closed, occasional slow twitchings of the left arm and the gradual development of rigidity and spreading of the sensory and motor symptoms over the whole left side; also production of left hemianopsia and increasing dementia. The diagnosis of atypical general paralysis was corroborated by the autopsy, which showed atrophy of especially the posterior part of the right hemisphere without focal lesion, but marked narrowing of the cortex and distention of the ventricles, and contralateral gliosis of the whole left part of the cerebellum, with partial degeneration of the cortex; the histological process was typically that of general paralysis, which was much less marked in the left hemisphere. There was a probability of syphilitic infection nineteen years before the onset. Technically the case showed the decided advantages of injection of the brain with 10% formalin before removal at the autopsy.

GENERAL PARALYSIS WITH FOCAL SYMPTOMS.

DR. A. HOCH of Waverly reported two cases. CASE I. In the course of a year at first repeated convulsive seizures; later, attacks of twitching on the right side; then sudden aphasia with palsy of the right side. Under observation euphoria and general dullness; motor aphasia, paresis and ataxia of right arm, with frequent

twitching. Later, involvement of whole right side. Death in convulsions. Autopsy: — Lesions of general paralysis with much greater involvement of left side; the left hemisphere weighed 112 gm. less than the right.

Case 2. Complained of headache, stupid feeling and inability to express himself; at times irritable. A year later, apoplectiform attack. Following this, persistent paraphasia with difficulty to understand written and spoken language. Appreciation of defect. Hemianopsia. Argyll-Robertson pupil on the right side. General euphoria and irritability. Death in convulsions. Autopsy revealed the usual lesions of general paralysis with more pronounced changes in the left hemisphere, which weighed 120 gm. less than the right.

The last two papers were discussed together.

Dr. Bullard asked Dr. Meyer whether he had found astereognosis or not. He said it was unusual to find cerebellar trouble in such cases in which the hemisphere of the opposite side is affected. In the reports of autopsies of feebleminded, this seems to be the ordinary occurrence (in which one hemisphere is more especially affected), to have the opposite cerebellar hemisphere likewise affected.

Dr. Meyer replied that he did not speak of astereognosis on account of the presence of anesthesia. He was inclined to utilize the case in corroboration of his view that the anterior central convolution is the essential motor region, plus, of course, some immediate sensory activity, but that the parts behind the Rolandic fissure are essentially reception stations also of influence in the work.

DOUBLE OPTIC NEURITIS WITHOUT ASSIGNABLE CAUSE.

Dr. Howell Pershing of Denver reported a case of this character in which the course was acute, and when the neuritis began to subside, it subsided rapidly in one eye while it advanced in the other. The patient was otherwise in perfect mental and physical health.

Dr. Patrick had seen a case of typical choked disk due to simple chlorosis, the patient making a complete recovery under treatment for the chlorosis.

Dr. H. K. Mitchell of Philadelphia mentioned the case of a girl seventeen years of age who made a perfect recovery from a pronounced double optic neuritis with apparent meningeal symptoms.

Dr. Bullard expressed the opinion that in many of these cases there might be a certain amount of hydrocephalus.

DEVELOPMENT OF THE NEURO-FIBRILS IN THE NERVE CELL.

Dr. Stewart Paton of Baltimore exhibited microscopical specimens illustrating the development of the neuro-fibrils in the nerve cells. He explained that they make their appearance in the nerve cell of the embryo, first in the apical processes, and about the time of birth can be stained in the cell bodies in the larger cells of the cerebral cortex. They develop later than do the Nissl bodies. He also demonstrated their degeneration in pathological processes.

Dr. E. W. Taylor said that the work of Dr. Paton was new in this country. He thought it a matter of very great importance as to whether we can attribute any definite significance to the alteration found in the neuro-fibrils.

ELECTION OF OFFICERS.

The following-named gentlemen were elected for the ensuing year: President, Dr. Frank R. Fry of St. Louis; Vice-Presidents, Dr. Hugh T. Patrick of Chicago and Dr. William G. Spiller of Philadelphia; Council, Dr. Charles L. Dana of New York and Dr. J. J. Putnam of Boston; Secretary and Treasurer, Dr. G. M. Hammond of New York.

Recent Literature.

The Latin Grammar of Pharmacy and Medicine. By D. H. Robinson, Ph.D., with an Introduction by L. E. Sayre, Ph.M. Fourth edition, with elaborate Vocabularies, thoroughly revised by Hannah Oliver, A.M. Philadelphia: P. Blakiston's Son & Co. 1903.

This small book is intended for the use of students in pharmacy and medicine, who have not received a sufficiently classical education to be familiar with the necessary Latin terminology. As such it has proved useful in the hands of the writers, who are also teachers. We confess to a hope that ultimately English terms may be so widely used that such an aid will not be necessary. In the meantime we can commend this Latin Grammar to elementary students.

Modern Microscopy. A Handbook for Beginners and Students, combining: I. The Microscope and Instructions for its Use, by M. I. Cross. II. Microscopic Objects: How Prepared and Mounted, by Martin J. Cole. Third edition, entirely revised and enlarged, to which is added III. Microtomes; Their Choice and Use. pp. xvi, 292. Illustrated. Chicago: W. T. Keener & Co. 1903.

This small handbook discusses matters relating to microscopy, which we are inclined to think even experienced users of the microscope do not know. Particularly does this remark apply to the chapter on optical construction. Information is also given regarding the fixing and staining of sections, and a certain number of methods are detailed. A chapter is added on the subject of microtomes, which should prove useful to those concerned in fitting out laboratories. We note in passing that a 2% to 4% solution of formaldehyde is recommended as a fixative, but not infrequently a 5% to 10% solution of the commercial "formal" is preferable. The book is well printed and amply illustrated.

THE BOSTON

Medical and Surgical Journal

THURSDAY, DECEMBER 3, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

SCIENTIFIC STUDY OF OLD AGE.

IT has been suggested that if infancy and its diseases is worthy of special and detailed study, old age should likewise receive far more attention at the hands of scientific men than it has hitherto been accorded. Whether with our increasing differentiation we shall come to have professorships on senility is open to question, but we have long been convinced that, in general, the subject has been neglected and that the interest of medical men is far less active concerning the disorders which afflict the aged than in those prevalent in the young and middle-aged. The reasons for this are apparent. The worth of the individual to the community grows less in the declining years of life; younger men assume the responsibilities, and the inevitableness of the final outcome, born of experience, is so deeply rooted in the human mind, that the afflictions of age are looked upon as, in a measure, physiological and therefore unavoidable. A worthy book on the diseases of the aged remains to be written.

There have, however, never been lacking certain men who have refused to accept the popular verdict of the physiological length of life, and urged the possibility of its continuance long beyond the usually allotted time. The elixer of life will, no doubt, continue to be sought, not only by the visionaries, but also by the sober-minded man of science. With Brown-Séquard's attempts to restore the vigor of youth still in mind, we find a new champion of the cause in the person of Elie Metchnikoff, widely known for his original and somewhat radical work on leucocytes, and now professor at the Pasteur Institute in Paris. He has found opportunity to write a book,[1] somewhat popular in character, on "The Nature of Man," in which he discusses in much detail the disharmonies of human life, the ever-present fear of death and a possible way out of the difficulties of our existence through a scientific study of old age, in which the leucocyte plays a conspicuous part. The book is a wholly serious attempt at a solution of the mysteries of life and death, in which science is set up as the high priestess of our faith. Where philosophical and religious systems have failed to bring peace, Metchnikoff thinks science may step in, and by dispelling the fear of death, adjusting disharmonies and postponing death for fifty or more years may bring the solution which he believes has hitherto been sought in vain.

When the scientific man wanders from his chosen field and discusses final problems, his speculations, though usually not weighty, are entertaining and often suggestive. This is certainly true of the book before us; we doubt if the arguments will disturb the peace of mind of the philosopher, or exalt the standing of science, but they are highly original and suggestive of the path which future study may take.

About half the book is taken up with a discussion of our origin from lower forms, and the resulting disharmonies in our organization as exemplified in the digestive system, the reproductive apparatus and in the instinct of self-preservation. In general, he finds from this analysis that these disharmonies with our surroundings are the source of all our troubles. The attempts made by religious and philosophical systems to diminish these ills are discussed in two chapters, with the conclusion that they have both miserably failed. Our final recourse must, therefore, be to science, and from science Metchnikoff apparently gains a fleeting satisfaction, although he admits that the world at large remains to be educated in the lessons it has to teach. Old age demands scientific study, if we are to arrive at conclusions of value, and in a most entertaining fashion Metchnikoff gives the results of his researches and speculations on the significance and causes of growing old, and of possible means of prevention of conditions ordinarily regarded as inevitable. Put into scientific language, he finds that: "In senile atrophy the same condition is always present, the atrophy of the higher and specific cells of a tissue and their replacement by connective tissue." For this the phagocytes are ultimately responsible. "I am," he says, "justified in asserting that senile decay is mainly due to the destruction of the higher elements of the organism by macro-

[1] "The Nature of Man. Studies in Optimistic Philosophy." English translation. G. P. Putnam's Sons.

phags" [large phagocytes]. Whitening of the hair is an example of the phagocytic activity of leucocytes, which take up the pigment. From this and similar arguments it is maintained that the leucocyte is largely responsible for the signs of age, the high types of cells finally yielding to the inroads of the leucocytes as the resistance of the organism is gradually weakened. The following sentence, which we quote, shows the degree of respect which Metchnikoff maintains toward the leucocyte: "The phagocytes are endowed with a sensitiveness of their own, and by means of a sense of smell or taste are able to recognize the nature of their surroundings. According to the impression made upon this sense, they approach the object which arouses it, exhibit indifference to it or withdraw from its vicinity." It behooves us therefore, in our fight against old age, "to strengthen the higher elements and to weaken the aggressive capacities of the phagocytes." May this not be accomplished by a serum obtained from macerations of human organs, injected in the usual way? Metchnikoff thinks this not impossible, though manifest difficulties lie in the way of obtaining satisfactory organs for experimental purposes. Finally, when life has been prolonged far beyond the hundred-year mark, it is hoped that an instinct for death may replace the instinct for life, and so the cycle of man's life be made complete, ending in a normal old age and a positive desire for death. It is the function of science to bring this consummation, repudiating personal immortality, and regarding man as "a kind of miscarriage of an ape, endowed with profound intelligence and capable of great progress."

This, in general, is Metchnikoff's solution of the puzzle. It has the merit of originality, of a somewhat uncertain scientific basis and of being the product of the serious thought of a man eminent in science. It will not appeal to the philosopher; it will strike no sympathetic chord in the mind of the theologian; it will not, we suspect, be forthwith accepted by his brother scientists, but the book, nevertheless, will be read widely; it will excite discussion and may do something toward stimulating investigation into the pathology of old age.

REGENERATION OF THE SPINAL CORD.

IN our issue of June 26, 1902, we took occasion to discuss the validity of the evidence in a case reported by Drs. Stewart and Harte of Philadelphia of suture of the spinal cord. Another case somewhat similar in character has recently been reported by Dr. C. Harvey Rodi of Calumet Mich., to which allusion is made in the *Journal of the American Medical Association* for Nov. 21. We have not the original article at hand, but from the brief account given by our contemporary it appears that, following an injury, the cord was said to be entirely severed, save for a filament about the size of a pin connecting the two parts, which were separated about an inch. An operation of some sort was done, and, according to the statement, the following day sensation began to return in the lower extremities. Thereafter rapid improvement took place, and at the end of a year the patient was able to get about on crutches.

Commenting on this case, our contemporary remarks that "the little band of spinal tissue seemed to have acted like the catgut connection which has sometimes been made in widely divided nerve suture." It also argued that there must have been considerable restoration of structure to account for the restoration of function. As we before said, evidence that the spinal cord is capable of such regeneration as the foregoing maintains must be absolutely convincing before it can be accepted, in the light of our knowledge of the regeneration of the central nerve tissue. The statements made by our contemporary on the basis of the article to which we have alluded seem quite incomprehensible. The possibility of incorrect observation must be absolutely excluded before we can be justified in claiming such an extraordinary regeneration of nerve tissue as this case evidently implies. Naturally such observations are of the very greatest importance surgically if they can be completely substantiated.

A MULTIPLICITY OF CONGRESSES AND EXHIBITS ON TUBERCULOSIS.

WE beg to call the attention of our readers to a letter on another page of this issue from Dr. S. A. Knopf regarding the multiple congresses and exhibits, national, international and local, concerning tuberculosis, which are projected for the years 1904 and 1905. One "international" congress is announced to meet in St. Louis in October, 1904; another "international" congress is called to meet in Washington in April, 1905; there will be a postponed meeting of the previously established triennial Congrès International de la Tuberculose at Paris, Sept. 26-Oct. 1, 1905.

Independently of these "congresses," it is

proposed to hold two "Tuberculosis Exhibitions," one in Baltimore in January, 1904, and one in St. Louis during the Louisiana Purchase Exhibition.

The mere statement of such a situation suggests directly the desirability of its correction. Dr. Knopf offers a proposition for a basis of action.

MEDICAL NOTES.

EPIDEMIC OF TYPHOID AT BUTLER, PA. — Typhoid fever, to a most exceptional extent, is prevalent in Butler, Pa. Upwards of a thousand cases have occurred, with a considerable number of deaths, and new cases are continuing to appear. The source of the epidemic has apparently been shown to be the water supply used in the town, which has been polluted by previous cases of typhoid fever in the vicinity. Nurses and financial aid are being provided for the town, which has been practically demoralized by the extent of the epidemic.

SLEEPING SICKNESS. — Progress is apparently being made in the etiology of the so-called sleeping sickness of South Africa. Recent experiments in Uganda, conducted by Lieutenant-Colonel Bruce, in conjunction with Dr. Nabarro and Captain Grieg, apparently establish the fact that a parasite belonging to the sporozoa is constantly found in the cerebrospinal fluid of patients suffering from the disease, and that monkeys inoculated with this cerebrospinal fluid, or with blood containing a similar parasite, present all the symptoms of the disease. Secondly, it has been shown that the disease is endemic in regions where the tsetse fly is prevalent. Present indications, therefore, point to the fact that the disease is due to trypanosomes introduced through the agency of the tsetse fly.

MEMORIAL HOSPITAL, RICHMOND, VA. — A pamphlet descriptive of this hospital, opened last August, indicates that Richmond has therein a remarkably well-arranged and thoroughly equipped institution. The medical and surgical staff is elected from the faculty of the Medical College of Virginia.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Dec. 2, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 53, scarlatina 39, typhoid fever 19, measles 143, smallpox 0.

BOSTON MORTALITY REPORT. — The number of deaths reported to the Board of Health for the week ending Nov. 28 was 188, as against 210 the corresponding week last year, showing a decrease of 22 deaths, and making the death-rate for the week 16.25. The number of cases and deaths from infectious diseases was as follows: Diphtheria, 52 cases, 3 deaths; scarlatina, 13 cases, 1 death; typhoid fever, 13 cases, 4 deaths; measles, 124 cases, 1 death; tuberculosis, 22 cases, 30 deaths; smallpox, no cases, no deaths. The deaths from pneumonia were 32; whooping cough, 1; heart disease, 32; bronchitis, 5; marasmus, 5. There were 6 deaths from violent causes. The number of children who died under one year was 32; under five years, 51; persons over sixty years, 40; deaths in public institutions, 51.

ANNIVERSARY OF NURSES' ALUMNÆ ASSOCIATION. — The thirtieth anniversary of the Alumnæ Association of the Boston City and Massachusetts General Hospital Training Schools was held on the evening of Nov. 24 at the Massachusetts General Hospital. Addresses were made by Miss Linda Richards and Dr. Richard C. Cabot.

A BROWN UNIVERSITY MEDICAL SCHOOL. — It is vaguely rumored that Brown University of Providence is to take over the College of Physicians and Surgeons of Boston as a university department of medicine. It is suggested also that Mr. Rockefeller, whose interest in Brown is well known, may be financially responsible for this contemplated move.

HOSPITAL FOR ARLINGTON, MASS. — Owing to the fact that land originally given as a site for a hospital in Arlington has been considered unsuitable for this purpose, the Supreme Judicial Court has allowed the trustees of the property the right to sell. Another site has been selected, and the proposed hospital will now be pushed to completion.

INDUSTRIAL SCHOOL FOR CRIPPLED AND DEFORMED CHILDREN. — According to the last report of this institution, it is stated that the new building, which has been in process of construction, is nearing completion, but that funds will be needed for its equipment. The present building on Newbury Street has long been inadequate for the needs of this growing work.

TYPHOID FEVER AT WILLIAMS COLLEGE. — After careful investigation it appears that the recent outbreak of typhoid fever at Williams College was due to infected cream. The cases have

been attributed to cream obtained from a single can, which had been contaminated by infected water accidentally introduced into it from a receptacle in which the can had been placed to cool.

Second Jury Disagreement in Vaccination Cases. — For the second time a jury in the Norfolk Superior Court has returned a disagreement in a case involving a question of vaccination. The case, which has excited considerable interest, was one in which the town of Hyde Park, Mass., was sued for $10,000 in each of two cases for action of the school committee, which refused to allow attendance of two children at school during the recent smallpox epidemic, although they were said to have proper medical certificates regarding their unfitness for vaccination.

NEW YORK

Public Baths. — Plans have been filed with the Building Department for two new permanent public baths, to be erected for the city at a cost of $115,000 each. They are to be of two stories and constructed of brick, with limestone decorative trimmings, and will be located, one in East 11th Street and the other in West 60th Street.

Endowment of Hospital Beds. — New York Lodge No. 1, Benevolent and Protective Order of Elks, has arranged to endow in perpetuity, at an expense of $15,000, two beds in the Post-Graduate Hospital. The money is to be paid in installments within a period of eighteen months, and the hospital agrees to place the beds in a private room.

Bequest to Hospital. — W. B. Leeds of New York, president of the Rock Island Railroad, has given the sum of $10,000 to the public hospital in Richmond, Ind., where he formerly resided.

Opening of St. Vincent's Hospital. — St. Vincent's Hospital at West New Brighton, Staten Island, borough of Richmond, a branch of St. Vincent's Hospital in Manhattan, was formally opened by Archbishop Farley on Nov. 25. The premises include the spacious mansion and grounds formerly the country seat of W. F. Garner, who, with his wife and other members of his family, was drowned on his yacht, the *Mohawk*, off Stapleton, twenty-seven years ago. The hospital accommodates about two hundred patients, and will inaugurate the first ambulance service ever mantained on Staten Island. On Nov. 23 the medical staff of St. Vincent's, Manhattan, gave a reception to the archbishop at the hospital, and afterwards entertained him at a dinner at Delmonico's.

Obituary.

GEORGE J. ENGELMANN, M.D.

By the death of Dr. George J. Engelmann, which occurred Nov. 16, at Nashua, N. H., the medical profession loses a conspicuous member. The immediate cause of his death was pneumonia. Dr. Engelmann was born July 2, 1847, in St. Louis. His father was a man distinguished in science, and particularly in botany. Dr. Engelmann was graduated at Washington University in 1867, and later was given the degree of master of arts by the same institution. He received his medical education in European universities, and in the war of 1870 and 1871 was surgeon in the German army. Returning to this country, he began the practice of his profession in his native city in 1873, where he remained until he came to Boston in 1895.

During the greater part of his professional life Dr. Engelmann devoted himself to the subject of gynecology, upon which he wrote many articles, and became widely known for his work in this department of medicine. He was professor of gynecology at the Missouri Medical College until 1894. He was the founder of the St. Louis Obstetrical Society, president of the Boston Obstetrical Society, president of the Southern Surgical and Gynecological Society in 1890, one of the charter members of the American Gynecological Society and the president of the same in 1900, honorary president of the gynecological section of the International Medical Congress in 1884, honorary president of the International Congress of Obstetrics and Gynecology at Brussels in 1892, Amsterdam in 1899 and Rome in 1902; a trustee of the Missouri Botanical Gardens, St. Louis, from 1880 to 1894; and a fellow in the Washington Academy of Sciences.

In addition to his strictly professional activity he was a wide traveler and a student both of ethnology and archeology. He presented to the Peabody Archeological Museum of Cambridge a valuable collection of flints and pottery which he had collected, and the Smithsonian Institution of Washington also received from him various collections. One of his last published articles, which excited a very considerable degree of comment and discussion, was on the subject of sterility. Dr. Engelmann was a ready writer, fluent talker and a man of wide general information.

Miscellany.

AN ENGLISH OPINION OF FOOTBALL.

Prof. John F. Atkinson of London, who recently came to this country on a professional visit to Canada, saw the Yale-Harvard football

game on his way back to New York. He made the criticism that American players appeared to show too much the feeling that they were in the sport for nothing else but to win, rather than for the sport itself. "That," he said, "is a good spirit, but when you carry it to the length that you do in your American game of football, the training that the players must receive to be fit for such a game is very likely, I think, to be a disadvantage to them in after life. In England we develop our university athletes with the idea of giving them a foundation for continued physical training, that they will not give up when they finish their training." Dr. Atkinson is president f the Footballers' Hospital and Institute of London, which outside of the football season is open to other athletes, including cricketers and oarsmen. He expressed the opinion that professional football ought to have more of a vogue in America than it does, and stated that the great majority of those applying for treatment at the Footballers' Hospital (sometimes as many as twenty-five a day) were members of the hundreds of English professional teams. He finds, however, that the injuries received by these players are comparatively much slighter in character than injuries among American players.

DIABETIC INTRAOCULAR LIPEMIA.

DR. W. HALE WHITE of Guy's Hospital reports in the *Lancet*, Oct. 10, 1903, a case of diabetic intraocular lipemia, in which the blood was examined during life. The ophthalmoscopic appearances are shown in an appended chromolithograph. The arteries and veins contain blood of a similar color, a deep cream, which in the larger vessels passes into a pale salmon color. The vessels appear a little larger than usual, the whole retina is pale. The description accords with that given by Heyl in 1880 in the *Transactions of the American Ophthalmological Society*.

Most recorded cases of diabetic lipemia have been fatal, and it has been suggested that the lipemia is the cause of the coma. This view is not generally accepted, and numerous fatal cases of coma without lipemia are on record. In Dr. White's case as the patient's condition improved the lipemia disappeared. No relation could be established in this case between the lipemia and the diet.

Correspondence.

AMERICAN AND INTERNATIONAL CONGRESSES ON TUBERCULOSIS AND TUBERCULOSIS EXHIBITS FOR THE YEARS 1904 AND 1905.

NEW YORK, Nov. 27, 1903.

MR. EDITOR: During the past few months I have been the recipient of a large number of inquiries concerning the various tuberculosis congresses (American and international) which have been projected for the years 1904 and 1905. The multiplicity of these various congresses and the similarity of their names leads naturally to great confusion. It would be really too great a task to undertake to answer in full and individually all the letters with which I have been honored. I therefore ask you to grant me the space to give the desired information in your esteemed paper, so that all the readers of the JOURNAL who may be interested will have a clear idea of the various congresses, their officers and time and place of meeting.

It is announced that a congress on tuberculosis is to be held in St. Louis on Oct. 3, 4, and 5, 1904, under the name of "International Congress on Tuberculosis." Upon careful inquiries I learned the following facts about this congress: Mr. Francis, the President of the St. Louis Exhibition, has been approached by the officers of the "American Congress on Tuberculosis," which was founded some years ago by Clark Bell, Esq., a lawyer of the city of New York, to sanction the holding of an international congress on tuberculosis in connection with the Louisiana Purchase Exposition. From a letter received from Dr. E. J. Barrick of Toronto, Canada, the now president of this American congress, I learned that Mr. Francis has appointed the above-mentioned Mr. Clark Bell Chairman of the Committee on Organization. Mr. Clark Bell is also the Treasurer and Chairman of the Executive Committee of the "American Congress on Tuberculosis," season 1903–1904; a Mr. Samuel Bell Thomas of 290 Broadway, New York, is the Secretary of the latter. The officers of the International Congress are not yet elected. I was desirous to learn the names of other medical men interested in this congress, and Dr. Barrick very kindly wrote me, on Nov. 16. that he had asked Mr. Bell to furnish me the desired additional information, but nothin; has thus far been received.

The other international tuberculosis congress announced is the one to meet in Washington, D. C., April 4, 5 and 6, 1905. It is to be held under the auspicies of "The American Congress on Tuberculosis for the Prevention of Consumption." The following is a list of the officers of this latter organization: Honorary President, Dr. Henry D. Holton, Brattleboro, Vt.; Member Executive Council, Dr. Charles O. Probst, Columbus, Ohio; President, Dr. Daniel Lewis, New York; First Vice-President, Dr. E. A. Egan, Springfield, Ill.; Second Vice-President, Dr. Frank Paschal, San Antonio, Texas; Fourth Vice-President, Dr. Irving A. Watson, Concord, N. H.; Fifth Vice-President, Dr. Charles Wood Fassett, St. Joseph, Mo.; Secretary, Dr. George Brown, Atlanta, Ga.; Treasurer, Dr. P. H. Bryce, Toronto, Canada.

Before going any further I should like to call the attention of your readers to the difference in name of the two American congresses. The one is "American Congress on Tuberculosis," the other "The American Congress on Tuberculosis for the Prevention of Consumption."

The congress which was to meet under the name of "Congrès International de la Tuberculose" at Paris from Sept. 26 to Oct. 1, 1904, has been recently postponed to the year 1905. The President of this congress is Professor Brouardel, Honorable Dean of the Faculty of Medicine of Paris. The General Secretary is Dr. M. Letulle, Professor Agrégé of the Faculty of Medicine, residing at 7 Rue Magdebourg, Paris. This congress will be divided in two sections, the medical and the social:

I. In the medical section the following subjects will be discussed: (1) New methods for the treatment of lupus. (2) New methods for the early diagnosis of tuberculosis. (3) Comparative studies on the different forms of tuberculosis.

II. In the social section: (1) Etiological factors in tuberculosis. (2) Value of different means for the treatment of tuberculosis. (3) The voluntary insurance and the mutual societies in the combat against tuberculosis.

The congress will furthermore form a technical section under the name of "Museum of the Congress."

There will be held during the coming year independently of the above-mentioned congresses two tuberculosis exhibitions, one in Baltimore, Md., and the other in St. Louis, Mo. The Baltimore "Tuberculosis Exhibition" will be held in January, 1904, under the combined auspices of the Tuberculosis Commission, the State Board of Health and the Maryland Public Health Association. Details are in charge of Dr. W. S. Thayer, President of

the Commission; Mr. John M. Glenn, Secretary; Dr. John S. Fulton, Secretary of the State Board of Health; and Dr. Marshall L. Price. Dr. Henry B. Jacobs has been selected Chairman, and 250 prominent professional men and laymen have been asked to act as an advisory committee. A series of lectures will be given, the object of which will be to present the extent and effects of the disease in a striking manner. The pathologic, hygienic, sanatorium and sociological aspects of the tuberculosis problem will be practically demonstrated by specimens, charts, literature, instruments, photographs and plans. All communication concerning the exhibition should be addressed to Dr. Marshall Langton Price, 10 South Street, Baltimore, Md.

The other tuberculosis exhibition will be held in St. Louis, in connection with the Exhibition of Social Economy and under the Sub-section of Hygiene, of which Dr. J. N. Hurty of Indianapolis is Superintendent. To avoid multiplicity of exhibits, Dr. Hurty has put himself in communication with the General Secretary of the International Bureau for the Prevention of Consumption at Berlin, Professor Pannwitz, so that the exhibits which the European countries contemplate sending shall also come under his direction.

All indications point toward success of both exhibits, and it is to be hoped that they will fulfill their high purpose and at the same time be a credit to American physicians and hygienists. Considering the various congresses, I do not hesitate to express a feeling of deep anxiety. The first one mentioned, which for reason of brevity I will call "The Bell Congress," because it owes its inception to Mr. Clark Bell, has, to my knowledge, not the support of our best-known men in the field of clinical medicine, hygiene, tuberculosis pathology or tuberculo-therapeutics. The second congress in point of time, which again for sake of brevity and clearness I may call "The Lewis-Brown Congress" (names of the president and secretary), while it has many distinguished men of various state and provincial boards of health among the members, has, like the Bell Congress, thus far not among them the men we are wont to look up to as leaders in movements of this kind. No such men as Biggs, Billings, Bowditch, Flick, Jacobi, Janeway, Klebs, Osler, Otis, Trudeau, Tyson, are connected with this congress.

What are our confrères across the water to think if they hear of two American congresses on tuberculosis, and each having an international one under its auspices? The European authorities found it best, instead of having a triennial congress, to allow one more year to intervene. This will make the congress in Washington and the one in Paris convene in the same year (1905).

I hope this letter, which I address to the medical profession in America, will result in a satisfactory solution of this very complicated problem. If President Francis of the St. Louis Exposition desires that a tuberculosis congress shall be held in St. Louis, let him call to his aid some of the men whose names I have mentioned as leaders in our profession. They will counsel with him on the advisability of such a congress, and if it is decided that one should be held, Mr. Francis can be assured that the best men of Europe and America will come to St. Louis to contribute to its success.

The officers and members of the Lewis-Brown Congress must realize that they cannot expect to have their international meeting in Washington successful, when, six months later, there will be an international congress in Paris. I hope that there will be enough patriotism and national pride for all interested to realize that two American congresses on tuberculosis is an anomaly, and that, if the St. Louis Congress is to be a success, it must be in the hands of medical men well and favorably known in this country and abroad.

As a solution of the problem I beg leave to suggest the following: During the tuberculosis exhibition in Baltimore next January, all interested should meet on a certain date on this neutral ground for the purpose of coming to an agreement about a single representative national or international tuberculosis congress to be held in America. There too should be formed a national committee on tuberculosis which will be in touch with the internationa tuberculosis congress which will convene in Paris in 1905

S. A. KNOPF, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, NOV. 21, 1903.

Deaths reported, 2,958; under five years of age, 723; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 626, acute lung diseases 529, consumption 302, scarlet fever 19, whooping cough 6, cerebrospinal meningitis 6, smallpox 13, erysipelas 9, puerperal fever 3, measles 24, typhoid fever 56, diarrheal diseases 83, diphtheria and croup 105.

From whooping cough, New York 2, Philadelphia 1, Pittsburg 2, Boston 1. From erysipelas, New York 1, Chicago 4, Philadelphia 1, Baltimore 1, Holyoke 1, Adams 1. From smallpox, Philadelphia 7, Pittsburg 6. From scarlet fever, New York 8, Chicago 2, Philadelphia 4, Baltimore 2, Pittsburg 1, Malden 1, North Adams 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Nov. 7 the death-rate was 16.2. Deaths reported, 4,691; acute diseases of the respiratory organs (London) 271, whooping cough 54, diphtheria 55, measles 55, smallpox –, scarlet fever 41.

The death-rate ranged from 5.7 in Kings Norton to 22.8 in Warrington, London 16.1, West Ham 16.8, Brighton 11.6, Southampton 11.4, Plymouth 18.6, Bristol 13.7, Birmingham 18.3, Leicester 11.8, Nottingham 16.5, Liverpool 19.5, Bolton 17.1, Manchester 20.5, Salford 22.3, Bradford 18.6, Leeds 20.1, Hull 13.4, Cardiff 13.0, Rhondda 15.7, Merthyr Tydfil 18.2, Hornsey 8.0.

METEOROLOGICAL RECORD.

For the week ending Nov. 21, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING NOV. 26, 1903.

SAWTELLE, H. W., surgeon. Granted leave of absence for two days from Nov. 27. Nov. 25, 1903.

GASSAWAY, J. M., surgeon. Department letter granting Surgeon Gassaway leave of absence for one month, amended so that said leave shall be for 28 days from Oct. 13. Nov. 13, 1903.

STONER, G. W., surgeon. Leave of absence for five days from Nov. 24, 1903, under paragraph 189 of the regulations.

WICKES, H. W., past assistant surgeon. Granted leave of absence for five days from Nov. 28. Nov. 23, 1903.

CLARK, T., past assistant surgeon. To proceed to St. John, N. B., and assume temporary charge of service during absence of Assistant Surgeon W. C. Billings. Nov. 24, 1903.

LUMSDEN, L. L., past assistant surgeon. Upon expiration of leave of absence to remain at New Orleans, La., and await assignment. Nov. 20, 1903.

BILLINGS, W. C., assistant surgeon. To proceed to Washington, D.C., and report to chairman of examining board to determine his fitness for promotion to the grade of past assistant surgeon. Nov. 24, 1903.

KERR, J. W., assistant surgeon. To proceed to Washington, D. C., and report to chairman of examining board to determine his fitness for promotion to the grade of past assistant surgeon. Nov. 24, 1903.

ROBINSON, D. J., assistant surgeon. To report to chairman of examining board, Port Townsend, Washington, to determine his fitness for promotion to grade of passed assistant surgeon. Nov. 24, 1903.

CORPUT, G. M., assistant surgeon. To proceed to Washington, D. C., and report to chairman of examining board to determine his fitness for promotion to the grade of passed assistant surgeon. Nov. 24, 1903.

CURRIE, D. H., assistant surgeon. To proceed to San Francisco, Cal., quarantine, and assume temporary charge of service during absence of Passed Assistant Surgeon H. S. Cumming. Nov. 24, 1903.

MANNING, H. A., assistant surgeon. Relieved from duty at Stapleton, N. Y., and directed to proceed to Honolulu, T. H., and report to chief quarantine officer for duty. Nov. 23, 1903.

MAGUIRE, E. S., pharmacist. Department letter granting Pharmacist Maguire leave of absence for thirty days from Dec. 5, 1903, amended so that said leave shall be from Dec. 1. Nov. 21, 1903.

BOARDS CONVENED.

Board convened to meet at Washington, D. C., Dec. 7, 1903, for examination of Assistant Surgeons W. C. Billings, J. W. Kerr, and G. M. Corput, to determine their fitness for promotion to the grade of passed assistant surgeon. Detail for the Board: Assistant Surgeon General L. L. Williams, chairman, Assistant Surgeon General W. J. Pettus, Assistant Surgeon General G. T. Vaughan, recorder.

Board convened to meet at Port Townsend, Washington, Dec. 14, 1903, for examination of Assistant Surgeon D. E. Robinson, to determine his fitness for promotion to the grade of passed assistant surgeon. Detail for the Board: Passed Assistant Surgeon J. H. Oakley, chairman, Passed Assistant Surgeon H. S. Cumming, Passed Assistant Surgeon M. H. Foster, recorder.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING NOV. 28, 1903.

E. O. HUNTINGTON, surgeon. Sick leave extended three months.

A. M. FAUNTLEROY, assistant surgeon. When discharged from treatment, ordered to the "Scorpion."

J. F. URIE, surgeon. Detached from the Bureau of Medicine and Surgery, Navy Department, and ordered to the "Missouri."

W. R. DUBOSE, medical inspector. Ordered to duty as assistant to the Bureau of Medicine and Surgery, Navy Department.

C. T. GRAYSON, acting assistant surgeon. Detached from the Naval Proving Ground, Indian Head, Md., and ordered to the Naval Hospital, Washington.

SOCIETY NOTICES.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. —The thirteenth annual meeting of the Western Surgical and Gynecological Association will be held in Denver, Colo., Dec. 28 and 29, 1903.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION. —The thirteenth annual meeting of the Mississippi Valley Medical Association will be held at Cincinnati, Ohio, Oct. 11, 12, 13, 1904.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. —The sixteenth meeting will be held at the New Piedmont Hotel, Atlanta, Ga., Dec. 15, 16 and 17, 1903.

RECENT DEATHS.

HORACE CARR WHITE, M.D., M.M.S.S., died in East Somerville, November 26, 1903, aged sixty-seven years. Dr. White was born in Bowdoin, Me., and was graduated from the medical department of Bowdoin College in 1859. He practised for a time in Lisbon Falls, Me., and in 1861 entered the Union Army as assistant surgeon in the Eighth Maine Regiment. In 1874 he established himself in Somerville, and has since been prominently identified with the Somerville Hospital and medical matters in that community. He was a member of many medical and non-professional societies.

BOOKS AND PAMPHLETS RECEIVED.

Infectious Diseases. Their Etiology, Diagnosis, and Treatment. By G. H. Roger, Professor Extraordinary in the Faculty of Medicine of Paris. Translated by M. S. Gabriel, M.D. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1903.

Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. By Prof. Dr. Carl von Noorden. Authorized American Edition. Translated under the direction of Boardman Reed, M.D. Part IV. The Acid Autointoxications. By Prof. Dr. Carl von Noorden and Dr. Mohr. New York: E. B. Treat & Co. 1903.

Report of the Commissioner of Education for the year 1902. Vol. I. Washington, D. C. 1903.

The After-Treatment of Operations. A Manual for Practitioners and House Surgeons. By P. Lockhart Mummery, F.R.C.S. (Eng.), B.A., M.B., B.C. (Cantab.). Illustrated. New York: William Wood & Co. 1903.

The Antiseptic and Germicidal Properties of Glycerin. By M. J. Rosenau. Bulletin No. 16. Hygienic Laboratory, Treasury Dept., Washington. Sept., 1903.

Some Remarks on the Maternal Circulation in Pregnancy. By H. O. Nicholson, M.D., M.R.C.P. (Edinb.), of Edinburgh. Reprint. 1903.

GENERAL PERITONITIS COMPLICATING SCARLET FEVER.*

BY JOHN H. MCCOLLOM, M.D., AND JOHN BAPST BLAKE, M.D., BOSTON.

GENERAL peritonitis due to streptococcus infection as a complication of scarlet fever is extremely rare. That this condition may exist and not be recognized is possible, for the patient in a given case may be so delirious as to prevent a diagnosis being made, or the prostration due to the attack of scarlet fever may mask the characteristic symptoms to such an extent as to render a diagnosis impossible. When we take into account the comparative frequency of endocarditis, pericarditis and pleuritis, it would seem to prove that this complication is possibly more frequent than is generally supposed. In a clinical experience of over 8,000 cases of scarlet fever there has been a limited number of patients whose symptoms would cause one to think of the possible occurrence of this complication, but the speedy subsidence of all symptoms and the ultimate recovery of the patients would seem to prove that peritonitis could not have existed. In two instances, however, out of the 8,000 cases peritonitis did actually occur, as is shown by the following clinical reports. In these cases the attacks of scarlet fever were not specially severe, and there was no cause for anxiety until the occurrence of the abdominal symptoms. It was not reasonable to suppose that scarlet fever *per se* was the cause of the condition, but that it was due to streptococcus infection. The great difference in the severity of attacks of scarlet fever is due not to the poison of scarlet fever itself, but to streptococcus infection. This has been proved many times by means of cultures. If streptococci are found in cultures from the nose and throat the prognosis is graver than when this organism is not found. A careful study of the literature of scarlet fever proves that general peritonitis as a complication in this disease is extremely rare.

Frankel, in *American Medicine*, Vol. 2, No. 29, reports three cases of necrotic ulceration of esophagus and stomach following scarlet fever. General peritonitis is not mentioned.

In Gould's "Year Book" no cases are reported in the last four volumes.

In the "Reference Handbook of Medical Science," Vol. 7, page 313, this statement is made: "Peritonitis occurs most rarely, and is usually purulent."

Osler, in his "Practice of Medicine," does not allude to peritonitis as a complication of scarlet fever.

Wood and Fitz, in "Practice of Medicine," make a slight allusion to this condition.

In the "American Text Book of Diseases of Children" it is stated that general peritonitis may occur as a complication of the various exanthemata. Page 580.

In Holt's work, "Diseases of Infancy and Childhood," the following passage occurs: "Of acute infectious diseases peritonitis is most frequently seen with pneumonia and scarlet fever." Page 416.

In the "Cyclopædia of Diseases of Children," Keating, general peritonitis is not mentioned.

In Oppenheim's "Medical Diseases of Children" he says that general peritonitis may be traced to the acute infectious diseases. Page 203.

In Allbutt's "System of Medicine," Vol. 2, page 150, tables of complications are given not mentioning general peritonitis, but says that other complications occur in less than 1% of cases.

Bauer, in "Ziemssen's Cyclopædia of Practice of Medicine," Vol. 2, page 282, and Wardell, in Reynolds' "System of Medicine," say that scarlet fever is sometimes a cause of general peritonitis.

In Pepper's "System of Medicine," Vol. 2, it is mentioned that general peritonitis may follow scarlet fever.

Somerset, in the *New York Medical Journal*, Vol. 72, page 981, in a study of 2,500 cases of scarlet fever and complications, does not allude to general peritonitis.

It will be seen that although some of the authors above quoted allude to the possible existence of general peritonitis in the course of scarlet fever, they do not report any specific cases, and perhaps do not lay sufficient stress upon the possibility of its occurrence. For this reason the two following cases are reported in detail. Both present several symptoms in common, but they differ in course of the disease, the treatment and the result. It is possible that mild peritoneal involvement may be found on careful examination to be more common than is at present believed; but if the following cases are typical of their class, another serious element is added to the already too long list of scarlatinal complications and sequelæ:

CASE 1. J. E., five years of age, entered the South Department of the Boston City Hospital on April 10, 1900, suffering from diphtheria. Both parents were consumptive; the child had had measles in the previous summer, and had been sick with a "sore throat" for five days before entrance. Two days after entrance the skin flushed, and on the following day the diagnosis of scarlet fever was obvious There was some nasal discharge. Twenty-three days after entrance he vomited and complained of pain in the abdomen, but nothing could be found on physical examination. The urine became slightly albuminous and the tenderness and rigidity of the abdomen continued, as did the vomiting. Ten days later the umbilicus began to protrude, the area around it being reddened, swollen and painful; the abdomen was distended and dull in the flanks. Forty-three days after entrance, the child was tapped in the middle line of the abdomen, and twenty-one ounces of pus withdrawn, a culture from which showed streptococcus pyogenes; on the following day the umbilicus ruptured and fluid leaked from it for several days. On May 31 the child was aspirated in the seventh space, left posterior axillary line, and a few drachms of pus withdrawn from the thorax; on this day the right ear was noted to be discharging slightly. Two weeks later, while steadily improving, his friends insisted upon taking him home, and as he had finished desquamating he was discharged against advice, signs of fluid being still present in the chest and abdomen. Four months later

* Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital.

he was shown at a meeting of the Boston City Hospital Clinical Club, apparently well.

CASE II. W. S., thirty-one years of age, was admitted to the South Department April 22, 1903. His family history was good; he had had measles, pertussis and varicella during childhood, and rheumatism later. He had been sick for six days before entrance, the onset being accompanied by sore throat and vomiting. He had a brilliant scarlet fever eruption, and also a systolic murmur at the apex, which was in the fifth space outside the nipple line. The abdomen was negative. He progressed without complications, his general condition being good, until thirteen days after entrance, when a sight trace of albumen was found in the urine, and he was slightly nauseated. On the following day there was pain in the abdomen, but no spasm or tenderness. Early on May 9, four days after the appearance of the albumen, he complained of great abdominal tenderness and passed no urine at all. Distension, rigidity and muscular spasm rapidly developed. The legs were drawn up and the face became pinched. He was seen by Dr. Abner Post at 6 P.M., who recommended laparotomy, which was performed by Dr. J. B. Blake about two hours later. Under ether the abdomen was opened in the median line below the umbilicus. There was free discharge of thin pus, followed by a curd-like substance. The intestines were red and congested. The appendix, gall bladder and other abdominal organs were negative. The peritoneal cavity was flushed with several quarts of hot saline solution and drained with seven gauze wicks. No obstruction of the intestines was found, though they were everywhere distended with gas. The patient rallied, and for a few hours seemed a trifle better. The suppression of urine continued, however, in spite of salt infusion and enemata; the vomiting increased the pulse became weaker, and he died twenty-five hours after the operation. Culture from the pus showed streptococcus. The urine, two days before operation, was smoky, contained a trace of albumen, and a sediment of normal and abnormal blood, blood casts, epithelial and refracting casts, a small amount of pus and some round cells. At the time of operation the urine contained 1% albumen.

The autopsy was performed on the following day. The undertaker had already partially embalmed the body, punctured the intestines and stomach in numerous places, and filled the abdominal cavity with an acrid fluid containing formalin. This changed the peritoneal appearances decidedly. No retroperitoneal focus of pus was found. There was an easily separated fibrin layer on the diaphragm, spleen and liver, and a similar layer found lining both pleuræ.

There were small cauliflower masses of fresh red deposit on a chronic thickening of the edge of the mitral valve curtain, with small amounts of fibrin clinging to it.

The capsules of the kidneys were under some tension and yielded a slight hernia of the substance on section. The left kidney was only one-third the size of the right. There were two complete ureters from each kidney to the bladder and four distinct openings into the bladder. This is a very unusual condition, and is, according to Gould, the eleventh case on record. (A. H. Gould, Am. Journal Med. Sciences, March, 1903.)

The anatomical diagnosis was:

Acute fibrino-purulent peritonitis (cause unknown).
Acute bilateral fibrinous pleuritis.
Acute vegetative mitral endocarditis.
Acute nephritis.
Acute splenic tumor.
Acute bronchitis.
Celiotomy.
General arterio-sclerosis.
Chronic mitral endocarditis.
Bilateral double ureter.
Chronic adhesive pleuritis.

These two cases present in common a series of complications, a late development of the peritoneal symptoms and an absence of local purulent foci. The family history of the child suggests a tubercular peritonitis, but the culture from the pus showed streptococcus. The child's temperature began to rise and fluctuate several days before abdominal symptoms were noted; part of this rise may have been due to an involvement of the middle ear, but at least a part of it was probably due to the beginning peritoneal infection, which was gradual and comparatively painless in its onset. In the other case, the onset was very acute, suggesting sudden intestinal obstruction and rendering an operation imperative, in spite of the almost complete suppression of urine.

We had, therefore, in both cases, a peritonitis occurring late in the course of scarlatina, due to streptococcus, and independent of any local inciting cause; it was apparently only a part of a very widely distributed general infection involving other serous cavities, as well as excretory organs, special sense organs, and a part of the circulatory system. It seems fair to assume, therefore, that the peritoneum was infected through the blood, as was also the pleura. This is of course a difficult thing to prove. Cultures taken from the blood in the fatal case might have thrown some light upon it. There is no good reason, however, for doubting that infections of the peritoneum through the blood may occur. There is no more obvious explanation in this case and much that would be consistent with it.

TREATMENT.

If the signs of peritoneal infection are slight in degree and extent, palliative measures alone, such as enemata, turpentine stupes, rectal feeding, will suffice. If, however, the pulse steadily rises, and pain, tenderness and spasm increase, the indication for drainage is imperative. The condition of the kidneys is the most definite contra-indication to operation, and whenever possible cocaine should be substituted for ether. The operation should consist of a rapid celiotomy, thorough irrigation with hot salt solution and drainage. Unless there are definite local symptoms, the incision should be in the middle line. To favor drainage, hot, moist dressings, frequently changed, are desirable. Salt solution under the breasts and by rectum, and water by mouth if the patient is not vomiting, are all definitely indicated. Stimulation should be free, but alcohol may be contra-indicated by the nephritis. Caffein, strychnia and digitalis may be used energetically.

The prognosis is always grave, and a successful outcome like that in the first case may not often be anticipated.

WAS HE INSANE? A STUDY IN MENTAL DIAGNOSIS.[1]

BY C. A. DREW, M.D., BRIDGEWATER, MASS.

Medical Director Massachusetts State Asylum for Insane Criminals.

H. J. B., a Hebrew, thirty-five years old, born in England, was admitted to the State Asylum for Insane Criminals, Jan. 22, 1902, from the

[1] Read before the Plymouth District Medical Society, April 15, 1903.

State Prison in Charlestown, where he had been serving a five to nine years' sentence from March 26, 1897, having been convicted as a "common and notorious thief." The medical certificate on which his commitment was based reads as follows:

CHARLESTOWN, JAN. 17, 1902.

HIS EXCELLENCY W. MURRAY CRANE, ETC.: We have examined H. J. B., thirty-five years of age, committed March 26, 1879, as a common and notorious thief, sentence of from five to nine years, and would respectfully report.

When B. was first committed he worked in the harness shop. He began to agitate the men and was placed in Cherry Hill, where he began to write to all the authorities and to lawyers, telling of the illegal actions of the officers of the prison and wishing to begin actions in law against some of them. He claims to have been admitted to the bar in Dakota. He was arrested in London, Brussels and New York as well as Boston. Perhaps there is no inmate of the prison who has given more trouble to all concerned than he.

At our first examination he began telling in legal terms how unjustly he had been treated before his trial and claimed that from the first he was a victim of persecution and conspiracy; that his sins were sins of omission (neglecting to say his prayer often) only, and not commission. He related how many people would be defendants in cases he would bring against his persecutors. He also showed some wood and iron that had been placed in his food. The examination lasted over two hours.

At the second examination he recognized us and began to say that we were engaging in a conspiracy to pronounce him insane in order that his enemies might get possession of his property. He rehearsed nearly all that he said at the former visit and taking his oath that he was an innocent man. That in all of the former arrests in London, Brussels, New York and elsewhere he had been exonerated, and that the so-called obtaining money under false pretences was proven to be legitimate business. He asked us to examine two bottles of medicine that had been given to him from the prison dispensary and then demanded that we should make a thorough analysis of them both, but at once claimed that we should use neither what he showed us at the former visit nor the request for examination of the medicine at this visit as evidence of delusions on his part. He quoted law to prove that if we did not at once take steps to inform the proper authorities that he was unjustly held, improperly treated and a victim of an outrageous conspiracy, we were guilty of concealing evidence and would be defendants in suits which he would bring against us. At times he would stop his conversation and examine if any people were listening to him; at another time he would get up from his chair, go to the door, and ask for the deputy just to see if he were trying to overhear our talk, although we had told him that the deputy had returned to the yard. He is very suspicious of almost everybody that comes in contact with him. We were with him over four hours at the second examination, although we were convinced at our first that B. is a litigious paranoiac. The little legal knowledge that he has is the nucleus about which are formed all his ideas of his relations to his fellowmen and their conduct to him. He has employed no less than six lawyers since he has been an inmate of the prison and has discharged them all because he became convinced that each one had been influenced by the warden and he has told about others he had employed and discharged.

We feel that his proper place is at the asylum for insane criminals.

It may be remarked that this certificate is long and strong. It seems to establish delusions of persecution — one of the most characteristic symptoms of that form of mental alienation called paranoia. We learn that this prisoner has been under observation nearly five years, that he began to agitate other prisoners and was placed in Cherry Hill soon after his sentence in 1897. It may be explained that Cherry Hill is a building with large, well-lighted and well-ventilated rooms for the isolation of incorrigible prisoners. We learn further that the prisoner was very insistent in his efforts to bring suits at law against the prison officials and others, and from other sources we learn that in the opinion of certain friends he had a mania for bringing suits at law even before his last arrest and sentence. Those conversant with psychiatric literature will recall that under the names of "querulent insanity," "quarreling insanity," or "litigious insanity" the majority of Continental writers as well as prominent alienists of England and America have written concerning these people with a so-called "mania" for quarreling. The majority of medical writers have considered certain of these people insane, even when no clearly defined delusions could be demonstrated, and have generally classed them as paranoiacs,[3] although Krafft-Ebing seems inclined to put them under the heading of "moral insanity" and Berkeley considers the litigationists better classed with the ethical inbecilities. So far then as this propensity for litigation has weight, — and we shall wish to refer to this phase of the question again, — it substantiates the diagnosis of the committing physicians, for it is counted competent supporting evidence of mental degeneration by the majority, at least, of recognized authorities in mental medicine. The extreme suspiciousness of the subject is another strong pillar supporting the diagnosis, because extreme suspiciousness is a common and prominent characteristic of most all paranoiacs.

Passing the leading symptoms in review, we have a strongly litigious propensity and apparent delusions of persecution, conspiracy and poisoning, with extreme suspiciousness, — the common accompaniment of such delusions, — truly a strong syndrome on which to base a diagnosis of litigious paranoia. If the suspicions of poisoning and ideas of persecution could be established beyond peradventure as delusions, in the medical sense, and if it could be shown that the man had at some time been frank, truthful and honest, insanity would be established beyond a reasonable doubt, although we might then have doubt as to the form of insanity. But the whole evidence tends to show that the man was never truthful, frank or honest, and it is almost self-evident that a man's natural temperament, character and education must be considered before we can determine whether he reacts in a physiological or pathological manner to his environment.

On admission, physical examination of H. B. was negative, except that the pupils were seemingly myotic, — reacting very slowly to both light and accommodation, — while the patella reflex was very slight. These variations from the average were not greater than is occasionally found in individuals in whom there is no suspicion of organic disease of the central nervous

system; and, as frequent subsequent examinations failed to disclose other neural anomalies of significance, the conclusion seemed justifiable that the apparent myosis and diminished knee-jerk were normal to the individual. It ought to be noted, however, that the opposite condition, — a dilated pupil and exaggerated patella reflex, — is more common in patients of a neurotic organization, to which class H. B. clearly belonged, and that a spastic myosis is about the most common eye symptom in paresis. The mental examination was continued for from one to two hours at a time for several consecutive days and the first impression was strong that we were talking with a victim of early paresis. Paretic, paranoiac or moral imbecile seemed to be the diagnostic question.

Our patient manifested quite enough egotism for a paranoiac. He was perfectly coherent and had a good command of English, but his memory seemed poor, in that his long story would differ in some essentials from day to day and there would be many inconsistencies in his statements of alleged facts. "Oh, I do not claim to be a lightning calculator," he would say, when his attention was called to the fact that his dates were badly awry. It is written in our case records that "His story is very disconnected, either because of a disturbed brain or because he is lying so rapidly that he cannot maintain the proper sequence of events. Any discrepancy brought to his notice he immediately cleverly explains, but in a way to vary his original stories considerably. The good nature and optimism which he shows, the ease with which he speaks of large amounts of money and extensive commercial interests, his good-natured egotism, the many discrepancies in his stories, the readiness with which he explains, though not always satisfactorily, together with some suspicious physical signs, the contraction and slight mobility of both pupils and almost absent knee-jerk, give rise to a strong suspicion of paresis."

This is not at all like the typical paranoiac if we use the term in the restricted sense of the "original nonomania" of Sohmer and the "primary nonomania" of Spitzka and Kellogg. The paranoiac's memory is commonly good, often preternaturally good. Morbid introspection has seemingly fixed every event of his life in self-consciousness and so exaggerated its importance that each personal experience for a series of years is faithfully reproduced as to dates and consistently as to sequence of events.

With the paretic the symptom-complex is strikingly different. Here we have an organic disease of the brain, a chronic meningitis with atrophy and softening of the brain cortex, the product of "civilization and syphilization," as Krafft-Ebing has tersely put it. A good-natured dementia is the leading characteristic. Grandiose accounts of his experiences — apparent mendacity — is the rule; petty acts of dishonesty are very common. A jolly good fellow and a spendthrift, a lover of good wine and bad women, in the early stages, frequently a petty criminal later on, almost surely bedridden in four years, with far advanced motor and sensory palsy, he yet insists that he is "all right," that he has lots of money, hosts of friends, many wives, perhaps, and that he never felt better in his life.

The imbecile is of another kind, for his troubles are many and his chief mission seems to be to make trouble for others. That particular imbecile called the moral imbecile — because the moral sense is most conspicuous by its absence — has been well called first cousin to the paranoiac. It is doubtless true that a bad heredity — an unstable nervous organization, a vice of constitution — is the soil from which both have grown, yet there are important differences.

H. B.'s previous history as related by himself was so long that he was asked to give it to us in writing, hoping to get an abridged edition. The written autobiographic statement was "toned down" a good deal from his verbal statement, and I can only include enough to illustrate the nature of his statement and the writer's coherence of thought.

FEB. 5, 1902.

GENTLEMEN: In accordance with my arrangement with you, I herewith send you a brief statement relative to certain transactions and facts related to you verbally. I am the son of M. B., of London, England. My father was owner of the city of London Printing Works at one time, also owner of the Rotary Ticket Printing Machine (patent). My father was a promoter, financier and private banker in London and has successfully floated many large companies. I was informed that my father had purchased and brought out the International Cable Company, the Bermuda Cable Company, the Quartz Hill Gold Mining Company, the Parcherry Mining Company, the Wala Wynad Mining Company, the Santa Rosalia Mining Company, the Washington and Seattle Breweries Company, the Iowa Pacific Railway Company, and many other large companies too numerous to mention, but which will be more particularly set forth by my relatives and others. . . . I am a lawyer, studied law in London, England. Educated in Dublin and London. Was manager for M. Barn & Co., Law and Mercantile Agency, New York. Was manager and president at one time of the Joseph Jackson Company, incorporated, at 258 Washington St., Boston. Was manager for the Rollins Harlow Company at 1 Beacon St., Boston. I was in partnership with Frederick H. Jackson, Real Estate Broker, 23 Court St., Boston, Mass. I am informed that the said Frederick H. Jackson is a man of means. I have lived at Wellington, Mass., and kept two horses and carriages and owned my own furniture there. I lived at 321 W. 14th St., New York city, and owned furniture there and valuable paintings. I am perfectly willing to make any statements written or verbally as to the above facts and you have my full permission to write to the parties above referred to.

(Signed) H. J. B.

This rather incredible story written with care, without the embarrassing factor of a cross examination, was not made wholly of imaginary "mind stuff" as are the roseate ideas of the general paralytic. He was the son of a once wealthy Hebrew whose name and address he correctly gave. He was petted and very much indulged as a youth, as will be shown by other evidence. The proportion of truth and falsehood in the history, as a whole, could be fairly

judged from his mother's letters, which have an intrinsic value of their own besides throwing a flood of light on our patient's peculiar mentality. It will be admitted that the absurd statements of the paretic and the persecutory and expansive ideas of the paranoiac are sincere beliefs, due in the one case to active brain disease, and in the other class to a slowly progressive psychical degeneration. On the other hand, many sane people delight in " drawing the long bow " and the talent for weaving a thread of truth into a fabric of falsehood so cleverly that the single thread will first catch the eye of the casual observer is a characteristic accomplishment of the moral imbecile, and the habitual liar whose sanity is not usually questioned. When cornered by a cross examination, H. J. B. would admit that some of these many companies successfully ' floated " by his father were " brought out " on paper only, and I would here observe that nothing more clearly marks the difference between the absurd fancies of the paretic or the systematized delusions of the paranoiac and the " fish stories " of the imbecile, than the efforts of the latter to support each falsehood with two more of a little different shade. A series of letters, remarkable in some ways, were received from patient's mother. These letters, to my mind, are of sufficient psychological interest to be read in full, but in a reasonable time limit I can only quote here and there. In her first letter, dated Feb. 7, 1902, she writes:

Your letter to my husband was handed to me. I do not know as I shall give it to him, as he is at present suffering from acute heart trouble. In the meantime I shall be perfectly explicit with you, although I am not filling up your enclosed form. My son is of ill-balanced mental and physical organization, neurotic, hysterical, of strong passions, weak moral force (in fact of no moral fiber), no sense of duty, a victim of an exaggerated form of intellect which causes him to see and judge matters as a horse's eye sees an object. He is clever and artful and in him the disease would be moral insanity. A sister and brother of mine are in the asylum. Our unfortunate son was not properly brought up. His father showed him an extravagant example and would not have him taught bodily work. He was indulged in every whim, as his father is a man with no sense of responsibility.

A second letter, dated Feb. 28, '02, gives added information of interest and further illustrates the mother's mental organization. She writes:

Anything you ask shall be answered per return mail. . . . My son's affliction did not spring *ab initio* from any involvement of neural processes, although through hardship injury may have subsequently occurred. I assure you that instead of his conceptional faculties being impaired, to my mind they are vivified. Strange to relate, more like a fairy tale, every word he related, as you have written, respecting his father and himself is truth, but in the abstract. In detail, they would admit of a very different construction to what he would have you understand. He has not drawn on his imagination for the events of which he made you acquainted, but he is either mendacious or misled as to the results. You asked me at what period I noticed a change in my son's demeanor. He was always obstinate and ungovernable and when at a very youthful age he consorted with bad companions of both sexes, then the influence of a mother was quite overthrown. Mind, he seemed to be possessed of great ability and great industry and huge capacity to work in what occupation suited him. Here we get great force misapplied producing *crime*, as it invariably does. His defects are congenital and the law of heredity in this instance is painfully substantiated. His, notwithstanding his great capacity, is a low order of human intellectuality. Two senses fail him to balance the overwhelming forces of his nature: *Sense of danger, of the law of results and sense of responsibility.* Admitting this, then where can the poor human vessel look for ballast. In palliation and extreme grief for the strait he has fallen in and the awful result of the " sins of the fathers," etc., in pity bear in mind that he had an over-indulgent father, who had not the capacity to control him or to show him a good enough example to restrain him. I was adjudged a hard mother because I wanted to spare the child and not the rod. As this tended to break the peace and disturb the rest of the household I was bade to desist. Hence the result. . . . They tell me that I am a pessimist, that unhappy being whom everybody wants to avoid for the sake of the bliss of living temporarily in a fool's paradise. It may be true. Can I help it? . . . Have I not been deprived of the power to enjoy? I am resigned, for an Almighty power animates me to throw myself into the breach and save those that would otherwise be lost. I have brought up ten children credibly (except the eldest). All my daughters are exceptional honors to me. My husband's businesses have failed and we are in financial straits. I am at the helm and dare say will steer through all right with Divine help.

On March 28 the mother writes again:

As you see him now so he has always been, hounding me for money to gratify his whims to squander it. On the other hand, from his writings, etc., he is not a fit subject to be in a lunatic asylum. In justice I must say this, because people are at large who are not so logical or constructive as he is. If people with an *idée fixé* were always confined, the world would be one huge lunatic asylum. Although he is morally obtuse, and although in the world, not of the world, merciless, ungrateful, unnatural and unprincipled, without the slightest force of natural instinct, morally a monster, still he is not what many thousands would pronounce insane. We know he is the victim of an obscure brain disease. Many times puzzled, I often think it is malformation of the brain, with strong passions, and no moral force to govern all. . . . He was always litigious. Of course there is policy and method in this, for when a swindler is discovered he relies on his clever lawyer to find a technical point for him to elude conviction and consequences. This is all to me something too shocking from my point of view and really my brain seems to be giving way. I feel as if I had been smelling nitrate of amyl. I am an old woman and shall be getting brain lesion with it all, no doubt paralysis. My nerves and muscles all ache. I am fast losing power of volition. What shall I do?

While physicians may smile at the mother's analysis of the case, I think members of this society will agree that her observations were keenly intelligent and her deductions not very wide of the mark. If one wished to write a thesis on the relationship between genius and insanity to prove Dryden's oft-quoted clause, " Great wits are sure to madness near allied," the forceful and pathetic letters of this highly-gifted Jewish mother would serve as strongly presumptive evidence. The mother writes again on April 10:

It is not that Harry is so litigiously mad. He is revengeful, it is true, and craving for notoriety. What he really is, is a blackmailer — a past master in the art of insinuation and blackmailing. When he goes to New York he will commence the blackmailing profession over again and get himself run in again. No, Mr. Drew, I will not undertake the onus of accepting the charge of him. . . . It would be better for me to go to the devil than to bring the devil upon me. . . . I wonder if you read

his one part deceitful letter, the other part as impudent, arrogant and overbearing as ever.

Apparently the mother's high tension organization had been taxed almost too far by the son's importuning letters, covertly threatening if she did not send more money to publish his grievances in the newspapers, using his own notorious record as a weapon to extort money from his family through their natural fear of a sensational publicity which would certainly injure the other children and further stain a respected family name. Twelve days later she writes again and now, the mother instinct being again dominant, she argues in defence of her son that he may not be returned to prison, even though she cannot have him sent to an asylum in England, as had been proposed. Both explanation and argument are so creditable to the mother's heart and intelligence, and so interesting from a psychological viewpoint, that I venture to quote further from a letter dated April 22:

While I thank you for your goodness in endeavoring to get Harry sent here to an asylum in London, I dare not bid him to be brought over. Did I do so it would at once break up the home and scatter its inmates. My daughters are working might and main at honorable professions to help me to get a living for themselves. One of them is engaged to an influential man here. My husband has only to receive a shock — he will die. Therefore they object to my bringing over sure trouble. They affirm that Harry would not rest in an asylum here, but would insist and succeed in making himself heard to air his grievances. The newspapers would ring with the unusual news, the members of my immediate family, where they were previously respected, would be surely shunned, no doubt their professional engagements canceled, my husband killed, myself paralyzed by despair, and all for what? To save the feelings of one unworthy refractory being. How can I contemplate the commission of such a crime? I dare not do it. Dr. Drew, that man cannot be sane. Nor is he. It may be true that were he to speak in his lucid, able and logical way to even experts in insanity they would not detect the flaw but declare that only a man in possession of his senses could so ably argue and manipulate documents and seize on technical points of law to get in the thin edge of the wedge to let himself out.

They might not agree that his is an obscure form of dementia, a case, to dive deeply, clearly and concisely into it, where the objective mind is more or less clouded or impeded whilst the subjective mind is permitted a force and liberty which would not belong to it were he in a condition of complete sanity. With his avowed declaration to fight law and power, to go to New York to blackmail Chapin, regardless of consequences, even any medical man decided to maintain that he is as lucid and logical and clever as any other man on the same plane, if not even more so, must at the same time admit that there is a departure from the normal balance and recognize his mental irresponsibility. The man has gone mad. His subjective mind is sole and supreme in the display of its functions. Thus — what is it we perceive? Why — a recollection of one rooted experience, one grim resolve, the *idée fixé* of the monomaniac, which will possess and play the tyrant with his mind, cause him to pursue his suicidal purpose to the bitter end, always regardless of consequences, as unreasonably and fatally as the moth flies in the flame.

The contents of these letters is my best excuse for the lengthy quotation. The son's style in writing is strikingly like his mother's. The following, to his wife, was written on one of those days when he was apparently on good terms with her, but he was a master of blandishments to obtain money or gain a fancied vantage:

MARCH 12, 1902.

MY OWN DARLING WIFE: Just a few lines to tell you I received a letter from my mother on Monday and it was enclosed to Dr. Drew. I understand my mother's *meaning* and everything is satisfactory. When you come to see me on the 26th of March I will give you a draft for some money and I will explain things fully to you what to do. I shall draw on a certain person at sight and the money is to be paid to you and you alone, as you are my wife and I cannot trust strangers. I shall not call upon you to pay any one else but Mr. Fishacher, yourself and myself. I have received some very satisfactory letters from New York and Boston. I cannot write it. Everything is going *well*. Cheer up, little wifie. God is helping us. I have had some blank drafts sent to me and I shall have a letter all ready for you and draft on the 26th of March positively. Write to me at once and tell me all the news. Write to my mother again and tell her not to write to Dr. Drew again. Be careful what you and Mr. Fishacher say to Dr. Drew. I shall explain all when I see you. I have some startling and good news for you. I dreamed last night of you all and of Queenie playing the piano and Clarence. All you, my three darlings, were kissing me and loving me. I am lonely at times without you, dear. You said that our children would write to me last Sunday. I have not received any letter yet. Write often to me and cheerful letters, as it is good for me. I am taking fresh air as you wished. Your poor husband is battling against the breakers, but he will come into port and although tossed and wounded on the ocean of life sees the lighthouse not far off. Our ship will soon sight land, my wife. Cheer up. God bless and guard you all. Your loving husband,

(Signed) H. J. B.

P. S. — Goodnight, love, and kisses . . . . Be sure and be here on the 26th of March. Write me you are coming, love. . . .

The following, to his mother, was dated March 28, 1902:

MARCH 28, 1902.

MY OWN BELOVED MOTHER: Your letter duly received enclosed again. I again ask you to write to me direct to Mr. H. J. B., State Farm, Bridgewater. It is not necessary to put word "asylum." Now let us come to some common-sense talk. I agree with you it is bad to be robbed by lawyers. Recapitulation, recrimination and transportation seems to be your peculiar mania and writing chronic lovely incriminating epistles about insanity in my family and such untruths and foolishness, and giving Dr. Drew and the State Board of Lunacy the power to hold me indefinitely. You are trying to burv me alive and turning the key on me with double padlocks. Clever muddlers! I had arranged everything well. Mr. Fishacher and my wife came on the 26th of March and in the presence of Dr. Drew my lawful wife said the words, "Dr. Drew, I have come for my lawful husband; his sentence has expired, and I, his lawful wife, am here to take him into my custody." Dr. Drew replied, "I regret, but I must have an order from the State Board of Lunacy." Now the State Board of Lunacy is a tool of Dr. Drew's and it is simply a seesaw formula game, exposed in the newspapers before, robbing me and burying me alive in a living tomb. However, Mr. Fishacher has arranged with the Commissioners to give me a ticket of leave and the State Board of Lunacy must let me go if my wife, who is my lawful legal guardian, takes me in her custody. Everything is arranged and poor Gertrude is on deck ready. We shall not make a demand until the $250 is here. Send the draft to Gertrude at once. Do not muddle matters, for God's sake. I shall follow out your idea in many ways. Remit to my wife, Gertrude B., at once. I am satisfied she is faithful and loving. She lay in my arms all day and is pining to get me back with her and the children. Do not delay a moment. Leave all to me. Mr. Fishacher and Gertrude and myself will arrange everything. On receipt of the money, wifie will get me a suit of clothes, some

shirts and pay my fare and I shall come out right. The reason why I want the money at once in my wife's hands is because when she sees the Board of Lunacy with Mr. Fishacher she will state that she has money to take care of me and that I will not be a charge on the state, and Mr. Fishacher has got the ticket of leave ready from the commissioners and police. Remit to Gertrude at once. Do not muddle me into my coffin, as that will be the next step — my coffin. You have all muddled me into a madhouse and the next will be death. Stop muddling. You have a dangerous pen, writing about insanity. The insanity dodge adopted by lawyers is good in some cases, but not in all. Use tact and judgment. Stop this ghastly work of thwarting my able efforts for release. Remit and you will soon get a cable from me when I am free. Gertrude must have money in hand to state she is able to take me Do you understand or are you obtuse? When you wanted money I sent it to you. I need help now from a lunatic asylum. I know, my own beloved mother, you mean well, but it is a case of life and liberty and I must speak plain. Be sure and remit at once. Instead of your coming over, my wife will do your work for you and take me. Send her the money. I can be out now in an hour, but she must have cash to say I am all ready and not a burden to the state, etc. I am now at your pleasure, waiting in the madhouse for funds for help from you. Cable remitting. May God bless you and keep you and guide you! I shall find lots of work to do and will be a good faithful father to my darling children and a good husband, and a faithful son to father and you. I long to kiss you both again. Good bye. Your own loving son,

(Signed) H. J. B.

P. S. — Remit cable. Remit to Gertrude, she is faithful and true. I have found it out. Remit. Waiting. Help! I shriek a sane man from the madhouse. Help! Help! Help! Remit cable.

(To be continued.)

A NEW METHOD OF CLOSING THE ABDOMEN AFTER LAPAROTOMY.*

BY FRANK A. HIGGINS, M.D., BOSTON.

ACCORDING to our present customs the ideal closure of the abdominal wall after laparotomy would seem to be attained by a method of careful approximation and suture of each individual layer by fine, absorbable and perfectly sterilizable suture material, which could be inserted without the necessity of tying knots, and without the necessity of perforating the skin by sutures. The ideal method of closure would also obliterate all so-called dead spaces and be able to prevent all fluid accumulations within the layers.

Skin sutures, knots, permanent suture material of all kinds, absorbable sutures which cannot always be perfectly sterilized, and dead spaces allowing fluid accumulation within the layers of the abdominal wall are the chief difficulties, aside from septic material introduced at the operation, which interfere with obtaining perfect results, and are the questions which confront one in attempting to decide the best way in which to perform the work.

Many methods have been proposed and used for the closure of the abdominal wound — so many, in fact, that it would seem almost impossible to devise another possessing merit. This is very likely so, but still it is not probable that the last word has been said on this any more than on any other subject connected with surgery. New methods will undoubtedly be evolved in the future, and very probably new materials for suture superior to anything we know of at present. With some of the present methods of suture of the abdominal wall the results, both temporary and permanent, are almost ideal in many of the cases. It seems evident, then, that any further advance must be directed towards the improvement of the technic and to the devotion of more careful attention to details.

There are practically only two methods of abdominal suture, the mass or through-and-through suture and the layer or tire suture, all others being essentially modifications of one or the other of these two. Each method has its advocates, but the superiority of the layer method in most cases is becoming generally evident to surgeons and writers. It is not my intention to review or discuss at length the question of the different methods of closure of the abdominal wall after operation, or to argue for or against any particular method, any more than may be necessary to point out and demonstrate the feasibility and advantages of the modification which I suggest.

The layer suture is generally regarded as the nearest approach which we can attain to the natural conditions existing before operation. This, with some combination of the mass suture, probably offers the strongest barrier possible to hernia and to infection through accumulation of fluid within the walls, and this modification has been adopted as a satisfactory compromise by a number of surgeons. The tier suture is chiefly objected to because of the danger of the so-called dead spaces and the time necessary for its use. The extra time is not usually an important factor, as the anesthetic may generally be omitted as soon as the peritoneal suture is begun, and the whole wound is commonly closed before the patient makes any disturbing efforts to move. In the comparatively few cases in which the shock is a vital element then technic has to be abandoned and every attention given to rapidity, and the mass suture becomes necessary.

The second objection raised against the layer suture is that it leaves at least two dead spaces, and under these circumstances a wound is likely to become filled with blood. The longer the wound, the greater this danger. That there is greater liability of infection taking place when dead spaces are present is also generally admitted. These objections are undoubtedly important ones.

Of course if any source for septic infection has been introduced or left in the abdominal wall, the exercise of pressure by the mass suture will not eliminate it. Yet the abscess in the abdominal wall generally arises from the infection of fluid accumulations of blood and lymph, by the less virulent forms of bacteria from the skin. If these fluid accumulations are prevented, the bacteria, present only in limited quantities, do not find the most favorable soil for development and are usually eliminated without giving rise to trouble.

*Contributed to the fourteenth series of Medical and Surgical Reports of the Boston City Hospital.

Permanent suture material in the abdominal wall seems in general to be undesirable because so many cases have occurred in which it has caused irritation and eventually required removal. Probably the constant strain and tension on the abdominal wall and the frequent contraction of the abdominal muscles have more or less to do with the irritation caused by permanent foreign material in this particular part of the body.

Sutures of absorbable animal material such as catgut, of the sterilization of which we can never be perfectly sure, are never used by many men, but the choice for the present at least must lie between this and non-absorbable sutures. I have always used fine catgut, and have never had bad results which could be attributed directly to it, and therefore I shall probably continue its use until some more favorable absorbable suture is developed.

The objections to sutures passed through the skin are well known. They arise from the cutting and irritation which they cause and from the presence of the skin micrococci. If the sutures are passed from within outwards and the metal guard I propose is used, these difficulties become practically nil.

Knots, which are often of considerable size, to be secure against untying, seem to me to be occasionally a source of irritation in the abdominal wall. This occurs especially in thin patients and at the lower end of the incision where the fascial suture is tied and the knot becomes practically subcutaneous. Occasionally as late as two or three weeks after operation a wound will open a little at this point without suppuration after primary union has apparently taken place. This is not a serious condition, but it is annoying, and is often rather slow in healing. I know of no way of accounting for it except on the theory that the knot in the fascial suture, which is just beneath the skin in these cases, causes irritation. The method recently proposed of suturing the fascia with a removable silkworm gut suture might obviate this difficulty. I have not used this method, because this suture must be removed within two weeks, and it seems desirable to me to have a suture in the fascia which will remain about three weeks.

There are three important considerations to be kept constantly in mind in every operation, abdominal or otherwise. These are, first, the preservation of the life of the patient; second, the securing of results tending to the improvement of the patient's condition; and, third, the after results and the appearance of the patient.

With the first two conditions this paper is not concerned. Under the third arise several conditions which we may consider. The frequency of ventral hernia has been greatly diminished by the layer suture, by the avoidance of drainage, and by the securing of aseptic healing of the wound. Hernia may occur also as a direct result of fluid accumulation within the abdominal wall, causing fistulous openings and ending in secondary suppuration. The importance of the prevention of fluid accumulations in the abdominal wall has been repeatedly pointed out. It has been authoritatively stated that " nothing is more conducive to primary healing of wounds than the absolute avoidance of all oozing or accumulations of blood, which may become infected and give rise to suppuration after the wound is closed."

A judicious combination of the mass and tier suture methods of closing the abdominal wall undoubtedly overcomes the most serious disadvantages of either method used alone. The through-and-through suture itself, as used at present, has never proved very satisfactory as I have seen it used by others or in my own work. Trouble frequently arises from the fact that these sutures have to be tied tightly in order to bring the layers and the skin together. After the first few days these stitches begin to cause considerable redness around the sutures where they penetrate the skin; and where they cross the wound they cut through the skin and not infrequently give rise to suppuration and to stitch abscesses. Further infection ensues unless at this time the irritating sutures are cut and removed, and then a weak corrosive dressing is necessary to check the inflammation just starting up. These through-and-through sutures of silkworm gut, which are almost sure to cut through the skin more or less as described, give rise to additional scars on the abdomen, which later are often seen as welts from one-quarter to one-half inch in length running at right angles to the direction of the wound. The early removal of these through-and-through sutures is apt to end in some separation of the edges of the wound, entailing delayed union and a wider scar.

Some surgeons deny that the appearance of the wound after healing is of any importance, and do not take into consideration at all the looks of the resulting scar. If the functional result is good that is all that is necessary, claiming that whatever the appearance of the scar may be, it does not matter to the patient. I believe that this is true to a certain extent with a certain number of patients. With other patients I have found that the idea of having any abdominal scar is very objectionable, and of such importance does it appear to them that they will not consent to have any abdominal operation performed except under urgent indications. I have known operations put off for this reason only, even when there has been actual pelvic pain. It is also true that many patients do not inquire or think about these things in connection with an operation. I have also heard patients criticise the work done at certain hospitals and by certain surgeons because some friend who had been operated upon by another man had a narrower and shorter scar. This may be a comparatively small matter which the older surgeon with a widely established reputation does not need to consider in his work. Very likely also he does not have to answer the questions that are propounded to the younger man, and, moreover, his results are more likely to be taken without question than are those of the young surgeon.

Very small incidents are often known to exert great influence, in matters of much importance, for the good or for the detriment of a man. Especially is this apt to be true at the beginning of a man's career. I believe that at all times the abdomen after operation should be left in as good a condition as possible with regard to both strength and looks, and that in the long run, other things being equal, the man who does this and who pays careful attention to details will be the more successful and obtain the best results.

The question then arises: how can the factors which prevent the rapid and uncomplicated healing of the abdominal wound best be prevented? In the writer's opinion, by the use of the tier suture in combination with the mass suture, by the introduction of mass sutures in such a manner that they cannot irritate and cut through the skin, and by the exercise of suitable counter-pressure along the whole length of the incision in the abdominal wall. Dead spaces have not heretofore been thoroughly overcome by the mass suture unless these sutures are put in much closer than has been customary in the writer's observation. As used, however, they have sufficed for all practical purposes in the great majority of cases.

Some two years ago the writer, who has always believed in the tier suture, became convinced of its disadvantages from the results in some cases of his own, and attempted to overcome the possibility of fluid accumulations in the abdominal walls by a modification of the mass suture. This modification had never been tried elsewhere so far as I am aware; at least, though I have not made an extensive search of the literature, I had never seen it suggested. It consisted in passing several mass sutures of fine catgut — No. 1 chromicized, preferably, because of its strength and lasting qualities — through the various layers of the abdomen, from the peritoneum outward to, but not through, the skin. This constituted a buried mass suture of absorbable material, which included all the structures in the abdominal wall except the skin. The peritoneum and fascia were sutured with running catgut suture before these mass sutures were tied. After these were tied the skin was sutured in the usual way. This method was abandoned, although no trouble whatsoever was experienced from its use in the few cases in which it was tried. The chief reasons why this method of introducing the mass suture was given up were that the knots in the mass sutures came just beneath the surface of the skin, and I feared would in many cases cause sufficient irritation to interfere with union. In addition, I did not like the idea of leaving any more suture material than was absolutely necessary to be absorbed by the tissues in the abdominal wall. This modification possessed the attractive feature of having absolutely no penetrating sutures in the skin, provided the subcuticular suture was used; but its disadvantages seemed to outweigh its good points.

More recently I have again been devoting considerable attention to the subject of the abdominal suture and the obliteration of dead spaces, which I believe it is unwise to neglect. The mass suture as at present generally used is unsatisfactory, because it cuts through the skin and gives rise to redness, to irritation and to scars. It frequently results in stitch abscesses, and on this account often has to be removed before the union has become firm.

Granted that the mass sutures are necessary, it has always seemed to me that the desideratum is proper and effective counter-pressure against these sutures. The idea of a narrow metal plate with perforations, as shown in Figure 1, first occurred to me. This plate in actual practice was abandoned because it was found that, unless the sutures were put in with considerable care and at the expenditure of more time than was desirable, they were not likely to come opposite the perforations in the plate. The same metal plate with serrations in the edges, as shown in Figure 2, was also abandoned for much the same reasons. In using this plate, however, it was found that it did not matter where, along its edges, the sutures were tied. They held equally well wherever placed, and there was no opportunity for the plate to slip either way. Consequently the metal strip with straight parallel edges, Figure 3, has since been used. The plate is a strip of thin, nickel-plated copper about one-

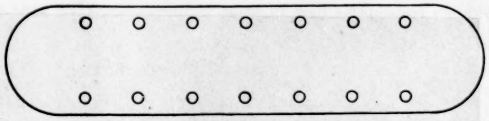

Fig. 1.

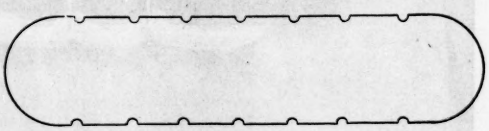

Fig. 2.

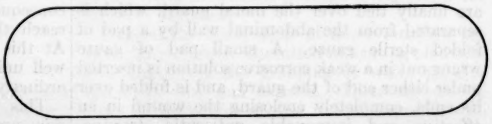

Fig. 3.

thirtieth of an inch thick. It is stiff enough not to be bent by the sutures, but is easily bent by the fingers in case it needs to be adjusted to any inequalities in the surface of the abdomen.

I will state briefly the method by which it seems to me best to close the abdominal wound after laparotomy. The mass sutures of silkworm gut are introduced by double-threaded large curved needles. One suture is placed at either end of the wound, and one or more between, depending upon the length of the wound, fewer being needed than without the metal guard. The ends of these mass sutures are clamped and held on either side by heavy clamps which by their weight hold the sutures tight and prevent any danger of the intestine or omentum slipping beneath them. The peritoneum is then closed by a running suture of fine unchromicized catgut, the fascia by fine twenty-day chromicized gut, and the skin with a subcuticular suture of fine silkworm gut or horse-hair. The mass sutures are finally tied over the metal guard, which is separated from the abdominal wall by a pad of folded sterile gauze. A small pad of gauze wrung out in a weak corrosive solution is inserted under either end of the guard, and is folded over its ends, completely enclosing the wound in an effective and immovable antiseptic dressing. This acts effectually as a barrier to any outside infection, while nothing but sterile gauze comes in contact with the surface of the wound. Figure 4 shows the metal guard in place, with the mass sutures tied and the antiseptic gauze at the top and bottom ready to fold over. The outer dressing need then be only a comparatively small one. Usually on the fifth day after operation the first dressing is done, and the mass sutures, having performed their function, are cut. They are not removed till the day following. Subsequent dressings are repeated every second or third day, and the subcuticular skin suture is removed in from ten to fourteen days. The mass sutures, having merely perforated the skin for a short time, leave no permanent scar.

The through-and-through sutures should not be tied under more tension than one would use without the metal guard. In this way the circulation is not interfered with, the vitality of the tissues is not lowered, and there is no cutting through of the sutures, at least on the surface. The gauze beneath the metal guard is of advantage in that it relieves the skin from direct pressure of the metal, and that it absorbs the slight amount of blood from the skin and whatever may be expressed by the counter-pressure. In addition, the metal guard holds the dressing absolutely in place without adhesive straps, and consequently no outside source of infection can reach the wound until after its first dressing. At this time the wound should be sufficiently well united to insure it against infection under ordinary conditions.

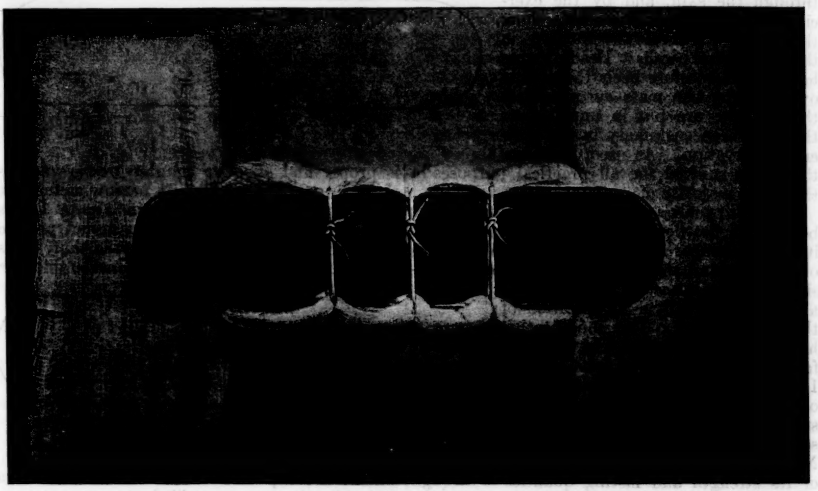

Fig. 4.

This modification which I propose, and have now used for a number of months with great improvement in my results, may at first appear unnecessary and cumbersome, but in actual practice it does seem to possess decided advantages. In the first place, it in no way interferes with the perfect and aseptic healing of the wound. It eliminates the chief objections to the layer suture without increasing materially the time needed for closure. It effectually controls all

oozing of blood and serum into the wound, so that it becomes rarely necessary to ligate any of the vessels. The accumulation of all collections of blood within the layers of the abdominal wall is thereby prevented. Stitch and other forms of abscesses become practically eliminated. With its use several advantages in its favor have appeared which were not apparent or expected at its conception. One is that the pressure of the metal guard promotes adhesion between the layers in the abdominal wall, and a distinct non-inflammatory induration may be felt running along on either side parallel with the edges of the wound. This, I believe, tends to the formation of a firmer and stronger cicatrix than any other method yet proposed. It also tends to prevent stretching apart of the edges of the skin, and results in a linear scar.

The writer, in conclusion, would say that he does not so much regard this as a new method of abdominal suture, as he does that it is another step in the technic of the closure of the abdominal wound, and one by which many of the disadvantages of the layer and the mass sutures may be overcome. It requires very little extra time for its application, it promotes union, and it gives additional strength and improved appearance to the abdominal wall. I do not expect its advantages to be appreciated without a trial, but I do believe, from my own experience, that after a fair trial others will be convinced that it has certain advantages in many cases.

Since this paper was begun the writer has been trying, in place of the metal shield, transparent plates of celluloid or pyrolin. With plates of this material, pads of sterile gauze are placed alongside either edge of the wound, but do not press directly upon the surface of the wound itself. Glass plates might be used in the same way.

This method possesses the attractive feature that the outer dressing may be removed daily if desired, and the healing observed without being obliged to disturb or dress the wound. The writer would merely mention this latter device as a suggestion here. He does not intend at the present time to advocate its permanent use without more extended trial.

ALBUMINURIC RETINITIS.[1]

BY ALLEN GREENWOOD, M.D., BOSTON,

Ophthalmic Surgeon to the Boston City Hospital.

It is well known that frequently the presence of an optic neuritis will lead to the discovery of a previously unsuspected cerebral tumor, but it is even more frequent that the presence of a characteristic retinitis will lead to a diagnosis of chronic nephritis, in cases where renal disease was previously unsuspected. It is the frequent experience of every oculist to find in patients whose only complaint is a dimness of vision, the ophthalmoscopic picture of albuminuric retinitis, resulting in the diagnosis of a fatal renal disease. Out of 26 cases I have seen in private practice, in only 5 was there any previous knowledge of kidney disease. It is in relation to the prognosis of such cases, however, that albuminuric retinitis is of the greatest aid; a prognosis, indeed, than which there is scarcely any more certain. By a very brief ophthalmoscopic examination, a diagnosis and prognosis may often be given which seem little short of miraculous to the friends and physician of the patient. That the possibilities of diagnosis are apparent to laymen as well to physicians is evidenced by the experience which probably happens to all oculists of having patients present themselves with the request that their eyes be examined to see if they show anything indicating kidney disease. Physicians certainly appreciate the prognostic importance of this condition, for I have many times been called in consultation in cases of well established chronic nephritis to see if the ophthalmoscope would aid in the prognosis. It is well known that the prognosis as to the length of life in most cases of chronic nephritis without retinal complications is very uncertain, while with them there is a certainty such as is established in but few chronic diseases.

The ophthalmoscopic appearances of albuminuric retinitis are so well known and described in all the modern textbooks that I will only mention them in part and very briefly. In Norris and Oliver seven forms are spoken of as capable of differentiation, viz.:

(1) Typical albuminuric retinitis.
(2) Degenerative albuminuric retinitis.
(3) Hemorrhagic albuminuric retinitis.
(4) Albuminuric chorio-retinitis.
(5) Albuminuric neuro-retinitis.
(6) Albuminuric papillitis.
(7) Saturnine retinitis.

In actual practice these various forms merge into each other, and often a number may be nearly equally prominent, so as to make it impossible in many cases to name the variety. After having watched several cases from nearly the beginning to the end, one is inclined to consider that many of the so-called forms are but stages in this inflammatory and degenerative disease of the retina, choroid and nerve. In some cases and in some stages one or more of the pathological conditions predominates, hence the different varieties.

Besides the usual signs of neuro-retinitis, the most characteristic alteration indicating albuminuric retinitis is the grouping of white patches about the disc and macula. These are due to fatty degeneration of the retinal elements and exudates, and vary much in size and shape. In the macula region they often run together, forming lines radiating out from the fovea like star points with lines of pigment deposit between. In some cases of albuminuric retinitis they are absent, and there may be only a few hemorrhages or a papillitis to suggest the correct diagnosis, the papillitis in rare cases amounting to a choked disc, so that in every case of retinitis or neuritis

the urine should be examined. The retinitis is almost invariably bilateral sooner or later, though usually more advanced in one eye. It is, I think, generally conceded that the pathological conditions are due to degenerative changes in the blood vessels of the retina, choroid and nerve, resulting in the inflammations, hemorrhages, exudates and degenerations which go to make up the usual ophthalmoscopic picture. These vascular changes are in some cases largely a part of a general arterial degeneration, and in others largely the result of slow uremic poisoning. The latest researches into the microscopical changes show an even greater involvement of the vessels of the choroid than those of the retina, and it has certainly been my experience to find extensive choroidal changes in quite a number of cases. I find that several times lately I have made the diagnosis of albuminuric chorio-retinitis where there has been extensive choroidal change with destruction of the choroid and laying bare of the sclera with the surrounding embankments of pigment.

After seeing a few cases of albuminuric retinitis, I found myself grouping them in two distinct classes based, not on retinal differences, but on the supposed primary pathological conditions which cause the chorio-retinal changes. The cases here reported illustrate this very well. The first group of cases include those where the endarteritis of the chorio-retinal vessels, with its consequent changes in the choroid and retina, is largely a part of a general arterial degeneration of which the chronic interstitial nephritis is also only a part. These cases occur in the old and middle-aged where the whole vascular system has become more or less subject to degenerative changes, from age as well as from impure blood, and the involvement of the chorio-retinal vessels only shows an advanced stage of a degenerative condition, which has existed for some time, and which almost invariably advances to a fatal issue. Death usually results from extensive kidney impairment causing uremia, or else one of the arterioles in the brain more diseased than its fellows, yielding to that increased blood pressure which comes with cardiac hypertrophy, causes a fatal hemorrhage. In these cases the chorio-retinal degeneration is less extensive and often the vascular disease in the choroid and retina causes visible pathological changes before the vascular disease in the kidney has advanced enough to produce a constant albuminuria, as shown in the first and eleventh cases of this group. The prognosis as to length of life is a little better than in the second group.

The second group includes those cases which are more correctly designated as cases of retinitis albuminurica, from the fact that they are directly caused by uremic poisoning of the blood from a distinctly demonstrable acute or chronic lesion of the kidney, usually of a parenchymatous or diffuse type. They occur mostly in youth and early adult life, showing a greater retinal destruction with consequent greater impairment of vision, and the prognosis is extremely bad in all but those resulting from the acute nephritis of scarlet fever and pregnancy. It is in the prognosis of both classes of cases of chronic nephritis associated with albuminuric retinitis that I wish to interest you particularly.

Regarding the length of life after the discovery of the retinitis, the following may help. Baroness Possaner found the following from the cases taken from 67,000 cases from the Zurich clinic and private practice of Professor Haab:

Men	from the poorer classes all died in two years.							
Women	„	„	„	„	68%	„	„	„
Men	„	„	better	„	59%	„	„	„
Women	„	„	„	„	53%	„	„	„

The longest period in the poorer class was six years, and in the better class, eleven years.

In a report by Bell at the Ophthalmological section of the American Medical Association, 100 cases collected from the private practice of various ophthalmologists are given, and of these 73% died in one year and 94% in two years.

Rogers collected 419 reported cases which included those of Possaner and Belt, and of these 90% died within two years.

In my private practice in the past twelve years I have seen 26 cases, and am able to report the subsequent condition of all but two. Of the 26 there are six living to-day, but none of these was seen prior to three years ago. Of the 20 who have died only two lived over three years. I shall only give a brief history of the two or three most interesting cases and a synopsis of the others.

GROUP I.

1. Miss E., aged forty-two, called on account of failing vision Dec. 18, 1891.

O. D. V. = 20–70. O. S. V. = 20–20.

O. D. well-marked neuro-retinitis, with numerous flame-like hemorrhages and spots of exudate. There was a large irregular patch of degeneration at the macula involving the choroid, with consequent embankment of pigment.

O. S. Slight neuro-retinitis with a few hemorrhages and spots of exudate about disc. Macula not involved.

Examination of urine showed specific gravity 1,012, and only the most minute trace of albumin. Three casts in 8 slides. Chronic interstitial nephritis. Examination a few days later by an expert chemist, who reported that no albumin or casts were present. A few months later, however, albumin and casts were easily found.

March 17, 1892, O. D. V. = 20–200. O. S. = 20–70 more spots of exudate and degeneration. Patient died August, 1893, from uremic poisoning, a few months after a cerebral hemorrhage, one year and eight months from time of my first seeing her.

2. Mrs. F., Natick, age fifty-five. Seen March 14, 1892. Retinitis with hemorrhages and exudates. No subsequent history obtainable. Urine — chronic interstitial nephritis.

3. Mrs. F., aged seventy. Seen Nov. 3, 1897. Had had a cerebral hemorrhage a few weeks previously with hemiplegia and hemianopsia. Fundi showed neuro-retinitis with flame-like hemorrhages and spots of exudate. Chronic interstitial nephritis. Died March 27, 1900. Lived two years four and one-half months.

4. Mr. C. O. L., age sixty. Seen Jan. 6, 1898. Neuro-retinitis with exudates. Urine—chronic interstitial nephritis. Died Nov. 6, 1899. Lived one year and two months.

5. Mrs. H. W. P., age seventy-three. Seen April 11, 1897. Albuminuric retinitis. Chronic interstitial nephritis. Died comatose Oct. 5, 1899. Lived two years and six months.

6. Mrs. R. H., age sixty-seven. Seen July 12, 1897. Neuro-retinitis, with exudates about the maculæ. Urine

— chronic interstitial nephritis. Died Dec. 5, 1897. Lived six months.

7. Mrs. M. B., age fifty-five. Seen July 30, 1897. Simply exudates about maculæ. Urine — chronic interstitial nephritis. Died March 8, 1900. Lived two years eight and one-half months.

8. Mrs. F., age thirty-five. Seen Jan. 15, 1896. Fundi show chorio-retinitis with a few hemorrhages and spots of exudate and degeneration. Chronic interstitial nephritis. Died March 14, 1900. Lived four years and two months.

9. Mrs. F., age fifty. Seen June 3, 1898. O. U. show a few scattered hemorrhages, and a few spots of exudate about maculæ, chronic interstitial nephritis. Died of cerebral hemorrhage, Aug. 11, 1900. Lived two years one month eleven days.

10. Mr. L. W., age eighty. Seen April 11, 1896, on which date I removed a cataract. The resulting vision being poor, I examined the fundus, finding albuminuric retinitis. The family physician found advanced chronic interstitial nephritis. The patient died Sept. 28, 1897, living one year and five months.

11. Mrs. W., age fifty. Seen June 12, 1896. Had neuro-retinitis, with abundant hemorrhages and spots of exudate. The family physician reported urine normal to the family, but in a year she developed chronic interstitial nephritis, and died in convulsions one year and six months after I saw her.

12. Mrs. H., age seventy. Seen July 6, 1894. Albuminuric retinitis, complicating incipient cataract. Urine of chronic interstitial nephritis. Died twelve months later.

13. Mr. T., age seventy-five. Seen Nov. 14, 1897. Fundi showed haziness of disc outlines, and in the region between the discs and maculæ were many small round spots of yellowish-white exudate. No hemorrhages or degenerations. The family physician reported ½% of albumin and existence of chronic interstitial nephritis. Died Feb. 26, 1898. Lived three and one-half months.

14. Mrs. S., age fifty-six. Seen July 12, 1902. Complained of dim vision and not being able to get glasses to help her. V. o. u. 20–200; incipient cataract o. s. Fundi showed neuro-retinitis with exudates about maculæ and one hemorrhage below right disc. Urine shows chronic interstitial nephritis. Died Nov. 12, 1902. Lived four months.

Added to this group are the following cases still living:

15. Mrs. P., age sixty-one. Seen July 26, 1900. Her family physician had discovered albuminuria from chronic interstitial nephritis, and sent her to me for help in prognosis. Neuro-retinitis with spots of exudate. No hemorrhages. Is still living two and one-half years after.

16. Mr. C., age sixty-seven. Seen Feb. 16, 1901. Has incipient cataract and neuro-retinitis, with hemorrhages. Chronic interstitial nephritis. Still living one year and eleven months after.

GROUP II.

1. Susie W., age sixteen. Seen Nov. 15, 1893. Seamstress; came for failing vision. Degenerative chorio-retinitis. No hemorrhages. Vision much reduced. No papillitis. Maculæ involved. Chronic diffuse nephritis. Died April 6, 1898, from uremic coma. Lived four years and seven months.

2. Miss G., age twenty-six. Seen Sept. 21, 1894. Watchmaker, came for failing vision. Degenerative chorio-retinitis o. u. Macula involved o. u. No papillitis or hemorrhages. Diffuse nephritis. Died Oct. 22, 1894, in uremic coma. Lived one month.

3. E. L., age sixteen. Seen April 12, 1899. Came for failing vision. Had to leave her work several weeks ago on account of poor eyesight. O. D. V. = fingers at two feet. O. S. V. = 20–100. O. U. the fundi show a large amount of whitish exudate about the disc, covering the edge and burying the blood vessels in places. Throughout the retina were numerous white spots of exudate. In the macula region O. D. there was the star appearance of radiating lines of degeneration with intervening lines of pigment deposits with a heap of pigment in the centre of the macula. No hemorrhages. In O. S. the same condition involving only half of the macula region. Chronic diffuse nephritis with urine solid on boiling. Died in uremic coma April 19, 1900. Lived one year seven days.

4. Miss P., age twenty-two. Seen July 6, 1893. Worked in watch factory till six months before. O. U. showed chronic retinitis with complete destruction of retina and choroid over large areas including the maculæ. Gray atrophy of optic nerves with arteries reduced to mere threads. No perception of light. Had uremic convulsions every day or two, and died in one six weeks later. Chronic diffuse nephritis, urine solid on boiling.

5. J. W. H., age thirty-four. His physician had diagnosed chronic diffuse nephritis. Two and one half years ago feet and legs began to swell. Six months ago his sight began to fail in left eye; right eye blind from injury. Seen May 1, 1901. Left eye showed a neuro-retinitis. The neuritis was so marked that the disc could not be seen. Region about disc and macula occupied by exudate. Few small hemorrhages. His physician informed that death would probably occur inside of a year. Died of uremic poisoning Nov. 29, 1901. Lived about seven months.

6. A. H., age thirty. Came to my office Aug. 27, 1901, for failing sight in both eyes, particularly the right one. Was not aware of any other physical disability. O. D. V. = 20–400. D. S. V. = 20–30. O. U. neuro-retinitis with hemorrhages about discs. Exudates and degenerations about maculæ. Urine showed chronic diffuse nephritis with ½% albumin. Died in New York, Nov. 19, 1901. Lived about three months.

Added to this group are the following cases still living or unheard from:

7. W. W., age twenty-two. Seen July 20, 1900. Complained of failing vision only. O. U. V. = 20–200. Fundi showed neuro-retinitis with exudates; and degenerations. His physician reported chronic parenchymatous nephritis. Left town soon after and I have been unable to trace him.

8. F., age twenty-six. Seen Aug. 7, 1900. Sent by his physician for help in prognosis, as he had a chronic diffuse nephritis. O. U. had well-marked neuro-retinitis with hemorrhages and exudates. The last report from him was to the effect that he had failed so much that he was obliged to give up all work.

To these should be added cases nine and ten of this group, which were cases of acute nephritis from pregnancy with complete recovery of the eyes and kidneys.

My cases are too few to deduct percentages from, but the following may be noted: Out of the sixteen cases of the first group, of one I have no subsequent history; four died within one year, four within two years and four within three years. Only one lived over three years, death coming in four years and two months. Of the two living neither dates back over two and one-half years.

Out of the ten cases of the second group, of one I have no subsequent history; four died within eight months; one died within two years; one died after four years and seven months: one was known to be alive two and one-half years after first being seen. The two cases occurring from pregnancy have recovered entirely.

From these cases and the many others of different observers, it is plain that the prognosis afforded by the discovery of albuminuric retinitis in cases of chronic kidney diseases is very grave, and that life is but rarely prolonged more than three years. It has been noticed that cases occurring in the better classes live the longest as a result of better hygienic surroundings and care. I feel sure that as we learn more about the body metabolism in such cases, and can give them the best diet and hygienic treatment, we shall

be able to retard the progressive decline, and materially lengthen life. How much capsulotomy may do in these cases will be told in the future. I realize that my clinical grouping of these cases is open to criticism, but I hope, in the near future, by post mortems and microscopical examinations to prove the grouping correct pathologically.

AS TO POPE LEO'S CASE — PLEURO-PNEUMONIA.

BY SAMUEL DELANO, M.D., BOSTON.

Now that Italy has poured a broadside into the diagnosis of the late Pope's case, the time may seem opportune for letting go with some guns of our own. It might be worth while, if merely for general principles' sake, to submit the diagnosis to the test of inherent probability; because general reasoning in a large percentage of cases furnishes so good a guide to follow. It must, however, be conceded that in a given instance this would not coincide with legitimate criticism, because one well-observed fact might show your most careful logic to be a non-sequitur.

Nevertheless it seems highly improbable that fibrinous pneumonia should be at work in an old man of ninety-three, sick some days before medical aid was summoned, lingering on some weeks, while in that time he could be up and dressed and give many audiences; with a temperature ranging irregularly over the lower fever scale, a respiration for much of the time in the neighborhood of 25 and the pulse around 85.

Inadequate as these items might seem, however, we should still have to keep silence, if only on the principle that in medical diagnosis the looker-on does *not* get the best of the game, had not there been a fatal flaw in the autopsy. Here, certainly, allegiance must waver, for, advancing a pathological diagnosis of gray hepatization of the lower lobe, this is made to rest upon the statement in the commentary that " from the cut surface an abundant dirty white fluid without gas oozed out, *showing complete hepatization.*" Of course, as a matter of fact, nothing could be much drier than the cut surface of gray hepatized lung and we thus not only have to do with an absolute inconsistency of statement, but the description fits no stage of pneumonia, — on the contrary comes very much closer to an edema in a compressed lung.

Yet the paramount reason for taking exception to the diagnosis of pneumonia in the Pope's case is that pleuritic effusion in sufficient quantity to aspirate is next to never associated with fibrinous pneumonia. And this furnishes the real object of this communication as well as the moral that the case points. That this is not the prevailing view and that clinical evidence might be put forward to the contrary, I am well aware, but my firm belief is that owing to a confusion of physical signs a great deal of error has crept into our conceptions. The point has obviously an important practical bearing, inasmuch as the prognosis and treatment of effusion and pneumonia are quite antipodal and because the early detection of fluid is necessary to a wise supervision.

To begin at the end, viz., the autopsy, that great controller of clinical observation,— autopsy findings offer next to no support to the idea of effusion combining with pneumonia; that is to say, personal observation of a goodly number of autopsies and a considerable search of records confirm the principle that pneumonia is not associated with effusion sufficient to influence the physical signs or yield on tapping; a teacupful of fluid there may be, perhaps, but this is no more than the agony or gravity would account for.

This fact if confirmed, would indicate at least that the tendency of pneumonia was not towards the establishing of effusion and it would only remain to determine how far the trend may be influenced by a prolongation of the case or by recovery.

How then account for the impression prevailing that many cases come in as pneumonia and end up with simple effusion or empyema? It goes back to nothing except the perversion and consequent confusion of physical signs. I leave out of account the rational signs which in these cases, especially of empyema, might cut a considerable figure in correcting the error.

The crux of the matter is that pleuritic effusion commencing as such idiopathically may in a certain good percentage of cases be characterized by a bronchial or sniffling respiration that easily passes for the respiration originating in solidified lung. The sophistication is especially apt to be the more successful because it is in very moderate effusions that the most suspicious signs occur, while towards the top of the fluid the sniffling respiration and the voice sounds of like character may be very near the ear. The discrimination may be a delicate task, but into that it is not my purpose to enter. Finally, if the chest fills up we may have a blowing respiration over the whole chest, the sound, however, being fuller and more amphoric than in the case of the smaller amounts.

In my experience empyema is especially apt to include the bronchial element in its signs and that, too, from the outset. I have observed a considerable number of empyemas starting with an all-round bronchial character in the lower back, this mounting higher till extended over the whole chest. The diagnosis of pneumonia was persisted in by a number of observers. Finally, that the chest was full could no longer be denied and operation was invoked. Cases such as these are undoubtedly reported as empyemas following pneumonia, yet there was no distinct demarcation in the physical signs; furthermore, the diagnosis of effusion at the outset was made as well, and it would seem justifiably. In the writer's opinion empyemas, as a matter of fact, are much more often effusion from the start and much more rarely associated with pneumonia than supposed. In the first place, if autopsy shows the marked tendency of pneumonia away from effusion, this fact emphasizes the unreasonableness of linking empyema to pneumonia through the medium of a large serous effusion, to become purulent

secondarily. Again, to trace the empyema back to a pneumonia eventuating in gangrene or abscess, is to follow another improbable route, because such cases are so ill that death steps in ahead of the empyema. Finally, if the cases are carefully studied it will be found that *quoad* pneumonia these empyema cases with bronchial signs are defective in the matter of rational signs, there being often nothing in that province to substantiate a pneumonia diagnosis, while, most important of all, the original physical signs did not correspond with the limits of a lobe.

What happened in the Pope's case seems then to have been this: Examining the patient, his physicians find as they reported bronchial signs over a limited area in the back (designated by ribs, but I have forgotten which) corresponding to the upper part of the lower lobe; as the basis of this a diagnosis of lobar pneumonia is made — in reality the signs with much more probability coincided with the upper limits of an effusion. In a few days convincing themselves that there was fluid, they tap and get a couple of pints. The diagnosis then expands into pleuro-pneumonia — pneumonia plus effusion. At the autopsy some weeks later the lung is reported still in a state of gray hepatization, notwithstanding its fluidity, *mirabile dictu !*

So then it seems within the bounds of probability to say that the Pope had no pneumonia, but only effusion, and let us trust we shall not be making the same mistake in the same way, because the trap is very often set. As to whether the effusion was of simple, tubercular or cancerous origin, we may leave his physicians and Professor Cardiarelli to thrash out.

Clinical Department.

RUPTURE OF THE TENDON OF THE EXTENSOR LONGUS POLLICIS; TENDON TRANSPLANTATION.

BY C. L. SCUDDER, M.D., AND W. E. PAUL, M.D., BOSTON.

UNCOMPLICATED rupture of a long tendon of the hand is rare. The following instance of a complete transverse tear of the left extensor longus pollicis tendon at a short distance from the muscle insertion is recorded both on account of its uniqueness and because the functional loss in this case was difficult to interpret. Moreover, a demonstration is furnished by such a case of the great value to the hand of the extensor longus pollicis muscle. It seems to us from a consideration of the following case that an understanding of the function of the thumb muscles is difficult:

Miss A., fifty-eight years old, a cook, fell in such a way as to strike the back of the left hand on the edge of a stone step. The bruised skin was treated with domestic remedies. There was some tenderness near the proximal end of the first metacarpal bone, and in dressing herself some pain was felt at that place, though there was no marked localized swelling. Three weeks later she was feeling practically well as far as the hand was concerned. One morning, in her work, she was kneeling on the floor and rested on her left elbow. No unusual feeling or event was noted, but after rising from the floor and attempting to take hold of a chair, the left thumb could not be used as before, and the thumb was flexed in the palm.

She was examined the next day and the movements of the thumb were found impaired as follows: extension of the proximal phalanx was practically absent so that the thumb was invariably closed upon by the flexed fingers in grasping movements. Feeble extension of the distal phalanx was readily and repeatedly performed. All movements of the metacarpal bone of the thumb were executed, though extension and abduction were of less range than on the sound side. There was no tenderness near the points of insertion of tendons over the phalanges; and no indication of the site of the rupture existed beyond the assertion of the patient that some tenderness on using the hand existed near the proximal end of the metacarpal bone on the dorsum.

The lesion was regarded as probably a rupture of the extensor brevis pollicis tendon near its insertion, without local signs of rupture at the seat of the tear.

Operation six weeks after the functional loss disclosed a rupture of the extensor longus pollicis tendon near to the lowest point of the muscular insertion, about opposite the proximal end of the metacarpal bone of the thumb. The sheath of the tendon was intact. A careful dissection along the wrist was necessary to find the retracted muscular belly which was some 6 or 7 cm. from the distal end of the torn tendon. Approximation of the ruptured ends was impracticable and the hope of uniting them was abandoned. A transplantation of the extensor longus pollicis tendon was deemed the best solution of the problem; and the tendon of the extensor carpi radialis longior was selected to receive the extensor longus pollicis tendon. This addition to the function of the radialis longior would impair the extension and radial abduction of the wrist but little and offered as good a prospect as any muscle tendon available that useful extension of the thumb might be restored.

The tendon of the radialis longior was partially cut on its radial aspect and split along its length about 3 cm. The distal fragment of the extensor longus pollicis tendon was cut transversely to secure a smooth and appropriate surface for its new attachment. Three fine silk sutures united the tendons thus prepared. Convalesence from the operation was uneventful.

The sequence of events in this case was probably the following: the blow from the stone step partially severed the extensor longus pollicis tendon without external wound. Three weeks later muscular effort completed the rupture of the tendon, with immediate loss of function. The explanation of the findings as to the altered function of the thumb after the complete rupture of the long extensor tendon is difficult if the description of actions of the extensor thumb-muscles given by most authorities is accepted. The first phalanx could not be extended; if the first phalanx, moderately flexed and abducted, was grasped by the observer the terminal phalanx could be flexed and feebly extended at will. The metacarpal bone could be extended, abducted and flexed with nearly normal range. For this patient, therefore, the extensor longus pollicis subserved almost wholly the function of extension of the first phalanx on the metacarpal bone; and the extensor control of the second phalanx was reinforced by other muscles, probably the abductor and short flexor of the thumb. The preservation of the extensor brevis pollicis, with loss of extension of the first phalanx, seems to be at variance with the usual statement of the anatomies (Gray, Quain, Poirier and Charpy, Testut.). It is likely

in our patient that the brevis functioned chiefly as an abductor of the thumb. Indeed, Gowers states that the brevis is the true abductor of the thumb, though he adds that it extends the first phalanx. If any anomaly of distribution of tendons existed, it was in no way indicated by the dissection.

In conclusion, this case gives support to the opinion that extensor longus pollicis is the more important of the extensor muscles of the thumb, and perhaps second to no single muscle of the whole hand in functional value. Moreover the extensor brevis pollicis acting alone has very feeble extensor control over the first phalanx.

Eight months after operation the function of the thumb is as follows: extension of the thumb is sufficient to permit all movements of the fingers alone, or grasping movements requiring the opposed thumb. The range of extension of the terminal phalanx is about one-third of normal; and in the proximal phalanx the last third of extreme extension is impossible. Perhaps the limit of improvement has not been reached, as the patient feels sure there is a steady gain in facility of thumb motions. This may mean that the cortical control of the thumb is gradually re-arranging itself to meet the new conditions. The results of the operation seem to be of great benefit to the individual, as the function of the thumb has, for practical uses, been restored.

Reports of Societies.

CONFERENCE OF STATE AND PROVINCIAL BOARDS OF HEALTH OF NORTH AMERICA.

EIGHTEENTH ANNUAL MEETING, HELD AT BALTIMORE, MD., OCT. 23 AND 24, 1903.

(Concluded from No. 23, p. 629.)

FIRST DAY, AFTERNOON SESSION.

THE DUTY OF SANITARIANS REGARDING VENEREAL DISEASES.

DR. HENRY D. HOLTON, Brattleboro, Vt., read a paper with this title. He emphasized the duty which should be recognized by sanitarians as resting upon them, of doing something to restrict the venereal diseases, which threatened society as no other communicable diseases did. The vital statistics of New York City in 1900 had a record of 31,145 cases of contagious disease, with 11,368 deaths, of which only 177 were from syphilis. Blascho claimed 150,000 syphilitics for Berlin, and the Committee of Fifteen 200,000 for New York City. To get an approximate idea of its prevalence the Prussian government requested that all physicians should report on April 30, 1900, every case of venereal disease coming under treatment. These reports proved that three quarters of a million people were afflicted yearly with venereal diseases in that country alone.

He said the foregoing statements would prove that venereal diseases stood next to tuberculosis and alcoholism, if they did not supersede them. They were permeating the very root of the population, as 15 to 20% of adult males were infected with syphilis, and about 80% of them had gonorrhea, tainting those yet unborn, maiming those born with the virus already in their blood, deteriorating the race and devitalizing the individual.

Instruction should be given in high schools and colleges, having reference to the prevention of these diseases.

Dr. Prieto, in a paper read at the International Medical Congress at Madrid, suggested the following regulations to be enacted into laws: (1) The law to declare the infection of any person with any form of venereal disease to be a crime. (2) That such crime against the person be punished by indemnification and imprisonment for a period of two years. (3) Where the offender could not indemnify the injured person by bearing the expenses of treatment and so forth, that the term of imprisonment or transportation be increased. (4) That the brothel-keepers be made to indemnify any person infected on their premises or by any of their licensed women, and in case of insolvency of the brothel-keeper, imprisonment or fine shall be enforced.

DR. HOLTON thought the rules of Prieto stringent enough to control the evil. However, to enforce them would require an enlightened and educated public sentiment of great strength. He would educate the medical profession; educate the public; follow this work by the enactment of wise laws which the educated public sentiment would insist should be thoroughly executed.

This paper was discussed by Drs. John S. Fulton, George R. Dean, G. P. Conn, Frank Wells, E. W. Cooper and Charles O. Probst. The general trend of the discussion was to educate the medical profession and the public in regard to the terrible ravages of venereal diseases and the practicability of limiting their spread by legislative enactment.

DR. PROBST then offered the following preamble and resolution, which were adopted by thr Conference:

Whereas, The great prevalence of venereal diseases, which is indirectly the cause of many deaths, is a matter of much concern to the public health; and

Whereas, The communication of these diseases to innocent persons must be largely due to ignorance, be it

Resolved, That a committee of three be appointed by the president to prepare a leaflet that would be acceptable to physicians to give to their patients, setting forth the precautions to be taken by one suffering from a venereal disease to prevent its communication to others, and to make such other suggestions as it may deem proper. Such instructions, when adopted by this Conference, to be recommended to State and Provincial Boards of Health for dissemination among the medical profession, and said committee shall report at the next meeting. (Committee unannounced.)

ANOTHER YEAR'S TEST OF THE MOSQUITO DOCTRINE OF THE TRANSMISSION OF YELLOW FEVER IN HAVANA.

Dr. John Guiteras, Havana, Cuba, said there had not been a case of yellow fever in Havana for the past two years except those that had been imported from other countries, chiefly Mexico. He then detailed the methods employed in combating this disease in Havana, which are familiar to our readers.

REPORT OF COMMITTEE ON PROMOTION OF UNIFORMITY OF REPORTS UPON VITAL STATISTICS.

This report was presented by Dr. Cressy L. Wilbur, Lansing, Mich. In the division of labor between the committee representing this Conference and the committee of the American Public Health Association, American Medical Association and others interested in the improvement of vital statistics, the special task had been selected of examining and reporting in regard to the forms of tables and general manner of presentation of statistical data employed in the annual, biennial, weekly, monthly or other reports of states and cities. In this purpose the United States Census Bureau had co-operated and had collected samples of the forms at present in use in nearly all of the registration offices of this country for the purpose of analysis and study by this committee. It was a difficult task to consider all of the forms in a comparative way, but it seemed desirable to do so before formulating a report as to the absolutely essential tables that were to be recommended for use in the various reports. The committee, therefore, reported progress and requested that additional time be granted for making a final report, which could probably be prepared before the next session of the Conference.

In addition to the work outlined above, the committee had co-operated, on behalf of the Conference, with the committees of the American Public Health Association and of the American Medical Association, the United States Census Bureau, and the Public Health and Marine Hospital Service, in the preliminary work for the co-operative study and improvement of the International Classification of causes of death, a report upon which would be presented at the session of the American Public Health Association, and also for the extension of adequate registration laws.

The report was accepted.

The following proposed national rules to govern the transportation of the dead were adopted by the Conference:

Rule 1. The transportation of bodies dead of smallpox or bubonic plague from one state, territory, district or province to another is absolutely prohibited.

Rule 2. The transportation of bodies dead of Asiatic cholera, yellow fever, typhus fever, diphtheria, membranous croup), scarlet fever (scarlatina, scarlet rash), erysipelas, glanders, anthrax or leprosy, shall not be accepted for transportation unless prepared for shipment by being thoroughly disinfected by (*a*) arterial and cavity injection with an approved disinfecting fluid; (*b*) disinfection and stopping of all orifices with absorbent cotton and (*c*) washing the body with the disinfectant, all of which must be done by an embalmer holding a certificate as such, issued by the state or provincial board of health or other state or provincial authority provided for by law.

After being disinfected as above, such body shall be enveloped in a layer of dry cotton, not less than one inch thick, completely wrapped in a sheet securely fastened and encased in an air-tight zinc, tin, copper or lead-lined coffin or iron casket, all joints and seams hermetically sealed, and all enclosed in a strong, tight wooden box. Or the body, being prepared for shipment by disinfecting and wrapping as above, may be placed in a strong coffin or casket and said coffin or casket encased in an air-tight zinc, copper, or tin-lined box, all joints and seams hermetically soldered.

For interstate transportation under this rule only embalmers holding a license issued or approved by the state or provincial board of health or other state or provincial authority provided for by law, after examination, shall be recognized as competent to prepare such bodies for shipment.

Rule 3. The bodies of those dead of typhoid fever, puerperal fever, tuberculosis, or measles may be received for transportation when prepared for shipment by arterial and cavity injection with an approved disinfecting fluid, washing the exterior of the body with the same, and enveloping the entire body with a layer of cotton not less than one inch thick, and all wrapped in a sheet securely fastened, and encased in an air-tight metallic coffin or casket, or air-tight metallic box, provided that this shall apply only to bodies which can reach their destination within thirty hours from the time of death. In all other cases such bodies shall be prepared by a licensed embalmer holding a certificate as provided for in Rule 2. When prepared by a licensed embalmer as defined and directed in Rule 2, the air-tight sealing and bandaging in cotton may be dispensed with.

Rule 4. The bodies of those dead from any cause not stated in Rules 2 and 3 may be received for transportation when encased in a sound coffin or casket and enclosed in a strong outside wooden box, provided they can reach their destination within thirty hours from the time of death. If the body cannot reach its destination within thirty hours from the time of death, it must be prepared for shipment by arterial and cavity injection with an approved disinfecting fluid, washing the exterior of the body with the same and enveloping the entire body with a layer of dry cotton not less than one inch thick and all wrapped in a sheet securely fastened, and encased in an air-tight metallic coffin or casket or an air-tight metallic box. But when the body has been prepared for shipment by being thoroughly disinfected by a licensed embalmer, as defined and directed in Rule 2, the air-tight sealing and bandaging with cotton may be dispensed with.

Rule 5. In the shipment of bodies dead from any disease named in Rule 2, such body must not be accompanied by persons or articles which have been exposed to the infection of the disease, unless certified by the health officer as having been properly disinfected.

Before selling tickets, agents should carefully examine the transit permit and note the name of the passenger in charge, and of any others proposing to accompany the body, and see that all necessary precautions have been taken to prevent the spread of the disease. The transit permit in such cases shall specifically state who is authorized by the health authorities to accompany the remains. In all cases where bodies are forwarded under Rule 2, notice must be sent by telegraph by the shipping embalmer to the health officer, or when there is no health officer to other competent authority at destination, advising the date and train on which the body may be expected.

Rule 6. Every dead body must be accompanied by a person in charge, who must be provided with a passage ticket and also present a full first-class ticket marked

"Corpse" for the transportation of the body, and a transit permit showing physician's or coroner's certificate, name of deceased, date and hour of death, age, place of death, cause of death and all other items of the standard certificate of death recommended by the American Public Health Association and adopted by the United States Census Bureau, as far as obtainable, including health officer's or registrar's permit for removal, undertaker's certificate, whether communicable or non-communicable, the point to which the body is to be shipped, and when death is caused by any of the diseases specified in Rule 2 the names of those authorized by the health authorities to accompany the body. The transit permit must be made in duplicate, and the signature of physician or coroner, health officer and undertaker must be on both the original and duplicate copies. The undertaker's certificate and paster of the original shall be detached from the transit permit and securely fastened on the end of the coffin box. All coffin boxes must be provided with at least four handles. The physician's certificate and transit permit shall be handed to the passenger in charge of the corpse. The whole duplicate copy shall be sent to the official in charge of the baggage department of the initial line, and by him to the secretary of the state or provincial board of health of the state or province from which said shipment is made.

RULE 7. When bodies are shipped by express, a transit permit, as described in Rule 6, must be made out in duplicate. The undertaker's certificate and paster of the original shall be detached from the transit permit and securely fastened on the coffin box. The physician's certificate and transit permit shall be attached to and accompany the express way-bill covering the remains and be delivered with the body at the point of destination to the person to whom it is consigned. The whole duplicate copy shall be sent by the forwarding express agent to the secretary of the state or provincial board of health of the state or province from which said shipment was made.

RULE 8. Every disinterred body, dead from any disease or cause, shall be treated as infectious or dangerous to the public health, and shall not be accepted for transportation unless said removal has been approved by the state or provincial health authorities having jurisdiction where such body is disinterred, and the consent of the health authorities of the locality to which the corpse is consigned has been first obtained; and all such disinterred remains, or the coffin or casket containing the same, must be wrapped in a woolen blanket thoroughly saturated with a 1-1000 solution of corrosive sublimate, and enclosed in a hermetically sealed soldered zinc, tin or copper-lined box. But bodies deposited in receiving vaults shall not be treated and considered the same as buried bodies, when originally prepared by a licensed embalmer as defined in Rule 2, and as directed in Rule 2 or 3 (according to the nature of the disease causing death), provided shipment takes place within thirty days from the time of death. The shipment of bodies prepared in the manner herein directed by licensed embalmers from receiving vaults may be made within thirty days from time of death without having to obtain permission from the health authorities of the locality to which the body is consigned. After thirty days the casket or coffin box containing said body must be enclosed in a hermetically soldered box.

RULE 9. All rules and parts of rules conflicting with these rules are hereby repealed.

OFFICERS.

The following officers were elected for the ensuing year: President, DR. JOHN N. HURTY, Indianapolis, Ind.; Vice-President, DR. JOHN S. FULTON, Baltimore, Md.; Secretary, DR. GARDNER T. SWARTS, Providence, R. I.; Treasurer, DR. JAMES A. EGAN, Springfield, Ill.

Time and place of next meeting were left to the officers of the Conference to decide.

Recent Literature.

Clinical Examination of the Urine and Urinary Diagnosis. A Clinical Guide for the Use of Practitioners and Students of Medicine and Surgery. By J. BERGEN OGDEN, M.D. Illustrated. *Second revised edition.* Philadelphia, New York, London: W. B. Saunders & Co. 1903.

This work falls into two parts. Part I deals with the chemistry and microscopy of the urine. After a brief description of the physical properties of the urine, the separate constituents, both normal and abnormal, are taken up, their properties described and the most approved working methods for their detection and quantitative determination given. This section contains but little which is not found in existing textbooks. At the same time the author is entitled to commendation for the care, accuracy and good judgment shown in his compilation.

In Part II special attention has been paid to the diagnosis and differential diagnosis of disturbances and diseases of the kidneys and urinary passages, the enumeration of the prominent clinical symptoms of each disease and the peculiarities of the urine in certain general diseases of the body. This to our mind is the most valuable part of the book. There is no other work in which the general subject of urinary diagnosis is presented in as satisfactory a manner as it is in this one.

This, the second edition, presents evidences of a careful revision, which brings the text well up to date. The most important changes are in connection with the determination of Urea, Uric Acid and Total Nitrogen, together with a brief mention of the subject of Cryoscopy and the addition of a section of B-Oxybutyric Acid.

We recommend the book, as a whole, as a very good one and one which will be found useful by both student and practitioner.

Practical Points in Nursing. For Nurses in Private Practice. With an Appendix containing Rules for Feeding the Sick; Recipes for Invalid Food and Beverages; Weights and Measures; Dose List; and a full Glossary of Medical Terms and Nursing Treatment. By EMILY A. M. STONEY, late Superintendent of the Training School for Nurses, Carney Hospital, South Boston, Mass. Third edition, thoroughly revised. pp. 458. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

The appended title sufficiently explains the scope of this book on nursing. It is a comprehensive treatise, sufficiently illustrated and excellently arranged for its purpose. We commend the wisdom which has led the writer to lay stress upon nursing in private practice. It is a matter of common observation that well-trained hospital nurses are often quite unable to cope with the exigencies and inconveniences met with in a private house. This book should go far toward rectifying this defect.

Egbert's Hygiene. A Manual of Hygiene and Sanitation. By SENECA EGBERT, M.D., Professor of Hygiene in the Medico-Chirurgical College of Philadelphia. New third edition, enlarged and thoroughly revised, in one 12mo volume of 467 pages, with 86 illustrations. Philadelphia and New York: Lea Brothers & Co.

Any work devoted to the subject of preventive medicine must necessarily require frequent revision in order that the reader may find therein the most recent as well as the most reliable information upon the topics presented. Dr. Egbert has recognized this fact in this third edition of his Manual. The work is well adapted for the purpose of a textbook for the teaching of hygiene in secondary schools and in medical colleges.

The topics treated are the following: Bacteriology, The Air, Ventilation and Heating, Water, Food, Stimulants, Personal Hygiene, School Hygiene, Disinfection, Quarantine, Sewage Removal and Disposal, Military Hygiene, Vital Statistics, The Examination of Air, Water and Food.

The book is up-to-date, convenient in size, trustworthy and practical, and may be recommended as a useful manual for the teaching of hygiene.

Das Schulzimmer. By P. JOHS. MULLER. Vol. I, No. 1. Berlin. 1903.

The most worthless trash, from a scientific point of view, are the so-called medical periodicals which constantly flood the mails, emanating from the multitude of firms engaged in the manufacture of patent medicines, patent foods, apparatus, etc.

It is therefore refreshing to open the pages of a new periodical issued by a manufacturer of school furniture and appliances and find a work devoted to the environment of the pupil while at school, treating of those topics which are essential to his health and comfort while in the schoolroom.

The illustrations are usually well made and the different topics are of a practical character. The principal article in this first number treats of the technical term known among school authorities as the " Distance," that is, the interval or space between a perpendicular line let fall from the edge of the desk, and a line let fall from the front of the seat upon which the scholar sits.

The Principles and Practice of Hydrotherapy. A Guide to the Application of Water in Disease. For Students and Practitioners of Medicine. By SIMON BARUCH, M.D. Second edition, revised and enlarged. Illustrated. New York: William Wood & Co. 1903.

Dr. Baruch stands as the chief apostle of hydrotherapy in this country. He has done much through example and precept to bring into notice this important, rational therapeutic measure. That this book has been widely read is attested by the fact that a second edition has recently appeared, in which there has been considerable revision, together with the addition of much new matter. In view of the fact that the recognition of the value of water in disease has been accepted, matter formerly required to fortify its claim has been omitted from this edition. A chapter on the principles underlying hydrotherapy in relation to recent physiological views is added, together with a chapter on insanity based upon observations made in large asylums. The appeal is again made for the greater benefits to be derived from methodical hydrotherapy and this volume, like its predecessor, gives much space to the details of treatment. Among general diseases typhoid fever receives greatest attention for sufficiently obvious reasons. We gladly commend this book to our readers, as we did its predecessor. Whatever the value or the uselessness of hypotherapeutic measures may be, it is perfectly evident that in most of our large medical centers the subject has been woefully neglected.

The Medical Record Visiting List or Physicians' Diary for 1904. New revised edition. New York: William Wood & Company.

This visiting list is well and favorably known to the profession. This new edition appears in a form similar to those which have preceded it, but shows certain changes in its contents. Among these are an increase in the amount of matter of use in emergencies, and a list of remedies and their maximum doses. The book fits conveniently into one's pocket, is attractively bound in flexible red leather and is manifestly of much practical use to the practitioner.

Physician's Pocket Account Book. By J. J. Taylor, M.D. Philadelphia: The Medical Council.

This small pocket volume is designed to be a physician's account book. It is so arranged as to permit the greatest degree of accuracy in the smallest possible space. Certain suggestions which may or may not be of use on methods of collecting bills are appended. As we said in commenting on a previous edition, the book should prove of use.

The American Pocket Medical Dictionary. Edited by W. A. NEWMAN DORLAND, M.D. Fourth edition. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Dr. Dorland also presents us with the fourth edition of a pocket medical dictionary, made on the same general plan as regards binding as the larger one. It is a compact little volume, provided with a generous number of useful tables.

The Medical News Visiting List for 1904.

This is the eighteenth year of issue of this excellent Visiting List. It retains all its old good features, and has been again revised and brought up to date. Is is issued in four styles: weekly, monthly, perpetual, co-patients. Those who have used this Visiting List before will continue to do so, and there is no better recommendation for its usefulness.

THE BOSTON

Medical and Surgical Journal

THURSDAY, DECEMBER 10, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: $5.00 *per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all oreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

SOME REPORTS UPON FOOD INSPECTION.

IN England under the authority of the Acts relating to Food and Drug Inspection, the local authorities are authorized to appoint public analysts for the examination of such articles as are offered for sale. The number of such articles examined in 1901 was 67,481, of which 26,143 were samples of milk. Of these samples of milk, 2,938, or 11.2%, were found to be adulterated. Legal proceedings were instituted in relation to 1,839 of these and there were 1,527 convictions. The number of samples of butter examined was 11,938, of which 1,224 were adulterated. Of cheese there were 1,652 samples examined, of which only 18 were below the mark of purity. Among other articles examined there were 202 samples of condensed milk, 530 of bread, 587 of flour and 1,374 of lard.

During the first few months of work under the Food Law of North Dakota, the chemist reports upon 851 samples. The food commission presents three principles which are laid down in the laws of North Dakota:

(1) Total prohibition of harmful preservatives in food products.

(2) Prohibition of the use of coal tar dyes in all food products and beverages offered for sale.

(3) All food products must be correctly labeled, and no deception must be allowed in the wording of the label which would mislead the purchaser or consumer.

Two chapters in this report relate to the use of preservatives and of saccharin in articles of food, and the names of many firms are published who offer fraudulent articles for sale. Considering the few months since the law was enacted, excellent results appear to have been accomplished in this state.

In the Seventeenth Annual Report of the Food Commissioner of Ohio, a pamphlet of 100 pages, five pages are devoted to the work of the Commissioner and the remainder to the finances of his department. Sixty pages, or 3-5 of the entire report, are given up to an unnecessarily lengthy statement of the sums paid to a small army of lawyers for conducting cases which the state should have required its own salaried officials to do. The entire amount appropriated for this work by the State was $40,000, of which $15,000 was used for legal services.

In the remaining pages we learn that 2,048 samples of food and drugs were examined during the year, of which 698 or 34% were adulterated. Of 777 samples of milk, 144 were adulterated, and of 303 samples of oleomargarine 300, or 99%, were adulterated. Just what is meant by adulterated oleomargarine the Commission does not state. Of 98 samples of whiskey, 66 were adulterated.

In Massachusetts the work of Food and Drug Inspection has been conducted for twenty years by the State Board of Health. In its last report upon this subject, a pamphlet of 48 pages, it appears that 10,470 samples of food and drugs were examined during the year, of which 2,989, or 28.1%, did not conform to the requirements of the law relative to adulteration.

Of the number of samples of milk examined 31.1% were adulterated or below the standard. It does not follow from this statement that so large a percentage was intentionally adulterated. The Massachusetts standard of milk is exceptionally high when compared with that of other states and countries, especially in the winter. A sample of milk taken on Sept. 30, may if examined on that day be found to be considerably above the standard, but if taken on Oct. 1, may be below it. since the law only requires that it shall contain 12% of solids on Sept. 30, but 13% on Oct. 1, and from that time till March 31. The cows do not appear to be aware of this fact, and hence the high percentage of 31.1 below the standard does not represent that percentage of dishonest dealing.

Attention is called to the fact that coloring matter is not largely used in milk, the amount of samples in which it was detected in the past nine years being only 7-10 of 1%. Preservatives were also found in about 4% of samples collected in the past five years. These were mostly obtained in summer.

Comment is also made upon the desirability of some standard for condensed milk. One of its valuable constituents, the fat or cream, varies from as low as 5 to as high as 11½%, or more, and the price does not necessarily indicate its value.

Of other articles of food, those which were found to be most adulterated were canned goods, 50%, cocoa 40%, flavoring extracts, 80%, honey 34%, and vinegar 66%.

The edition of the report published in 1896, relative to the amount of alcohol in tonics, bitters and other patent medicines having become exhausted by repeated requests for copies by members of the W. C. T. U., the Board has again published the same list with such additions of new articles as have been examined since that date.

The method adopted in England for measuring the relative amount of protection afforded by the Food and Drug Acts in different districts is the ratio of samples examined to the existing population. Under this somewhat arbitrary standard, the figures in these four reports present the following results:

Ratio of samples to the population

In England one sample to 475 persons.
In North Dakota one sample to 375 persons.
In Massachusetts one sample to 270 persons.
In Ohio one sample to 2,030 persons.

With reference to the amount expended in litigation only two of the foregoing reports furnish information. In Ohio $14,993.09 was expended in 1902 in attorneys' fees for the prosecution of offenders, or an amount much greater than is expended in Massachusetts for the entire work of Food and Drug Inspection.

The amount expended in Massachusetts for attorneys' fees has not exceeded $500 in the entire twenty years of work, the officials of the Board of Health being instructed to enter complaints in the courts without assistance except when such assistance becomes necessary.

DANVERS INSANE HOSPITAL.

THE annual report of the Danvers Insane Hospital shows a slight increase in the number of patients over preceding years. On Sept. 30, 1903, there were 1,160 patients, a gain of seven during the twelve months. The present hospital population would, however, have exceeded 1,200 had certain patients not been transferred. This hospital, like many others of similar character, is endeavoring to follow the classification of mental disease made by Kræpelin and popularized in this country through the writings and influence of Hoch and Meyer. This scheme of classification has the merit of being a logically founded system applicable to clinical cases. It would no doubt be well for psychiatry in this country if this classification were universally adopted in hospitals for the insane. The efficiency of the laboratory side of the institution has been advanced during the year under Dr. Barrett's management, the successor of the late Dr. Worcester. The records show that eighty-three autopsies were performed, being sixty-five per cent of all deaths.

As is usual in reports of this character, the needs of the future are dwelt upon, particularly in the way of added buildings. Among other requests, a small appropriation is desired for two plain buildings to serve for the treatment of patients suffering from tuberculosis. The difficulty of treating such patients properly in general wards, the fact that tents have not at this institution proved satisfactory, and the general desirability of separating tuberculous from other patients renders this request most reasonable.

We have previously commented upon the inadequate salaries granted medical men in hospitals for the insane, and the question is again taken up in this report by the Consulting Board of Physicians. Bewailing the loss of various efficient officers through this cause, the writer of this section of the report makes the following pertinent comments:

Unless the State of Massachusetts proposes to maintain a permanent training school for the superintendents of insane asylums, an intelligence office for the benefit of more liberal communities, she must offer inducements greater than she at present affords. An increase of at least thirty-three per cent for the head of the asylum, and an opportunity for family privacy in the shape of a separate residence on the grounds outside, are no more than proper. In this connection we quote from a letter received by the chairman and written by the superintendent of a New England insane asylum, not, however, a State institution. It refers to our discussion of this same subject in last year's report: "Will you allow me to tell you with how much pleasure I have read your report to the trustees of the Danvers Insane Hospital? It is not alone the wisdom of your remarks on occupation that I desire to commend, but your generous utterance anent salaries and decent accommodations for medical officers will appeal strongly to the judgment and sympathies of all readers of the report, including, I hope, the trustees. Having myself the separate residence and enjoying seemly treatment in other respects, I am the more desirous that my Massachusetts brethren in the State's service shall fare equally well, and it is for this reason that I take the liberty of thanking you for your hearty and valiant championship."

This attitude seems to us eminently fair and reasonable.

MEDICAL NOTES.

ROCK SALT AS A SPECIFIC FOR YELLOW FEVER. — The London *Times* is reprinting certain articles which appeared in its columns one hundred years ago. Under date of Nov. 14, 1803, appears the following somewhat quaint announcement :

An *American Chemist*, at New York, announces a discovery which he positively asserts to be the specific remedy for the yellow fever. It is rock salt, to be chewed by the afflicted patient; and the *saliva* to be swallowed, and afterward molasses to be taken in copious doses: the drink to be pure water. He denies that the infection of the yellow fever is contagious, or that it proceeds from the access of *bile* in the habit. On the contrary, he maintains that the defect of bile is a prevalent cause; and that the infection proceeds principally from the effects of *gas* arising from animal putrefaction; of which *gas* rock salt is asserted to be the neutralizer.

A CANCER RESEARCH FUND. — It is authoritatively stated that the Huntington Fund for cancer research will have its headquarters at the Loomis Laboratory, New York, and be under the supervision of Dr. B. H. Buxton and Mr. S. P. Beebe. This fund provides for work particularly along chemical lines rather than by the pathological and bacteriological means. For this purpose material in large amounts is requisite, and a general appeal has been sent out to surgeons and pathologists to donate such material to this work as comes into their hands.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Dec. 9, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 60, scarlatina 34, typhoid fever 11, measles 136, smallpox 1.

AMERICAN ACADEMY OF DENTAL SCIENCE. — The annual session of the American Academy of Dental Science was held on the evening of Dec. 2 in Boston. Dr. Thomas Fillebrown read a paper on " The Physiology and Art of Vocalism in Speaking and Singing." Officers were elected for the ensuing year.

PROPOSED PUBLIC GYMNASIUM FOR BROOKLINE, MASS. — At a recent town meeting it was voted by a considerable majority to establish a municipal gymnasium. In spite of certain opposition, on the ground of extravagance, it was finally decided, after a spirited discussion, that a gymnasium was desirable. Dr. Walter Channing was among those who favored its erection.

BABCOCK MEMORIAL WARD. — As a testimonial to the Rev. S. G. Babcock, the Peabody Home for Crippled Children is to have a memorial ward furnished by the citizens of Hyde Park, Mass. Mr. Babcock has devoted much time and energy to promoting the welfare of the institution.

BURNING OF MEDICAL COLLEGE BUILDING AT BURLINGTON, VT. — The medical college building forming a part of the University of Vermont was completely destroyed by fire Dec. 2. The loss is estimated at $220,000, covered by insurance. The source of the fire remains unknown.

BEQUESTS TO HOSPITALS. — By the wills of John Walter of Melrose and Mrs. Catherine Robertson of Newton the Melrose Hospital Association receives $250, and the Newton Cottage Hospital $100, respectively. The latter hospital is also a beneficiary to the extent of about $9,000, from collections made in Newton on " Hospital Sunday."

NO MEDICAL SCHOOL FOR BROWN UNIVERSITY. — In our issue of Dec. 3 we stated that it had been vaguely rumored that Brown University of Providence was to establish a department of medicine in Boston, with the possible financial support of Mr. Rockefeller. We are glad to correct the impression which this rumor may have conveyed, by saying that we have since learned on unquestioned authority that it is absolutely without foundation, and that Brown University is not contemplating the establishment of a medical school here or elsewhere.

NEW YORK.

ST. JOHN'S GUILD. — The annual meeting of the trustees of St. John's Guild was held on Nov. 17, and among the officers elected were Dr. Abraham Jacobi, as second vice-president, and Dr. John F. Erdmann, as a trustee to serve for five years. The general agent reported that during the past season the floating hospital *Helen C. Juillard* made forty-five trips and carried in all 35,549 persons — 10,135 women, 17,596 children and 7,818 infants. The other boat of the guild was not operated this year, partly because of lack of funds and partly on account of the comparatively little illness among infants and young children and the remarkable coolness of the sum-

mer weather. At the seaside hospital at New Dorp, Staten Island, there were received 499 infants, 562 children and 461 mothers, and the deaths numbered 45. The annual contributions to the guild aggregated $50,859.

THIRTY-FIFTH ANNIVERSARY OF PRESBYTERIAN HOSPITAL. — The thirty-fifth anniversary of the Presbyterian Hospital was celebrated on Dec. 5. The annual report of the hospital for the year ending Sept. 30 showed that 40,195 persons received medical or surgical service, or an average of 545 a day, a larger number than in any previous year; 68% of the patients were treated gratuitously, and the average cost to the hospital for ward patients was $2.51 per day. A new home for the nurses on 71st Street, opposite the hospital buildings, is now in course of erection.

SMALLPOX. — In the last monthly bulletin of the State Health Department, issued at Albany on Dec. 5, attention is called to the increased prevalence of smallpox with the advent of winter, and emphasizes the necessity of more general vaccination. Although New York City has escaped the disease thus far this season, its alarming prevalence recently reported in Philadelphia is certainly very menacing.

Obituary.

WILLIAM INGALLS, M.D.

WILLIAM INGALLS died at the Boston City Hospital on Dec. 1, 1903, in his ninety-first year. He was born and lived, up to the time of entering Harvard College, in his father's house, which was on Tremont Street opposite the Granary Burial Ground. He was of direct English descent. The first of his ancestors who came to this country was Edmund Ingalls of Lincolnshire, England, who died in Lynn in 1684. His father, William Ingalls, was a distinguished surgeon of Boston, graduated from Harvard College in the class of 1790, and died here in 1857. The son, the subject of this short sketch, entered Harvard College in the class of 1835, and at the time of his death was one of the twelve oldest living graduates, four of whom were his classmates, Dr. Charles Bemis of Medford, William F. Frick of Baltimore, Hon. Edward Lander of Washington and Charles H. Parker of Boston.

Dr. Ingalls received his medical education, as was often the custom at that time, in his father's office, and at the Chelsea Marine Hospital, from his brother-in-law, Dr. Charles Harrison Stedman, who was at the time the resident surgeon, and a member of that family of Stedmans which has furnished so many notable practitioners to our profession, among them Dr. Charles Ellery Stedman, a nephew and the closest friend of Dr. Ingalls. He, Dr. Ingalls, began his professional work in Boston, but shortly after his marriage, in 1840, to Miss Julia Davis of Roxbury, he moved to Laurel Hill, La., where he acquired a large general practice, and where he remained for six years. His practice in the South was in a country district, and he used to make his visits on horseback, carrying his medicines and instruments in the saddle bags. Sometimes he was obliged to ride a distance of forty miles before reaching his patient's home. Among those he attended was Gen. Zachary Taylor. During his six years in the South he passed through the experience of at least one severe epidemic of yellow fever, and, escaping the contagion himself, worked with untiring devotion for those who were its victims.

On his return to the North he was appointed surgeon to the Chelsea Marine Hospital, and, later, on relinquishing this office, settled in Winchester, where he soon secured a large general and consulting practice. Here he remained until the outbreak of the Civil War. He had always had the soldier's spirit, and, had he followed his own inclination, would have entered the army rather than the medical profession. But for being dissuaded by his father, he would have already done so at the time of the Mexican War. With the outbreak of the Civil War he at once volunteered his services, and was appointed as surgeon to the 5th Massachusetts Regiment of Volunteers, later as major and surgeon of the 59th Massachusetts, and still later brigade-surgeon to the artillery force commanded by General Tidball. The greater part of the time he was with the army of the Potomac, with which he saw much active service. He was with the army throughout the four years of the war, and was mustered out on June 2, 1865, with the honorable record of having performed every duty demanded of him, invariably, promptly, thoroughly, courageously, and of having displayed marked ability in every post of responsibility that he held.

His powers of endurance were extraordinary, and enabled him to support fatigue and privation as few others could. On one occasion he worked, with the exception of six hours' sleep, taken at odd moments, continuously for five consecutive days and nights, during which the only food he had was one glass of milk in the first twenty-four hours, and for the rest of the time a small bit of hard tack or bacon at long intervals. He was on his feet, and either operating or dressing wounds almost the entire time. "And," he said, when speaking of it, "I was not tired at the end of it." "In fact," he remarked on another occasion, "I never knew what men meant when they said they were tired out, until after I was seventy years old."

It is said that in times of battle it was his custom to be as near the firing line as his duties would permit, and that his interpretation of the limits of his sphere of duty, so far as they related

to the front, was liberal. In consequence of this tendency of his, he barely escaped the fate which overtook so many of the soldiers of the Northern army when the mine was exploded at Petersburg. In answer to a question he said, in his gentle voice, the tone of which seemed to contradict the thought that the joy of battle could ever have dwelt in him: " Well, perhaps we were rather far forward now and then, but I do not think improperly. Derby and I could never see any harm in it, and sometimes we thought that the boys rather liked to have us there, and perhaps found some comfort in our being near at hand."

At the end of the war he again resumed his civil work, this time in Boston, and was actively engaged in it during the ensuing twenty-one or two years, after which he withdrew and lived a retired life in Roxbury for the last twelve years.

He was appointed as one of the visiting surgeons on the staff of the Boston City Hospital in 1870. and held that position for fifteen years, being made consulting surgeon of the hospital when resigning his position on the visiting staff. He was also surgeon to the Children's Hospital when it was first opened, and contributed much toward its subsequent success.

He kept up his interest in many of the modern advances in the profession, and even in the last year or two attended, from time to time, meetings of the medical societies of which he was a member, and also visited the hospital. The last time of his doing so was within a month of his death, when he was present at one of the surgical clinics, where his head of thick white hair and venerable face formed a striking contrast with the youthful appearance of the students about him. He was in fullest sympathy with these young men who were pressing forward upon the threshold of the entrance to the profession, while he, his hand resting on the latch of its door of exit, already opening to let him pass, lingered a moment to look back at the eager beginners, and doubtless gave them his silent blessing and wished them God speed, for such was his wont.

As a surgeon his judgment was deliberate and well balanced. As an operator he was neither bold nor brilliant, but accurate, careful, thorough, effective and very neat. No one surpassed him in the after-care of the patient. He was nearly, if not actually, the first American surgeon to do a nephrolithotomy, extracting a very large calculus from the kidney, the patient living for many years afterward. In a series of two thousand consecutive obstetric cases attended by him, the larger part of which occurred before the introduction here of the aseptic regimen, there was not a single instance of puerperal sepsis, and only three deaths.

He remained free from the infirmities which are usually associated with the last years of so long a life, preserving his erect carriage, firm step, bright pink color in the cheeks, and an unclouded intellect until the end; and as it appeared in him, old age was beautiful.

With the death of William Ingalls the profession loses one of its number who, throughout an unusually long life, exhibited those qualities which have made the name " physician " one of the most honorable of titles, have earned for those who hold it the unquestioning trust, and for such of them as he, the gratitude and love of those who in sickness and suffering have known the beneficence of their touch and the comfort of their helpful presence.

He belonged to a generation of physicians who did not think their duties ended with the treatment of disease, but who were ever ready to take upon their shoulders the burdens of the members of the households of their patients and often became their most trusted friends and wisest counselors. He conceived his professional duties in the same spirit at that which animated the rugged old Scotch hero portrayed by Ian Maclaren in his story, " A Doctor of the Old School," which is the highest tribute to our profession ever paid to it, perhaps, in the English language, and William Ingalls might well have been taken as the model for Weelum Maclure.

There lived in the tender heart of this friend who has just died the gentle spirit which alone makes the gentleman. The virtues which are often upon men's lips only, he lived daily, and as though in recognition of the unfailing consideration he showed for others, death, in summoning him to rest, touched him also gently. The living friend has become a living memory, and as such, for those who knew him, will dwell in that chamber in which are stored the memories most treasured.

No more fitting words could be added to the farewell that is spoken to him here than those which were quoted on the day of his funeral — " Soldier of Christ, well done! "

CYRUS EDSON, M.D.

DR. CYRUS EDSON of New York died from pneumonia at the Roosevelt Hospital on Dec. 3, after a brief illness. He was a son of Franklin Edson, ex-mayor of New York, and was born in Albany, N. Y., on Dec. 8, 1857. He received his academic education at Columbia University, and was graduated with honor from the College of Physicians and Surgeons, New York, in 1881. He was one of the famous Columbia crew which won the Henley cup in 1878, the only time that an American four have ever had that distinction. In 1882 Dr. Edson was appointed Assistant Sanitary Inspector in the New York Health Department, and he was promoted through successive grades until he became Chief Inspector of the Second Division. In 1891 he was appointed President of the Board of Health. Among the other positions held by him were: President of the Board of Pharmacy, Vice-President of the American Society of Public Analysts, Visiting Physician to Charity Hospital and Assistant Surgeon of the 12th Regiment, New York State National Guard.

Miscellany.

SURGICAL ADVANCE IN THE UNITED STATES.

Dr. Frank P. Foster of New York contributes an article on this subject to the Christmas issue of the *World's Work*. The closing paragraph of the article we reproduce:

It will be seen from this brief sketch that our countrymen have not only given to the world the priceless boon of anesthesia, but have also materially advanced the surgery of almost every part of the human organism. American surgery has not a little to be proud of and stands securely on its own foundations. We are always ready to learn from others, and to that end numbers of our men annually visit European capitals for purposes of special study; but no longer, as in the remote past, do they seek for a general professional education in Edinburgh, London, Paris, Vienna, or Berlin, to mention those cities in the chronological order in which one or another of them was formerly the Mecca of the American medical student and young practitioner. Of course, the time will never come, and never should come, when American surgeons will cease their endeavor to learn all they can from those of other countries; but we feel now, as we have felt for some decades, that we can give quite as much as we are likely to take.

NEW YORK CITY TRAINING SCHOOL FOR NURSES.

The new buildings of the New York City Training School for Nurses, on Blackwell's Island, were formally opened on Dec. 2. There are now three of these, the central one being the present Nurses' Home, which was originally constructed and for some years used as the city smallpox hospital. They have been named respectively "Schuyler Hall," in honor of Miss Louisa Lee Schuyler, the founder of the State Charities Aid Association, which in 1873 organized the Bellevue Training School for Nurses, the first general school of its kind in this country; "Jones Hall," in honor of Mrs. Cadwalader Jones, who has been chairman of the Advisory Board of the School ever since its establishment in 1875; and "Rice Hall," in honor of Mrs. William B. Rice, for some years a member of the Advisory Board and at present one of the managers of the Bellevue Training School. Jones Hall is a four-story building, 35 by 100 feet, and contains on the first floor a lecture room, a drawing room, and two isolation rooms for cases of contagious illness among the inmates. Each of the other three stories has sleeping rooms for the accommodation of eighteen nurses. On the first floor of Rice Hall, a similar building which is not yet entirely completed, there will be the offices of the school, the chemical and bacteriological laboratories, and a room for the classes in dietetics, while the three upper floors will be devoted to sleeping rooms. A pleasant feature of the opening exercises was the reading of a letter from President Roosevelt to Commissioner of Charities Folks, in which he said: "I greatly wish I could be present . . . especially because it has been my good fortune to know and to work with Mrs. Cadawalader Jones, Miss Louisa Lee Schuyler, and Mrs. William B. Rice, and I should like to testify my regard for them, while congratulating you, and also those associated with you, upon being connected with so admirable a work." Bishop Potter made a short address and Dr. Edward S. Peck, chairman of the Examining Board, spoke of the improved methods in the training of nurses which it is purposed to adopt. Mrs. Cadwalader Jones told of the progress that had been made since the school was opened on Aug. 1, 1875, with sixteen pupils, and warm applause was called forth by a reference she made to a former Commissioner of Charities, the late Thomas S. Brennan, who in 1886 quarantined himself and personally supervised the cleansing and disinfection of the Riverside Smallpox Hospital to turn it into the Nurses' Home.

Correspondence.

A DENIAL FROM BROWN UNIVERSITY.

President's Office, Brown University,
Providence, Dec. 8, 1903.

Mr. Editor: My attention has been called to the fact that some one has reported to you that Brown University is to take over the College of Physicians and Surgeons in Boston as a University Department of Medicine. Kindly allow me to state in your columns that this rumor is entirely baseless. I cannot imagine how it originated — certainly not at Brown University. We have no intention of establishing a medical school, and no officer of the University ever dreamed of any connection with the College of Physicians and Surgeons.

Very truly yours,
W. H. P. Faunce.

THE PAUPERIZATION OF MEDICAL SERVICE IN BOSTON.

Nov. 28, 1903.

Mr. Editor: This is a subject worthy of careful thought, if, in the future, the honorable practice of medicine is to be regarded as a means of getting one's livelihood. One phase of it has been forced upon my attention recently, and not for the first time. Preliminary to narrating an illustrative case, let me state that several years ago, while in attendance at the meeting of the American Medical Association at Milwaukee, I asked the genial Dr. Sam French, a resident, to tell me where their city hospital was situated. "We haven't any," he replied, "the people of Milwaukee are industrious and self-respecting, and would have to be educated to the use of such an institution. They pay for medical service and could not think of getting it otherwise." What a contrast with the Boston of then or now! Is there an honest effort made in all Boston clinics to remind people of this self-respect when they are tempted to evade paying for treatment they can afford to pay for? If so, why should cases like the following occur? About a month ago I was called to see a little boy suffering from hip-disease, being treated at his home by the Children's Hospital. I examined the child and told the parents that with the treatment being given he would get well; that if they wished me to treat the child they would have to pay me and also inform the hospital authorities of their decision. They did both, that is, they agreed to pay me for my services (the father is a member of the fire department) and the mother called at the hospital and informed the doctors in attendance of their decision. A few days after I had commenced to treat the child (I did not do so until after the hospital was notified by the mother) a nurse from the hospital called, inspected my dressing, and remarked to the mother of the child

that she feared the child's leg would become shortened without the hospital traction treatment. A few days after this, a postal came from the hospital, requesting the child to be brought to the hospital and left there for treatment. It seems to me that persons who can afford to pay for treatment outside of clinics should be encouraged to do so, instead of attempts being made to prevent them from doing so as in the above instance.

The poor both worthy and unworthy, should always and in every case be given medical service for the asking, and indeed should be sought, for that their physical condition be made better. This letter does not apply to them; it treats of the efforts made to pauperize medical service — the efforts to prevent from so doing people able and desirous of paying for medical treatment. I feel it a duty to report such cases and trust that public medical opinion will prove corrective.

Respectfully yours,

EDWARD A. TRACY, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, NOV. 28, 1903.

Deaths reported, 3,250; under five years of age, 795; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 714, acute lung diseases 567, consumption 374, scarlet fever 35, whooping cough 6, cerebrospinal meningitis 8, smallpox 18, erysipelas 6, puerperal fever 5, measles 12, typhoid fever 74, diarrheal diseases 76, diphtheria and croup 100.

From whooping cough, New York 4, Boston 1, Springfield 1. From erysipelas, New York 1, Chicago 2, Pittsburg 2, Boston 1. From smallpox, Philadelphia 11, Pittsburg 7. From cerebrospinal meningitis, New York 3, Baltimore, Boston, Worcester, Brockton and Woburn, 1 each.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Nov. 14 the death-rate was 17.9. Deaths reported, 5,169; acute diseases of the respiratory organs (London) 182, whooping cough 51, diphtheria 61, measles 79, smallpox 1, scarlet fever 43.

The death-rate ranged from 6.0 in Hornsey to 32.2 in Warrington, London 16.7, West Ham 16.8, Brighton 10.8, Southampton 15.6, Plymouth 14.0, Bristol 14.6, Birmingham 21.4, Leicester 19.4, Nottingham 22.9, Liverpool 21.4, Bolton 18.3, Manchester 20.1, Salford 25.3, Bradford 22.1, Leeds 23.9, Hull 16.9, Cardiff 12.7, Rhondda 15.3, Merthyr Tydfil 18.9, Kings Norton 7.4.

METEOROLOGICAL RECORD.

For the week ending Nov. 28, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING NOV. 28, 1903.

A. R. ALFRED, surgeon. Commissioned surgeon, with rank of lieutenant, from Jan. 4, 1903.

E. R. NOYES, pharmacist. Warranted pharmacist from Oct. 20, 1903.

A. G. GRUNWELL, surgeon. Detached from the Naval Hospital, Washington, D. C., and ordered to the "Minneapolis."

D. N. CARPENTER, surgeon. Ordered to the Naval Hospital, Navy Yard, Washington, D. C.

E. R. NOYES, pharmacist. Ordered to the Naval Museum of Hygiene and Medical School, Washington, D. C.

RECENT DEATHS.

William Ingalls, M.D., M.M.S.S., died in Roxbury, Dec. 1, 1903, aged ninety years.

MALARIA AND MOSQUITOES OF WORCESTER. A YEAR'S OBSERVATIONS ON THE HABITS OF CULEX AND ANOPHELES.[1]

BY WILLIAM W. MCKIBBEN, M.D., WORCESTER, MASS.,

Assistant Resident Physician, South Department, Boston City Hospital.

It has been fully demonstrated that the plasmodium malariæ, like the smallpox germ, has only two known cycles in its existence — the asexual in man and a further or sexual development in the stomach wall of a certain genus of mosquito, called anopheles. Strikingly similar, but more recent discoveries are that spotted fever of the Bitter Root Valley, Montana, is due to a hematozoön which has as its intermediary host the gray gopher, and is transmitted to man by the bite of the tick; and that yellow fever is caused by a protozoön, — the myxococcidium stegomyia, carried by the brindled mosquito,— stegomyia fasciata. These analogies doubtless soon will result in the discovery of the etiology of other acute infectious diseases, when we cease to look so much for a bacterium as for a protozoön, searching in the skin and in the lymph and serous discharges rather than in the blood. The enormous pathological changes going on in the skin in such a short space of time, would suggest that a protozoön can be found there, not only in smallpox, but also in scarlet fever and measles, multiplying with a rapidity equal to that of the plasmodia malariæ in the red blood corpuscles.

It is to the Italians that we are chiefly indebted for our greatly increased knowledge as to the part that the anopheles plays in this life history of the malarial parasite. They in turn owe much to Dr. Theobald Smith for his work in demonstrating, in 1893, the fact that the malaria of cattle, or Texas fever, is carried by the southern cattle tick, and to Ronold Ross for his discovery in 1898 that the culex mosquito is the intermediary host in the malaria of sparrows. Among the names which deserve special mention is that of the French army surgeon, Laveran, who in 1880 discovered the malarial parasite; Dr. A. F. A. King of Washington, who in 1883 suggested the mosquito as being responsible for epidemic malaria; Sternberg, Councilman, Osler, MacCallum and Thayer in this country, and Patrick Manson, Koch and Golgi in Europe. But to the Italians Marchiafava, Bignami, Celli, Grassi and Bastianelli (1899–1900) belongs the honor of demonstrating experimentally the transfer of the parasite of human malaria by the anopheles mosquito. They also transmitted malaria by direct subcutaneous and intravenous inoculation, both in the febrile and apyretic periods, regardless of the stage in which the parasite existed. They caused paroxysms in from one half to three weeks after injecting even less than one drop of infected blood. And very natural it is that the Italian investigators should show so much interest, because in Italy 2,000,000 cases of malaria are recorded annually, with 15,000 deaths. The Adriatic railroad, 850 miles long, expends each year 1,050,000 francs to fight the disease. In the last twenty years the Italian army has had 322,000 cases. Five million acres of land on the peninsula remain uncultivated on account of malaria. The regions in Italy where the pestilence is most prevalent are those which contribute most largely to permanent immigration.

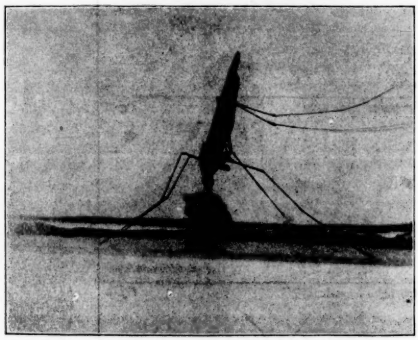
At the time when the sallow-faced soldiers were returning from Cuba in 1898, Worcester was collecting cheap Italian labor for constructing the Holden dam, and for extending various suburban lines of street railroads, while the Metropolitan water board was planning for the great dam at Clinton. Consequently Worcester represented a center where the Italian immigrants segregated into a large colony. Dr. Theobald Smith in the recent Shattuck lecture said, " It will be seen that I am putting the burden of starting new foci of malaria and of awakening the disease in the spring upon the older, latent or partly immune cases, who are in that stage of immunity which readily produces gametes after a relapse." Consequently the important part that the Italians, fresh from malaria-infected Italy, and the soldiers with these gametes latent in their blood, played in infecting the anopheles, is readily seen. With the source of the infection thus at hand, Worcester needed only the intermediary host.

This was present already in shape of the anopheles mosquito, harmless in the past because uninfected. She, by means of her pharyngeal pump, beautifully adapted for sucking infected blood, was ready in the course of ten days of proper temperature to give a hypodermic injection of sporozoites to the first unfortunate victim or victims she met. Water in which this female could lay her eggs and rapidly propagate her genus was another requisite in the chain; this Worcester furnished in an ideal way, so that the increase in the number of cases in the last five years has become serious and can no longer be ignored. The commercial progress of the second city of Massachusetts is dependent upon the good health of its citizens, particularly of the laboring classes, — Worcester being a great manufacturing center. It is this element in society which suffers greatest from malaria, being segregated into " three deckers " or tenements along the slow-moving grassy streams,— the ideal anopheles breeding places.

The employees of the factories consist principally of north country folk, in the shape of French Canadians, Swedes, Finns and Irish. Not having attained immunity by living in tropical or sub-tropical climates, they are especially susceptible to infection. In these non-immunes malaria manifests itself in almost every conceivable phase, from malarial sciatica to chronic malarial cachexia. The superin-

[1] Read before the Worcester Board of Trade, Nov. 21, 1902; Worcester District Medical Society, April 8, 1903; Boston Society of Medical Sciences, June 2, 1903.

tendent of the American Steel & Wire Company is authority for the statement that a conservative estimate shows that 10% of their 3,500 employees at the south works on the Blackstone river in Quinsigamond village were forced to give up work last summer on account of chills and fever; that he was threatened with having to shut down the central works altogether.



An elderly physician with an extensive practice in Quinsigamond village made the assertion that practically everybody in the village has had " the ague." He recalls one of the first cases there ten years ago when malaria was prevalent down the river, increasing in amount in inverse proportion to the distance from Providence. It is an exaggeration to say that every inhabitant of Quinsigamond village has had malaria, but it is a fact that every house visited gave a history of at least two sufferers. In the cellars adult anopheles were invariably found, easily recognizable at first sight by their characteristic resting positions,— their bodies at right angles to the surfaces on which they had alighted.

At the home of a well-to-do coal merchant all three of the servants had " swamp fever," while none of the members of the family suffered. Investigation showed that the servants' quarters were not screened, while the main part of the house was most carefully protected from nightly invasions of anopheles. The family had learned from experience that little pleasure could be derived from sitting on the veranda in the evening, owing to the fierce attacks of mosquitoes after sundown; they had not burned pyrethrum powder, however. Anopheles were found in both the cellar and barn of the house. Not three hundred yards away was Quinsigamond pond, made by damming up the river just above the wire mills; along the edges of the water in the thick grass anopheles larvæ were discovered quite easily. The supervisor of the Quinsigamond schools said that there was scarcely a day went by but that he was called upon to place a shaking lad on the radiator. This same supervisor instigated a meeting of the Worcester Board of Trade where three hundred representative citizens met to listen to a stereopticon talk on mosquitoes. The result was that a continued article on "Mosquitoes" was published in the *Worcester Magazine;* but nothing further came of it. South of Quinsigamond village, at Whitinsville, Mr. Whitin gave 25% as the loss in number from malaria of his French Canadian employees. Dr. Hodge of Clark University, Worcester, made a visit and showed him how easy it was to get rid of the mosquitoes — consequently the malaria — by draining, filling in, introducing fish and " petrolizing;" in other words, in not allowing the existence of any standing water, as all mosquitoes pass their larval stage in water as " wiggletails."

Last October the records of nine of the leading physicians visited gave a total of 2,565 cases of malaria treated from April 1 to October 1. One physician of South Worcester whose practice is largely along the Blackstone river and Still Water pond treated 560 cases in six months. He made the statement that almost every person in every house on certain streets had a history of periodic chills and fever. Needless to say, he did not have time to verify the diagnosis by blood examination. At a " mosquito talk " given in a hall on one of the streets along the river fully 50% of the 400 persons present confessed to having had malaria. During the summer months one hundred and twenty-five cases of the severest types of the disease were treated at the City Hospital, filling the medical wards to the exclusion of almost all other diseases, until the epidemic of eleven cases of typhoid, following a certain milk route, came in October. There were twenty-five house cases at Memorial and twenty-five at St. Vincent's Hospitals. The number of cases, including recurrent, treated at the out-patient departments of these three hospitals was too numerous to attempt to collect from the records, so with the several thousand addresses already obtained, a map was made out to show the relationship between the breeding places of the anopheles and the residences of the victims. A map of the city was procured and dots of red ink jotted down to indicate the adddresses of the sufferers. A capital " A," bearing more significance than in Hawthorne's " Scarlet Letter," indicated the points along the various streams and bogs where anopheles larvæ or adults were found. This also included some breeding places discovered by Dr. Hodge and his class in biology.

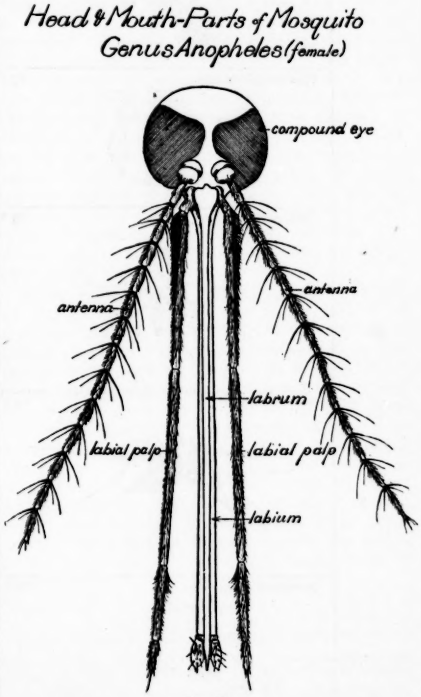
On completion of the map some striking facts presented themselves. It was seen that Worcester was completely surrounded by a malarial band, the center of the city being free except for the area around the below mentioned dumps and a few cases traced to sleeping at the lake, South Worcester, etc. The little red dots on the map rarely represented distances of more than one-eighth mile or two hundred yards from the banks of the Blackstone and Middle rivers, Still Water and Curtis ponds, Beaver and Mill brooks, and Lake Quinsigamond with its tributaries running through North Grafton to Milbury. Inside of the area thus surrounded were two foci of great importance, notably the Southbridge and Shrewsbury street dumping grounds and bogs. The latter borders on the aforementioned Italian colony and doubtless explains the rapidity of the spread of the infection with the coming of the latent cases. Back near the railroad at the corner of the Coliseum fence is a large stagnant pool, one half breeding culex and anopheles larvæ, the other half sterile, owing to a film of grease from the adjacent organic refuse. The tin cans on the surrounding dumps, half full of rain water, contain thousands of culex " wigglers," the adult mosquitoes being thick around the mouths of the cans. Across the street, East Park pond is free, owing to tadpoles, while Bell pond just above on the hill is also free because of its " trained edges," and because it contains hornpout and sun-perch.

Unfortunately hundreds of these little fish, which could well be utilized for stocking other ponds (gold fish costing ten cents a pair) are destroyed by being packed solid in a pipe which furnishes the water for East Park pond below. The number of cases was found to be in proportion to the number of inhabitants and number and proximity of anopheles. Under favorable conditions anopheles females thirsting for warm blood would fly a quarter of a mile, at times not even hesitating to go up a considerable hill. Being of retiring dispositions, they rarely came out of the grass and dark hiding corners by day; in fact, it was well-nigh impossible to get them to bite while it was yet light. This explains the old theory that malaria was due to an indefinite something called "miasm" coming up from a swamp at night. The writer recalls the time when his old family physician down south advised the avoidance of this mist or "bad air" after sunset. We now know that is the time anopheles begin to fly at large. We also know that the marsh gas seen bubbling up out of the bog is really harmless.

'Shame-faced, head-down anopheles." Photo. × 3 times (Dr. Hodge)

It is a recognized fact that mosquitoes, being so delicate of wing, will not venture out of the grass, bushes, trees, ivy or from the lee side of the house while a strong wind is blowing. This accounts for the great prevalence of swarms of culex on warm, sultry evenings; not only does the high temperature favor breeding, but the absence of breezes allows them to come out of their hiding places. The condition which best favors anopheles flying so great a distance as four hundred yards is that of a continuous but gentle breeze. This condition is present on most summer evenings — the wind blowing softly from the west; consequently, the fact develops that most of the malarial victims live east of the breeding places. This is true in Quinsigamond village, South Worcester, New Worcescester, "The Island," for two miles along Beaver brook, Mill brook and "The Sanctuary" at Lake Quinsigamond.

Culex is much more of a local insect. Being so addicted to the drink habit and being such a prolific breeder, she rarely flies more than one hundred yards away from her birthplace, so that every house suffering from swarms of culex will find the "wiggletails" close at hand in standing water, in a flower pot, tub, rain barrel, house drain, street catch-basin, old tin cans containing rain water, paint-pots, gutters, pools, ponds and bogs. Destroy the breeding places and the adults will all go away in search of water in a day or two. Both culex and anopheles were hatched from eggs, larvæ and pupæ. The adult females, watered and fed, were kept alive in bell-jars as long as two months. Without water the adults died within two days but went without food for a week or ten days, becoming greatly emaciated, however. Among the best food-stuffs were milk, bananas, grapes, grass and



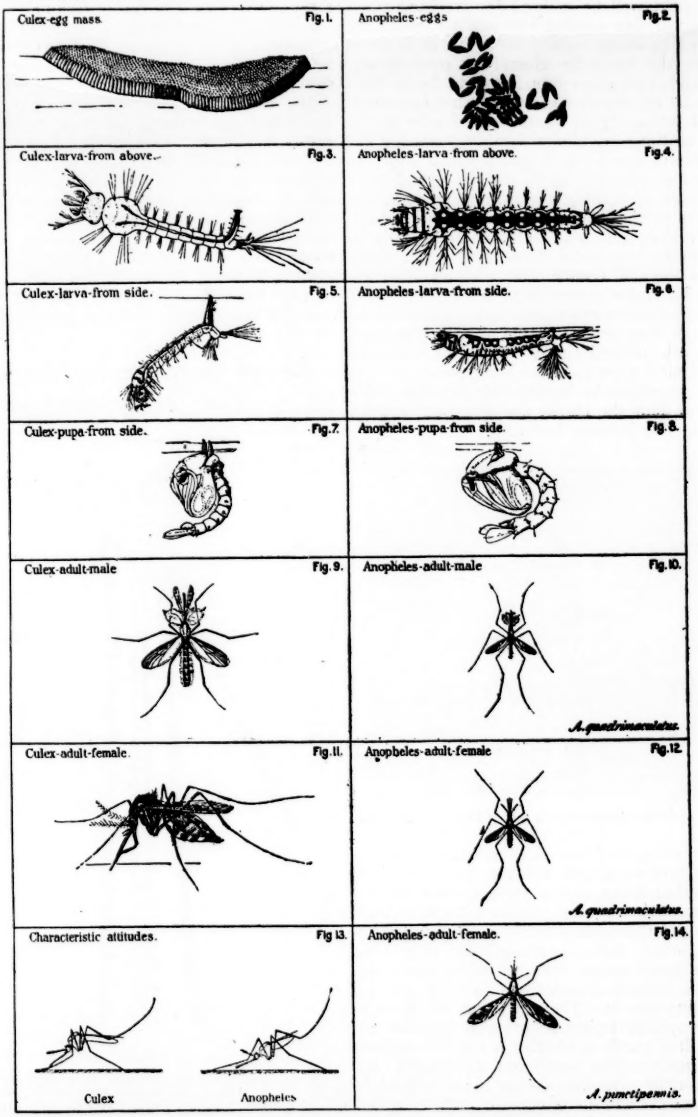


FIG. B.

sugar and water. Occasionally they were allowed a little human blood, the female anopheles attacking the hand viciously, not circling around looking for a "soft spot," as did female culex, but striking hard without hesitation or song; apparently anopheles did not secrete toxin in the salivary gland to the extent that culex did,

Figures B and C are from microscopic drawings used through the courtesy of Mr. Roy Cushman, Clark University, Worcester.

MOSQUITOES. PLATE

Copied by permission from Bulletin No. 25 new series, U S Dept of Agriculture (Howard, Notes on Mosquitoes)

DESCRIPTION OF PLATE.

Differences between Culex (the ordinary Mosquito) and Anopheles (the malaria-carrying Mosquito).

Culex eggs.—Two hundred to four hundred eggs laid at one time by one female, aggregated in masses side by side, large end down; egg mass concave above; general color of mass from above, brown; the larvæ issue from lower end of egg, directly into the water, about twelve to sixteen hours after the eggs are deposited. (Figure 1.)

(Description continued on p. 669.)

as no wheal or irritation was produced. The point of puncture could be made out distinctly, however. Consequently it is easy to see how persons while asleep could be bitten unawares. Female anopheles sank her proboscis half its length into the skin, and on one occasion continued to swell her abdomen with blood until she burst, the blood spattering around on the hand.

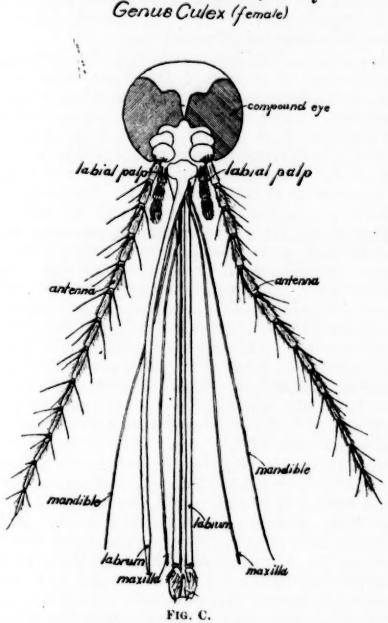

FIG. C.

Neither culex nor anopheles males could be made to bite; in fact the males lived only a day or two, dying after copulation. The females live on indefinitely under natural conditions, the exact duration of life not being ascertainable. They have many natural enemies such as dragon flies, bats, whippoorwills, night-hawks and winds; some females may possibly survive a whole season and then hibernate in an old barn, vacant house, cellar, or hollow-tree trunk; but in all probability very few females succeed in living more than a couple of months. The cellars of those houses within a radius of one hundred yards from the breeding streams presented an interesting appearance; so much so, in fact, that a flashlight was taken of a white-washed beam in Dr. Hodge's cellar in order to make a stereopticon slide. Dr. Hodge left his cellar windows open in November so the adults would hibernate there and specimens could be obtained for demonstrations at lectures during the winter. The result was that almost every available spot on the beam photographed was occupied by an adult female.

Dr. Hodge used small bottles with conical holes through the corks for collecting specimens, by placing the bottles down over the mosquito; when the bottle was filled, cotton was inserted in the holes. Thus the anopheles were easily separated from the culex, being differentiated by the resting position, the spotted wings (especially marked in anopheles punctipennis). the long labial palpi, larger bodies, and the fact that the hind legs rarely curled up over the tail as did those of culex. At a " mosquito talk " these bottles were passed around, and the room being warm the mosquitoes began to sing. By holding the mouths of the bottles to their ears the appreciative audience easily heard the shrill songs of culex on the one hand, and the low-voiced hum of anopheles on the other, the difference being very marked.

In the spring the impregnated females fly out to deposit their eggs on the water. To illustrate the rapidity with which culex breeds, this instance is cited: In order to obtain larvæ and pupæ for an evening lecture, at five o'clock a dozen dippers full of stagnant water were taken from a small pool in a bog where the deep grass and cat-o'-nine-tails were growing thickly. This water was strained through a net in order to get the larvæ or " wrigglers " into clear water in one bell-jar. The " wrigglers " were all culex, having long breathing tubes at the tail end, which they brought to the surface to protrude for air every two or three minutes, the bodies being at an angle of 45° with the surface, — head down.

(To be continued.)

Anopheles eggs. — Forty to one hundred eggs laid at one time by one female; eggs float separately on their sides; general color of eggs from above, black; the larvæ issue in three to four days. (Figure 2.)

Culex larvæ. — General color, brown; head and thorax wide; breathing tube long. (Figure 3.) Feed near surface, breathing tube extended up to air, body at angle with surface, head and mouth down (Figure 5); when disturbed, they sink with quick wriggling movements downward to the bottom. The larvæ become pupæ in seven to ten days.

Anopheles larvæ. — General color usually black, but varies (green, etc.); head and thorax relatively narrow, breathing tube short (Figure 4); feed near surface, breathing tube extended up to air, body parallel with surface, head also at surface, mouth downward when resting, but turned up to the surface to seize food by rotation of the head (Figure 6); when disturbed, they skate backwards over the surface of the water, only sinking when frightened. The larvæ become pupæ in about sixteen days.

The pupæ of Culex and Anopheles resemble each other somewhat closely. (Figures 7 and 8.) Differences exist, but are not sufficiently striking for ready appreciation. The culex pupa becomes an adult mosquito (imago) in about two days; the anopheles pupa in five to ten days.

Adults. — The males of both genera can be distinguished from the females of both by the tufted antennæ of the former. (Compare Figure 9 with Figure 11, and Figure 10 with Figures 12 and 14.) Culex adults (male or female) can be distinguished from anopheles adults (male or female) by the spots on the wings of the latter, small and brown in anopheles quadrimaculatus (Figures 10 and 12), large and black in anopheles punctipennis (Figure 14).

Culex adults, when resting on a solid surface, take a hump-backed attitude, the abdomen lying more or less parallel with the surface; anopheles adults take a straight position, the abdomen pointing away from the surface (Figure 13). In this regard, the difference between Anopheles punctipennis and culex is very striking, but is much less marked between culex and Anopheles quadrimaculatus. Anopheles females of both species can be further distinguished from all culex females since they possess long palps, giving them the appearance of having three "stings" instead of one. In the culex female the palps are so short as to escape observation.

NOTE. — These reproductions are unfortunately to no definite scale, and may give the impression that the culex is larger than the anopheles. It is just the reverse, however.

SOME CASES OF FACIAL ERYSIPELAS FROM EROSIONS OF THE NASAL SEPTUM.[1]

BY JOHN W. FARLOW, M.D., BOSTON.

IN all cases of erysipelas it is of great importance to find out if possible the point at which the infection enters the system. In scalp wounds, especially before the days of antiseptic surgery, erysipelas was the complication most feared. In obstetric practice, tears of the genitals were recognized as furnishing easy means for the much dreaded infection. In fact, all lesions of the skin or neighboring tissues may be the starting point where the germ of erysipelas finds lodgment and begins its rapid extension.

There is one form of erysipelas, facial, which seems particularly prone to occur where there has been no injury, a sort of "medical" erysipelas in contradistinction to the "surgical" form, and as there is no external lesion, a point of entrance is not looked for. The usual description of the disease speaks of it as beginning generally on one side of the cheek and then going over to the other side of the nose and face. As the outside of the nose is often the first part involved and as the germs in the air are naturally drawn into the nose, it is certainly reasonable to look inside the nose and see where such germs may find lodgment on a broken surface. Cracks and fissures of the vestibule, as well as pustules forming around hair follicles, may in certain instances become infected, but, in such cases, the first manifestation would probably not be at the bridge of the nose nor would the redness tend to spread so soon over the nose to the other side of the face.

The septum is the usual seat of nosebleed, ulcerations and perforations, and I think we may say without fear of being disputed that these lesions of the septum, especially erosions, are more common than all other lesions of the inside of the nose. If the septum is bent or irregular, or the mucous membrane atrophic, crusts form and are dislodged by the finger or by blowing, a raw surface is left and whatever enters the nose must pass this unprotected spot. The symptoms, other than profuse nosebleed, may be so insignificant that the patient is unaware that there is a very important lesion of the nose. No examination is made and the negative history causes the nose to be overlooked as a possible starting point of infection. If an examination is made when the erysipelas is well established the nostrils may be found inflamed and filled with secretions and crusts which are looked upon merely as a part of the disease, and no special attention is paid to anything but the outside of the nose.

If surgical erysipelas spreads from an external wound, proper cleansing and treatment of the wound itself are recognized as essential. The fact that erysipelas does not often result from surgical operations on the inside of the nose may perhaps be accounted for by the attention paid to the wound at the time of operation and its after-treatment, whereas in case of septal erosions the crusts may serve to hold the germ in contact with the wound and there is no free secretion to dilute it and wash it away.

The ethmoid region suggests itself as a possible starting point for erysipelas infection as being in close proximity to the part of the nose where the external redness commonly begins; but ethmoid disease is not nearly so common as are erosions of the septum and from its more protected situation is probably not so likely to furnish a favorable situation for the lodgment of germs other than those of influenza.

I was quite forcibly struck with the probable septal origin of a case of facial erysipelas in a lady seventy-five years of age whom I saw several years ago. I was called to see her in consultation on account of occasional spasm of the throat. There was nothing of importance found in the throat, but I made note of an erosion and crust of the septum in the right nostril. Two months later I was called again and found her with a temperature of 101°, headache, septum very red and swollen, and a decided erosion on the right side of the septum on which was some pus. The bridge of the nose on the right side was very red, tense and painful and the redness was spreading toward the cheek and eye. I removed the secretion from the nose and used antiseptic washes and powders as dressing for the wound. She had a bad night and the temperature the next morning was 103. She was mildly delirious and looked and was very ill. The erysipelas had spread to the other side of the face. The septum was again thoroughly cleansed, as well as every part of the nose, and her physician and nurse were most assiduous in seeing that the nose was kept free from secretion. The outlook seemed bad, but the next morning she was decidedly better and on the following day the conditions, local and general, had much improved and she was soon convalescent. Her physician agreed with me that the recognition and treatment of the intranasal condition were the important factors in preventing what looked like a fatal termination.

Miss L., forty years of age, had had a number of severe attacks of facial erysipelas at frequent intervals. She had a marked erosion of the septum which I treated. On one occasion the septum became reddened and there was beginning pain and redness of the bridge of the nose just as her former attacks had begun, according to her story. Thorough cleansing of the nose caused the symptoms to disappear in a short time and she went nine years without another attack, dying of renal disease.

Mr. A., fifty-two years, had a very severe attack of facial erysipelas. I examined his nose later and found a marked septal erosion with bloody crusts. On one occasion the nose became reddened on the outside, but treatment of the septum seemed to stop what the patient was very much afraid would be an attack similar to his former one.

These three patients had never complained of the nose sufficiently to lead them to have their

[1] Paper read at the Twenty-fifth Annual Congress of the American Laryngological Association, held at Washington, D. C., May 12–14, 1903.

noses examined, yet each had a large open wound at the time I saw them.

I am told that at the Massachusetts General Hospital all cases of facial erysipelas coming to the Department for Diseases of the Skin are referred to the Department for Diseases of the Nose and Throat for examination of the nose. Very possibly if this custom were more prevalent, cases of recurrent facial erysipelas might be much diminished in number.

Since the above was written I have seen a patient whom I treated three years ago for an erosion of the left side of the septum. For the four years preceding he had had repeated attacks of facial erysipelas, generally two or three times a year, beginning on the left side of the nose and extending to the hair. Since the treatment of his nose he has had no attack of erysipelas and his general health is better than for many years.

A CASE OF GUMMA OF THE FALLOPIAN TUBE.

BY GEORGE S. WHITESIDE, M.D., BOSTON,

Assistant Genito-Urinary Surgeon to the Boston Dispensary; Assistant in Anatomy in the Harvard Medical School.

About five years ago my attention was called to the subject of gummata of the uterine adnexa by reading a very suggestive little book called "Maternal Syphilis," by J. A. Shaw-Mackenzie.[1] Since that time I have been looking for cases, but in spite of having had the opportunity of examining a large number of syphilitic women, I have found but one, which I report below. I have not reported it before for two reasons — first, I wished, if possible, to collect other cases of a similar nature to put with it; second, I thought it advisable to wait, in order to make the report more valuable.

I have tried to look up the general subject of gummata of the tube, or syphilitic salpingitis, with comparatively poor success. The "American Year Book of Medicine and Surgery," from 1896 to 1903, inclusive, makes no mention of it.[2] The "American Textbook of Pathology" has four lines on the subject. It says, "Syphilitic salpingitis of the tube has very rarely been found in the syphilitic new-born infant, child or adult. The tube is enlarged, tortuous, inflamed, the lumen usually obliterated, and the muscularis infiltrated with masses of small round cells, — miliary gummas."[3] Taylor's "Venereal Diseases"[4] has not a very encouraging account. "Syphilitic affections of the ovaries are rarely met with. According to Lancereaux, they present a close analogy to syphilitic affections of the testicle, and are either diffuse or circumscribed. This author has only met with the diffuse form after it has arrived at the stage of atrophy; the ovaries were of the usual size or smaller than natural, fibrous in their structure, with scattered cicatrices, and destitute of Graafian vesicles, although the patients had not yet arrived at the usual age for the cessation of the menses. Lancereaux gives a representation of a case furnished by Dr. Richet, in which there was a circumscribed deposit of gummy material, similar to that found in syphilitic orchitis.

The symptoms of these affections are said to be a slight, dull pain in the region of the ovaries, possibly at the outset some increase in the size of these organs, perceptible on abdominal and vaginal palpation, a loss of sexual passion, and sterility. It is evident that these signs, taken in connection with the history of the case, can only furnish a probability of the nature of the disease, which may be further increased by the success of antisyphilitic treatment. No instance is known in which the Fallopian tubes have been affected with syphilis.

Certain cases in which uterine tumors in syphilitic subjects have yielded to the internal administration of iodine of potassium and mercurials render it probable that this organ is not exempt from the late manifestations of syphilis, but nothing more definite is known upon the subject, since post-mortem investigation has been wanting.

In Morrow we find:[5] "Syphilis in connection with these parts is almost unknown in literature, aside from a few random observations which mostly lack authenticity. Gynecologists apparently almost entirely leave it out of their calculations in the diagnosis of disease in this connection, and pathologists seem to have failed so far to find more than a few stray traces of its existence. Perhaps the ovaries are affected during secondary syphilis in a manner corresponding to the epididymis, but of this there could naturally be very little proof. Oftentimes women during the secondary stage of the disease suffer from functional disturbances in menstruation which are probably largely due to the general malaise associated with the early general symptoms; still, they may be in some measure dependent on local manifestations. The ovaries and tubes are rarely the seat of late syphilitic lesions of a gummatous nature. It has been questioned whether some of the sclerotic changes which are observed in connection with the ovarian connective tissues may not at times be due to syphilis, the same as in the testicle. This question has not as yet been settled, though it is very probable that some of these conditions are syphilitic in origin.

"Richet[6] records a well-authenticated case of gumma of the ovary. Lancereaux also has been quoted to have observed a well-defined tumor of the ovary which disappeared speedily after the introduction of antisyphilitic treatment.

"A case of gummatous salpingitis has been put on record by Bouchard and Lépine.[7] In this case both tubes were involved, and thickened to the diameter of the finger. On exposing them by means of an incision, three gummata about

[7] Gomme des Trompes. Gaz. Méd. de Paris, No. 41. 1866.

the size of a hazelnut were found connected with each tube. The canal was obliterated in each instance. Some time since I was called to treat a young woman of doubtful antecedents who announced that she had a pelvic inflammatory trouble, which was gradually getting worse in spite of the treatment she had received. Bimanual palpation disclosed in the region of the left broad ligament a tumor about the size of an orange, moderately tender. As she had already been under the treatment of a good gynecologist without favorable results, I put her on large doses of iodide of potash, although I could not obtain, notwithstanding the many opportunities she had apparently had for contracting the disease, a history of syphilis. The patient began immediately to improve, however, and after a time, the treatment being continued, the tumor gradually disappeared. Although this case does not absolutely prove syphilis of this region, still it justifies one in strongly suspecting that such was the case."

This case, reported briefly by Dr. Fuller, in Morrow's "System," is so much like my own that I will make no further apology for reporting my case, in spite of the fact that no absolutely irrefutable proof can be given that my case really was what I suppose it to have been.

Mrs. M. G., aged thirty-seven years, was referred to me June 14, 1899, by her family doctor. She had had eleven pregnancies; two miscarriages. She had a clear history of syphilis, dating back to 1894. Both miscarriages since that time. On Jan. 29, 1899, she gave birth to a stillborn fetus at or near term. Since that time she has menstruated as often as every two weeks, and recently, in June, 1899, "was flowing most of the time." Bimanual examination showed the uterus somewhat retroverted, slightly enlarged, freely movable. Tubes and ovaries apparently normal. June 21 I curetted the uterus. After-treatment consisted of corrosive douches, the administration of ergot and hydrastis. She menstruated July 20 and Aug. 17. When seen Nov. 7 she had not menstruated since Aug. 17. A probable diagnosis of pregnancy was made, and she was put on ten drops of a saturated solution of iodide of potassium, three times a day. Being anemic, she was given iron also. Fetal movements felt Dec. 24. Iodide of potassium continued. On May 1, 1900, after a normal labor, she was delivered without instruments, of a healthy child.

She came to me again Aug. 1, 1901, more than a year after the delivery of her child. She had been receiving no antisyphilitic treatment during the past year. She complained of pain, for two months past, in the right iliac fossa; worse at night. Some pain in back; headache; malaise. Too frequent and too profuse catamenia. Examination under ether showed on the right side a tumor the size of a large lemon, apparently the right Fallopian tube. She was ordered hot douches, rest, and the other usual remedies without success. She was averse to any surgical procedure, so in view of the history of syphilis, I thought it best to put her on a rigorous antisyphilitic mercurial and iodide treatment, in order, if possible, to absorb the tumor. I saw her at intervals of a week during the next two and a half months. Weekly examinations revealed the fact that the tumor was constantly growing smaller. An ether examination on Oct. 7, 1901, showed that the tumor had absolutely disappeared. During these ten weeks' treatment her symptoms had gradually improved, so that by the end of November, 1901, she considered herself well.

I saw her again in May, 1902, and in September, 1903. She has had no return of the tumor. With regard to the child born May, 1900, it lived about five months, never presenting symptoms of syphilis, but died of what I was told was broncho-pneumonia. I did not see the child myself. Autopsy refused.

This case is very similar to the one above quoted by Fuller, except that in his case the history of syphilis is less clear, and his was not preceded by a pregnancy. It seems unlikely, in this case, that the tumor of the tube should have been ordinary pyosalpinx. A normal labor with normal convalescence, an interval of a year of fairly good health, and complete disappearance of the tumor under antisyphilitic treatment, also the fact that two years have passed since that time and no recurrence has taken place, make it seem probable that this tumor was a gumma of the Fallopian tube. I report this case with the hope that it may call the attention of other physicians, particularly syphilographers and gynecologists, to the occasional possibility of the occurrence of syphilitic salpingitis.

THE INDOL OF THE FECES AS A MEASURE OF PUTREFACTIVE PROCESSES IN THE INTESTINES.

A. E. AUSTIN, M.D., BOSTON.

From the Medical Chemistry Laboratory, Tufts College.

FOR many years the measure of albuminous decomposition in the intestinal tract has been the amount of indican and ethereal sulphates in the urine, but this has led to many errors because it is a measure, not of this process, but of the completeness of the absorption of its products. We have only to cite, in illustration of this, the fact that a marked indicanuria may disappear when constipation, or normal stool, is replaced by diarrhea, or when laxatives are used; and further examination will show that while the aromatic products are diminished, they are still present, lessened only by the shorter stay of the fecal matter in the intestine. For the extent of this putrefactive process many causes have been assigned; atony of the intestines has been given as one by Rosenheim, which may, or may not, be associated with constipation, for many have daily stools and still an enormous indicanuria: this condition may also be associated with an ileo-colitis of so-called catarrhal nature with large amounts of mucin in the feces which may be due to these presumably irritating products, or may be the cause of them by production of the atony. The lack of free hydrochloric acid in the gastric juice has also been given as a cause, though, as will be shown later, it is very doubtful how much influence a small or large amount of this acid, necessarily neutralized after entering the intestine, may have upon this condition unless, as I have suspected, the excessively acid stomach contents in hyperchlorhydria may produce the chronic enteritis and hence the atony. Von Noorden,[1] who found no increase of the ethereal sulphates when hydrochloric acid in the stomach was

[1] Zeit f. klin. Med., 1890, 530.

wanting, says that "the stomach acid exerts no influence beyond the limits of that organ, and especially has nothing to do with intestinal disinfection." Deficiency of bile has been given as a cause, not because of its disinfecting properties, but because it stimulates intestinal peristalsis. Of this I have seen one case, not given here, which soon afterwards developed jaundice and was operated for gallstones, which were found; and one other, given in the list following, which was also operated, but in which they were not found, though the gall bladder was everywhere adherent. Deficiency of pancreatic juice is also given, and one of the following cases suffered from that, if one can judge from the mass of undigested muscle fibers present in the feces. As a last cause for the appearance of indol in the urine, Blumenthal and Rosenfeld have given the breaking down of cell tissue in fasting and severe organic diseases like cancer, pernicious anemia, etc.; this point, however, still remains *sud judice*, and it has not yet been positively proven that indol does persist, in death from starvation, to the end. When my work was begun, the Ehrlich dimethylamidobenzaldehyde reaction for indol in the feces had not come to my attention and so the older and more cumbersome method of extraction and weighing was used. Among the products of this putrefaction other than indol are skatol which, according to Baumstark,[2] is so vastly less than indol that it is of only the slightest importance; phenol. which, according to Strauss and Philippson,[3] was missed in the urine of over half their cases and which I could never find in sufficient quantity in a day's feces for estimation, though traces could always be found with Millon's reagent; and sulphuretted hydrogen, which Albu[4] says, varies so that no distinct conclusions could be drawn from its presence. For this reason I neglected all the aromatic products except indol. Since in conjunction with the indicanuria which was present in every case, calcium oxalate was present as a sediment in all the urines, and since Soetbeer and Krieger[5] have ascribed phosphaturia (phosphate of calcium) to catarrh of the colon, a quantitative estimation of the calcium in the feces of every case was made in order to determine whether absorption of indol or conversely, elimination of the calcium salt, was affected, since these authors claim that the normal eliminative powers of the colon for this salt are impaired in catarrh and an excess appears in urine. In most of the cases the nitrogen of the feces was also determined, since with a mixed diet a large elimination of nitrogen in the feces might indicate an impaired absorption or an increased motility, which was not present in any of the cases, or, at least, there was no diarrhea.

The method employed for determination of the indol, phenol, etc., was that given by Schmidt and Strassburger[6] and is as follows: The day's feces was first weighed and a portion weighed out for the determination of the water, which portion was afterwards destroyed for determination of the lime. Another portion was weighed out for the nitrogen estimation, and the remainder mixed with water until it formed a thin, soupy-like mixture and then one third distilled off; this distillate was then made alkaline with sodium carbonate to hold the fatty acids and a second distillate was made; this distillate was then made strongly alkaline to hold the phenol in check and distilled with steam as long as any indol was found to go over, which was easily seen by its floating on the top of the water; in order to remove those portions which clung to the distilling tube, ether was added to the last solution and its vapor dissolved out all the indol and carried it to the flask lying before the condenser. This watery solution of indol (and skatol) was repeatedly shaken with ether, the ether distilled until some began to fall out of solution and then allowed to evaporate spontaneously in a weighed beaker, dried in a vacuum over sulphuric acid and weighed. The solution from which the indol had been removed was then strongly acidified and distilled as long as Millon's reagent gave any reaction. Owing to the almost entire absence of phenol and fearing that it was escaping, the most of these distillations were made into bromine water. The portions of feces used for calcium determination were simply destroyed by the blast lamp and the ash extracted with acidulated water and the substance weighed as calcium oxyd. Before proceeding to a discussion of results, a brief *résumé* of the chemical features of the cases and amounts of the different substances under consideration is given as follows:

Case I. Stomach contents one hour after test breakfast: amount, 200 c.c., no free hydrochloric acid, lactic acid abundant, rennin present, 1:160, total acidity, 52; combined hydrochloric .51 per thousand; abundant sarcinæ ventriculi.

Feces, — amount twenty-four hours, mixed diet, 183.2 gms., numerous muscle fibers, a great many fat globules (Sudan III) and numerous shreds of mucus (colon washing always produced great masses of mucous shreds). The amount of indol found was .022 gms. and the urine showed a marked indican reaction as well as reduction (glycuronic acid).

Case II. Stomach contents, amount, 29 c.c. Total acidity, 84; free hydrochloric acid, 2.06, total hydrochloric, 2.48; erythrodextrin. Feces, amount twenty-four hours, 64.5 gms, dried residue, 20.19% or 13.0 gms. Large number muscle fibers, no fat, no starch, large number mucous shreds containing epithelial cells (shreds numerous with colon washing), no bilirubin, total nitrogen, .778 gms. (average of two estimations); indol and skatol, .280 gms.; phenol, mere trace; calcium oxyd, .341 gms.

Case III. Stomach contents, amount, 30 c.c. Total acidity, 48; free hydrochloric acid, 1.24; total hydrochloric, 1.75; lactic acid, trace. Feces, amount, 42.2 for twenty-four hours, muscle fibers very numerous, many needles of fatty acids, some mucous shreds; dried feces, 28.66%, or 12.09 gms.; nitrogen, .738 gms. (an average of two estimations); calcium oxyd, .464 gms., indol and skatol, .0568 gms.

Case IV. Stomach contents, amount, 100 c.c. Total acidity, 126; free hydrochloric, 3.12; total hydrochloric, 4.21. Erythrodextrin. Feces, amount, 99.2 gms., few muscle fibers, some connective tissue, no fat, hydrobili-

[6] Die Feces des Menschen, 136.

rubin. Dried feces, 23.6% or 23.41 gms.; total nitrogen (average of two estimations), 1.24 gms.; indol, .260 gms.; calcium oxyd, 1.19 gms.

CASE V. Stomach contents, amount, 48 c.c. Total acidity, 53. Free hydrochloric, 1.56; total hydrochloric, 1.85; trace of lactic acid. Feces; these were not weighed because obtained by means of an injection; no muscle fibers and no starch granules, numerous shreds of mucus, some with cells adherent; no fat. Indol in one day's feces amounted to .160 gms. Urine had a large amount of indican, and oxalates.

CASE VI. Stomach contents, amount, 140 c.c. No free hydrochloric. Total acidity, 6. Rennin, 1.80; total (combined) hydrochloric, .073; lactic acid present. Feces, amount 66.2 gms.; no muscle fibers; abundant fatty acid needles and fat globules; numerous mucus shreds (shreds also on colon washing); dried feces, 25.5% or 16.881 gms.; total nitrogen, .794 gms.; indol, .244 gms.; calcium oxyd, .549 gms.; urine showed a large amount of indican and urobilin. This is the case afterwards operated on my advice and that of others, by Dr. Brewster, for gallstones, but none were found.

All of these cases were regarded clinically as so-called chronic catarrhal colitis, or ileo-colitis, of which mucous colitis or ileo-colitis seems, from descriptions of others, to be a similar term. The term colitis was added when, in addition to the presence of large numbers of muscle fibers and bilirubin-stained shreds of mucus, similar shreds could be obtained in profusion by colon washing.

The stomach functions were examined secondarily as a means of determining what effect, if any, the contents which were passed into the intestinal tract had upon its condition. With reference to its secretion of hydrochloric acid, we may regard cases III and V, with elimination of 56 and 160 mgms. of indol, as normal; II and IV, with 280 and 260 mgms., as hyperchlohydrias; and I and VI, with 22 and 244 mgms, as hypochlohydrias; from this we should be compelled to say that the amount of acid in the stomach had little or no effect upon the formation of indol, as would be expected from the fact that most of the bacterial action takes place below the ileo-cecal valve, where the reaction is alkaline and all the acid formed has been neutralized.

With reference to motility of the stomach, judged from the amount withdrawn, it is evident that all are normal, having from 56 to 280 mgms., with the exception of I, having 22 and possibly IV, having 244 mgms., so that if the indol depends on motility, as is quite evident, impaired motility of the intestine is not necessarily associated with a similar condition of the stomach. With reference to absorption in the small intestine, by which the albuminous food is protected from the ravages of these micro-organisms throughout the colon, if we may judge from the nitrogenous waste, an inference that is only approximate, owing to the varied origin of this element and the difference in the digestibility and amount of foods, we have the lowest nitrogenous waste; .378 gms. with .056 indol, and the highest, 1.24 gms. with .260 indol, so that evidently no connection exists.

With reference to the amount of moisture in the feces, an increase of which is supposed to facilitate the growth of germs and hence the formation of indol, we find with varying moistures of 79.81%, 76.4%, 74.5% and 71.34%, 280, 260, 244 and 56 mgms. indol. There may be some connection in this instance, though the cases are too few to put much dependence upon it. According to Grundzach,[7] the average amount of calcium oxyd eliminated daily with a mixed diet is 1.316 gms. and in comparison with that, except Case IV, there was a marked diminution in the amount of lime eliminated by the intestine, and as before stated, if absorption follows elimination in its impairment it may account for the large amount of indol found, as well as the fact that calcium oxalate crystals were found in all the urines of these individuals, due, not to the increase in oxalic acid, but to the increased amount of lime in the urine which failed of elimination by the intestine.

The amount of indol found is vastly greater than that found by Baumstark, already quoted, who regarded 17 mgms. as an average normal quantity in the day's stool and whose greatest amount in a pathological condition (Achylia gastrica) was 114 mgms. My much larger amounts may be due to the fact that the skatol was reckoned with it; of their purity there could be no question, both from the method by which they were obtained, excluding all other products, as well as from their well-defined crystalline form, and the response of the one (indol) to Legal's reaction.

My inability to find phenol in weighable quantities can only be explained by the fact that it is absorbed and oxidized, for it is always difficult to find it in the urine, unless ingested in more than mere traces. Yet this substance is very prominent among those produced by a spontaneous putrefaction of albuminous material, and Simnitzki[8] found as high as .68% of the decomposed albumen in the form of phenol, keeping close to the amount of indol and sometimes exceeding it.

WAS HE INSANE? A STUDY IN MENTAL DIAGNOSIS.[1]

BY C. A. DREW, M.D., BRIDGEWATER, MASS.,

Medical Director Massachusetts State Asylum for Insane Criminals.

(Concluded from No. 24, p. 645.)

ANOTHER letter to his wife, throwing light on his mental content in an angry mood, was as follows:

APRIL 10, 1902.

Written under duress.

ORDERS.

To MRS. G. B. — (1) You are hereby ordered and directed by me, your lawful husband, to bring any money you may receive from Mrs. C. B., my mother, or from any party or parties on my behalf, to the above lunatic asylum and to deliver the same intact to me, and you are forbidden to remit by mail any money to me or deliver any money to Dr. Drew or any person or persons on my behalf. You are ordered to come yourself or send

[7] Zeit. f. klin. Med., 23, pp. 70.
[8] Zeit. f. physiol. Chemie, 39.99.
[1] Read before the Plymouth District Medical Society, April 15, 1903.

Queenie G. B., my daughter, with the said money, but not to entrust the same to any other person or persons.

(2) You are ordered to cause Queenie G. B. and Clarence W. B., my children to write to me forthwith and to have the letters here by Saturday, April 12, 1902.

(3) You are ordered to go to the State Board of Lunacy at once and make a legal demand for the father of your children's immediate release from unlawful custody.

(Signed) H. J. B.

A copy of the above orders has been sent to my attorney, Mr. Fishacher, Esq.

The foolish arrogance of these "Orders" might come from a paranoiac or an imbecile, but the paranoiac, if educated, has commonly more sense than to write such stuff to any one. The following explains itself:

FEBRUARY 21, 1902.

To the Manager of the Pinkerton Detective Agency, Boston, Mass.:

Dear Sir, — Upon receipt of this letter please send a reliable, trustworthy and shrewd dectective to see me. Tell him to bring blank drafts with him. I was robbed and unjustly sentenced to Massachusetts state prison and two months before the expiration of the sentence two unscrupulous quack doctors have conspired with officials and railroaded me to a lunatic asylum. I complain of foul play. I will not write full particulars, but will explain fully to your man. I have received a cable message from my mother in London, England, and my friends will be here soon. I am engaging reputable lawyers to reopen my case and to get an investigation. I am a lawyer. I have startling disclosures to make to your agent. Please make your charges as reasonable as possible and remember I am an attorney and may need you for many cases. Send your man at once and on his arrival I will pay him a good substantial fee. I have powerful friends. I have been sent to an asylum to save the officials from exposure, etc. Foul play. I cannot send any remittance by mail, as I do not want any one to know who I am drawing on or where my money is, owing to the trustee and attachment law being so strict in this state, and as I have legal trouble with my wife and she is looking to get alimony and to attach my properties, etc., and the officials here would know where cash is if I drew through them, as I should have to get a draft from them. Send good man with blank drafts. I will pay his fare and all expenses. Send as quickly as possible and be sure he sees me and tell him to be silent as to who he is. I need your man to hunt up evidence, etc.

Yours respectfully,

(Signed) H. J. B.

This letter to the Pinkerton agency, it may be noted, mentioning "legal trouble with my wife," antedated his loving letter of March 12 by eighteen days. He would not forget to write "bring blank drafts" in each of his many letters to lawyers, evidently thinking this suggestion best calculated to bring the lawyers quickly, and usually in his letters to the latter he promised payment in full for past services. When one lawyer came to see him, our patient did use the blank drafts brought as suggested, but he drew on another lawyer with whom he had formerly been on a friendly footing. This lawyer friend had also been promised full payment if he would come from New York city to co-operate with Massachusetts attorneys to obtain our patient's release. He had also been admonished to bring blank drafts. This New York attorney was evidently slightly indignant to find that our patient had drawn on him in favor of another lawyer. Some letters were exchanged, which we did not see, the Boston lawyer, who was paid by drafts on the New York attorney, acting as mail carrier for our patient. The following letter was written to the New York lawyer, in reply, evidently, to a sharp letter from the latter, who had discovered that his sometime friend, our patient, was not acting on the square with him. It reads as follows:

MARCH 27, 1902.

My dear Dave: Your letter duly received and contents noted. Your extraordinary epistle and the peculiar tone and indignant manner in which you write can only be appreciated by me, as I understand you are a fighter and an indomitable "toner," and I verily believe you would rather fight than eat and your bickering and quarreling with me, your own client, is proof to me that you are a very eccentric attorney in some small matters, but with all thy faults I love thee still, and look upon you as the faithful "wondertoar" young and reliable checkmating general that you always were. I mean you to try to checkmate my enemies in a legal manner. Let me explain a little. The fact that you say you never received a pawn ticket for ring and stud shows me that you have never received it, but I solemnly declare that I delivered it to the prison officials with a letter addressed to you, stating that the ring and stud had nearly run out and sent it to you as a present if it would be any use to you. This is over four years ago, and if you have never received it, then it only adds one more crime and felony to the list to be laid at the door of the unscrupulous prison officials and I am not to blame and you are not to be blamed. . . . Now let it be distinctly understood that I am not blaming you in any matters, but merely wrote you the other day because Mr. Bruorton stated that he had received a letter from you and that you asked him to go to the asylum and find out if I had the money to send to you for expenses and that you would have the affidavit drawn and sworn to if he desired you to do so, and Mr. Bruorton stated that he wrote you that you could use your own judgment as to the affidavit, but would not be responsible for the costs or for your expenses or for any work you might do for me. Upon receiving such a letter I immediately wrote to you to look at the past, etc., as I think, in view of the past and taking into consideration that I owe you nothing and that I have always faithfully and honestly remunerated you for your services that, to an old client, you need not be so particular and parsimoniously inclined. Mr. Fishacher, a Boston lawyer, was here yesterday with my wife and she stayed all day and dined with me. I delivered a letter to my wife to have registered a draft, etc., to you. Please come on and see this man at once on receipt of the cash from his brother. His brother's address is on the draft. In the meantime if any money arrives, I shall telegraph you $50, as I did before through the Western Union Co., as I have received a heartrending letter on Monday from my father and mother who state they are sending me money. Have faith in me, my brave legal warrior, and be patient and do not write recriminating epistles acting as an injured man when you are not. You have a peculiar faculty for quarreling. Do you remember the order of Judge Newberger dangling in mid-air and Judge Pratt's stays (while you wait) and the conflicting orders and toners moving mysteriously as if by peculiar power and severance, supplementary orders and referee Hess and referee Stein being removed. Dangerous on the other side. Look out, I am coming soon. I rest my case.

Your affectionate friend and client,

(Signed) H. J. B.

P. S. — Write soon.

It would seem, on the face of it, that a lawyer who would try to work the confidence game on his professional brothers must be very insane and it ought to be known in this connection that most of the attorneys to whom our patient wrote either did not notice his letter or else inquired by telephone or letter of the asylum officials concerning patient. Attorney Fishacher knew

the man and was trying to serve him, for his family's sake, in an ethical and honorable way. Another Boston attorney seemed to swallow his bait whole, made frequent trips to the State Farm, came and went, as a rule, without consulting with the asylum officials, until he obtained our patient's draft for $1,800: $300 for himself and $1,500 for a New York law firm as whose agent he professed to be acting. After this his visits were infrequent and we do not know how much he realized on those drafts, nor how he felt when he heard from that New York attorney on whom the drafts were drawn, and whom our patient addressed as " My dear Dave."

The conclusion was forced upon us that our patient was not a true paranoiac, or monomaniac. I will admit that, using the term paranoia in its broadest generic sense, it may include most kinds of mental deficiency outside of dementia, paralytica and the acute psychoses embraced by the manic-depressive syndrome. I do not forget that Dercum [2] and others would include under paranoia all cases of chronic systematized delusional insanity, and that Ziehen writes of stuperous and incoherent paranoia. Dercum's classification seems eminently rational and helpful, if we agree as to the limitation of terms, but we hold that our patient's so-called delusions had not the true ring, and to speak of " stuperous " and " incoherent " paranoia is, seemingly, to confuse paranoia with dementia precox, or a toxic insanity with confusion, else to give a class name to a late and unusual phase of a disease. We believe the phrase " constitutional inferiority with moral perversion " best covers our patient's abnormality. The direct question, " Was he insane? " cannot be properly answered by " yes " or " no." There is no doubt but that he knew the difference between right and wrong in the abstract, and with reference to every dishonest act he did, but this could be said of almost all paranoiacs. The weight of evidence seems to show that he could act or refrain from acting according to his judgment of which was the best policy. The fatuous folly of his judgments is beyond dispute. Insincerity, duplicity and mendacity were characteristics evidenced at every interview and in every letter he wrote. To the governor and the British consul his letters were couched in technical and well-turned phrases. To the lawyers he emphasized the fact of his being a Jew and of having powerful friends and rich relatives. To these, he wrote of being robbed and illegally sent to an insane asylum, but to his mother he wrote very little about being robbed. To her he cried " I am hungry and abused. Help! Help! I shriek a sane man from a madhouse! " We know this was not delirium. It was carefully penned, — all the exclamation points were in place. The motive was, manifestly, to touch the maternal heart, to work on the mother's nerves that she should send more gelt quickly. There was just a little basis for his claims of being robbed, but not by any prison official. A certain New York lawyer had obtained money from patient's mother, more than one hundred pounds, ostensibly for her son's defence. There was an effort to get more money, as the attorney's letters, which the mother forwarded, plainly evidenced. Our patient knew this, but it suited his purpose to make charges against state officials, because these charges received attention. To charge lawyers with getting money from his mother by misrepresenting the case would avail him nothing. People would laugh at that. May I requote a few significant lines to " Dear Dave," who resented being drawn on in favor of the Boston lawyer? " I verily believe," H. J. B. writes, " you would rather fight than eat and your bickering with me, your own client, is proof to me that you are a very eccentric attorney in some small matters, but with all thy faults I love thee still." This illustrates our patient's cleverness at cajolery and counts against paranoia, because a sense of humor is almost as rare to the paranoiac as a sense of honor is to the moral imbecile. It is difficult to conceive of a true paranoiac " jollying " another about anything.

The more we studied our patient, the more it seemed to be true that his mistrust of every one — his " delusions " if you please — were not the delusions of psycho-pathology, but rather false beliefs based on his peculiar experiences and his own self-consciousness. He had little knowledge of the reactions of an honest man's mind. The altruistic sense and the sense of honor were rudimentary, but these are the products of man's higher evolution and are probably rudimentary in most habitual and instinctive criminals. The primordial instincts of self-preservation and love of offspring seemed fairly developed, albeit his faulty judgments and ignorance of men and institutions as they are made his foolish pertinacity in wrongdoing seem suicidal. Read " Hard Cash," by Charles Reade. he would urge, in defence of his ideas. " Hard Cash " had apparently shaped our patient's beliefs and destiny in more than one sense. After we had studied H. J. B. for more than three months, I advised that he be returned to the prison from which he was committed. He was accordingly returned to prison, as per Section 101, Chap. 225, of the Revised Laws of Massachusetts, and held for about seven months, during which time there was no essential change in his condition. Early in December his mother came from England and was allowed to take her son, as his minimum sentence had expired. We were informed by the prison physician that his mother insisted to H. J. B. that she had all the legal knowledge necessary to free him and would not allow him to talk. " She was the only mortal able to control him in this respect," the physician added. It was understood that his mother proposed taking our hero to South Africa. The inference was not that the talented mother bore malice against that unhappy land, — rather that no indictment stood against our sometime patient there.

" If this man should kill some one would you hold him responsible? " was pertinently asked

by a physician whom I advised of my purpose to recommend the return of H. J. B. to prison. Being persuaded that there was no pathological condition present that would compel him to commit a homicide, I would hold him responsible as I would hold another weak-minded brother responsible. Not absolutely responsible, in a moral sense, nor entirely irresponsible, as the man suffering from brain disease, but sufficiently responsible to be kept in prison. Too much responsible to be allowed to prey on the truly insane. It is true that graded responsibility is debatable in medicine and not recognized by the courts, but we are not entirely responsible for the defects of the courts. The natural instinct of civilized man is to save life — his own first, then others. This order may even be reversed, in the highest types, in favor of the nearest and dearest by ties of blood. So it is that the instinct to kill is against nature and raises the presumption of psycho-pathology. The acquisitive instinct, on the other hand, is according to nature, and an exaggeration of this instinct is presumptive evidence only of moral deficiency, even to the making of a " common and notorious thief." We do not know that H. J. B. had any impulse to kill or do bodily injury to any one. His mother's testimony was to the contrary. Moral imbeciles are often exceedingly cruel and enjoy beating, cutting and killing for its own sake or for the sexual frenzy excited most intensely, — so to speak, — by the taste or smell of blood. Dr. Howard's heroine (?) Mizpra [3] was considered entirely irresponsible, possibly so from a purely academic viewpoint. It is doubtful if the courts would support the contention, and practical psychiatry might classify the case as not amendable by hospital methods. It was very clever of the author, therefore, to have Mizpra hurled into a yawning abyss before she reached an insane asylum.

To glance again at the mother's analysis of H. J. B.'s case, is it not reasonable to assume that the man's objective mind was in abeyance, that the subjective mind held supreme sway, forcing the individual on in his irrational course " as fatally as the moth flies in the flame "? Was his oft-declared purpose to fight his enemies in the courts — to " pursue them with the dog whip of the law and hang them on the gibbet of public opinion," a manifestation of the " one grim resolve, the *idée fixé* of the monomaniac "? Concerning the subjective mind hypothesis, a review of much of Thomas Hudson's [4] dual mind thesis would be needed for an adequate consideration of this phase of the subject. I will only observe that if the " subjective mind " is identical with an immortal soul, as Hudson holds, and is responsible for the atrocious acts of some persons on this planet, then the ancient theological conception of an unquenchable lake of burning brimstone seems to have a justification. As to our patient's passion for litigation being the fixed idea of a monomaniac, much more might be said than time will allow. A love of litigation may be but a manifestation of a quarrelsome disposition which, unfortunately, is not limited to the insane. So far as it is an evidence of insanity, it points to imbecility quite as much as to paranoia. The same may be said of inordinate vanity and love of notoriety which is nourished by the publicity of the courts. H. J. B. might have engaged and discharged a dozen lawyers while in prison for the mere love and excitement of it. It is probable that he did not intend to pay any one of them, except by promises or bogus drafts. Experience had taught him that letters to lawyers and state officials were forwarded. He was a forceful writer and a ready talker and loved to do both. Most of all he longed to get into court to show off his talents before newspaper reporters and a crowd. When pressed on cross examination, concerning the false charges he was reiterating against the prison officials, he once declared doggedly, " A man has a right to defend himself." This was the key to many of his " delusions," — created for a purpose. He believed all men to be dishonest tricksters, — this was a natural subjective reflection, — and he was doubtless disgusted to find so many lawyers who did not think as he did. Life in " Cherry Hill" was rather monotonous; why shouldn't he keep on engaging attorneys till he found one of his own kind, who would help him into court or get his letters published in the sensational newspapers? He was stubborn and opinionated — like many weak-minded men, and some others. His little knowledge of the law puffed him up and made him intolerant of advice, but he was not dominated by " one grim purpose." On the contrary, he was vacillating as most men, at least. To-day he knew his wife was true and loyal; to-morrow he was sure she could not be trusted in anything. This week he was willing to follow the advice of his mother and attorney Fishacher; the next week his only reliable legal adviser was the Boston attorney who was paid by drafts on the lawyer in New York. It does not seem wise to generalize broadly about these mentally inferior and morally perverted ones. Each case must be decided on its own merits. One might strongly defend the postulate that all instinctive and incorrigible criminals are insane, but practical considerations would forbid that these mingle with those suffering from brain disease. Indeed, the doctrine of limited responsibility is not incompatible with the administration of a modern humanely managed prison, and it ought to be known that the isolation building for incorrigibles called " Cherry Hill," at Charlestown, has very large rooms, larger than any single rooms I know of in an insane hospital, well ventilated and well lighted through the roof, with good plumbing, running water and a good bed in each room. Humanity has a right to expect similar provisions in each penal institution, for the line of demarkation between sanity and insanity is particularly shadowy in the criminal classes and it is better that asylum features be introduced into prisons than that the hospital and asylum standards should be lowered by prison necessities.

I would express the opinion, in closing, that the committing physicians were fully justified in giving H. J. B. the benefit of every doubt. They were supported, too, in the diagnosis of "litigious paranoia" by the teachings of some of the best authorities. My specified and implied reasons against the diagnosis run through this essay. I will only repeat that while paranoia and constitutional inferiority with moral perversion (moral imbecility) have much in common, may indeed be well called "first cousins," they ought to be separated clinically as readily as hereditary ataxia and locomotor ataxia are recognized as distinct disease forms. The parallel would not hold as to anatomical pathology, because these spinal degenerations have a clearly defined and well-known pathology, but that paranoia is a veritable psychical disease entity is evidenced by its distinct and fairly uniform stadia. It is essentially progressive, even though chronic, characterized by systematized delusions and hallucinations, especially of hearing, in the majority of cases. The systematic evolution, the distinct period of introspection and depression, followed by a period of delusional exegesis of his own morbid subjectivity, and the hallucinations which may begin to spur him on, followed again by an expansive and ambitious period, with its change of personality, — these are the landmarks by which we may know the true paranoiac. The moral imbecile is not so. He has false beliefs enough, certainly, but they change "with every wind of doctrine," like ordinary weak mortals. He has no period of depressive introspection. What little sense and judgment he has he keeps to the end of the chapter, barring the ordinary wear which all flesh is heir to. It is true that the moral imbecile may be far below the intellectual plane of the paranoiac — the differential diagnosis does not rest on the degree of mental defect. That the imbecile may be so defective as to be wholly irresponsible goes without saying. But call his condition "moral insanity," "the insanity of degenerates" or 'phrenasthenia," if you please, yet, in the absence of substantial evidence of brain disease, the natural criminal product of a neurotic organization and a wrong education hardly fits the legal conception of insanity. When the impulse of the perverted imbecile is towards rape and murder, as it so often is, the common conception of insanity should be strenuously opposed before opening the asylum doors to let the perverted one free, but when inordinate vanity and infantile judgment leads the individual habitually to seek gratification in the publicity of the courts, the hospital physician's duty to society may not necessitate a rigid adherence to medical as against legal conceptions of responsibility.[5] As the morbid man bent on suicide by hanging hardly ever shoots himself, so the imbecile seeking gratification through the courts rarely gratifies his unreasoning anger by personal violence to the object of his spite. Therefore it is that the weak-minded litigationist may be less harmful at large than among the insane, — than among other insane, if you choose to have it so expressed.

NOTE. — Several weeks after this paper was written, and less than five months after our hero was released on parole from the State Prison, letters began to come from H. J. B. from New York City, — registered letters, some of them, — notifying the asylum officials that legal proceedings were about to be begun for the release of several inmates of the Massachusetts State Asylum for Insane Criminals. Letters came from other counsellors at law in the same tone and spirit, giving notice of legal proceedings about to begin, "having been retained by Mr. H. J. B., etc." From these letters and other sources we learned that H. J. B. was "highly prosperous," "working night and day," "employing several lawyers," "supported by the most prominent people in our city (New York) who speak in the highest terms of his (H. J. B.'s) indomitable business acumen, responsibility and strict honesty." One of these assistant counsellors at law, H. J. B.'s "brave legal warrior," "dear Dave," subsequently came on from New York City, demanding to see certain patients in the name of H. J. B. and the Constitution of the United States. "Dear Dave" brought two baskets of fruit to asylum patients who had been wheedled out of their small supplies of delicacies for the benefit and promised favor of H.J.B., then "under duress," when he should have his "enemies" (?) figuratively on their knees before him. I wish to record this because it seems, on its face, an honest act and a promise kept. So far as it goes it indicates sincerity, and any evidence of sincerity, considered in relation to H. J. B.'s history, would strengthen the hypothesis of insanity. It seems that H. J. B. did not go to South Africa. His mother, we understand, settled the indictments against him in New York and there is evidence that his "indomitable business acumen" has been exercised on as high a plane as the "promoting" and "floating" of the "Iowa Pacific Railway" and the "International Cable Co."

[5] Peterson's brief and flexible definition of insanity — as good as any — reads, "Insanity is a manifestation in language or conduct of disease or defect of the brain."

Clinical Department.

DOUBLE CHOPART AMPUTATION.

BY CHARLES A. POWERS, M.D., DENVER, COLO.,

Surgeon to St. Luke's Hospital, Denver.

THE Chopart amputation has not borne a very good reputation. Its status in this country is expressed by Bryant,[1] who says:

"This operation is objectionable on account of the liability of the stump to become extended, causing the patient to walk on the cicatrix at the anterior extremity. The division of the

[1] Operative Surgery, Vol. I, Third edition, 1899, p. 449.

tendo Achillis during or subsequent to the operation is practiced to counteract this tendency, but frequently without permanent success. If the stump be confined in a flexed position during the healing, and for a time afterward, there is less danger of this annoying sequel. No preventive expedient addressed to this sequel has as yet afforded the patient practical immunity. The operation cannot be recommended as a substitute for those that are to follow in point of comfort and usefulness. Better service is secured with an artificial appliance after the Syme amputation than after Chopart's."

Such an opinion by a surgeon of the mature judgment and wide experience of Bryant must carry great weight. In England Jacobson and Steward [2] say, " The value of the operation has been a good deal disputed." The following objections have been raised to it:

(1) That the tendo Achillis, no longer counterbalanced by the extensor muscles, which have not lost their attachment, draws up the heel, tilting down the scar, which now becomes tender and irritable. (2) In the normal foot the weight of the body is transmitted through the astragalus to the other bones of the tarsus and metatarsus. When, as in this amputation, these bones have been removed the weight of the body tends to thrust forward the astragalus, no longer supported by the elastic bones in front, against the scar and thus renders this tender and crippling. The above objections apply to the operation performed for injury or disease, the next to amputation for the latter only. (3) If the operation be made use of in caries, this disease is likely to recur in the two bones left. In answer to the first two of the above objections it may be said that this tendency to tilting upwards of the heel and downwards of the scar may be met: (*a*) By stitching the anterior tendons — *e. g.*, tibialis anticus, extensor proprius pollicis, and some of the tendons of the extensor communis — into the tissues of the sole-flap with stout carbolized silk or chromic gut, so as to give them a fixed point by which they may counterbalance the tendo Achillis; (*b*) by cutting the plantar flap sufficiently long, and securing firm primary union; (*c*) by division of the tendo Achillis. (This, however, is only of fugitive value); (*d*) wearing a wedge-shaped pad in the boot; (*e*) preserving the scaphoid, when sound, so as to retain the attachment of the tibialis posticus."

Mr. Jacobson attributes the stitching of the anterior tendons into the tissues of the sole-flap to Mr. Delegarde of Exeter. He says that until it is more frequently made use of and a larger number of cases are collected the value of this amputation must remain somewhat undecided. He had taken this precaution of stitching the anterior tendons on five occasions and says that the stumps proved sound and useful.

As a minor contribution to the subject the following case is reported. Three years have

[2] The Operations of Surgery, Vol. ii, 1902, p. 713.

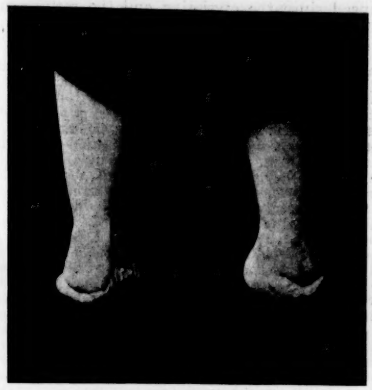

Fig. 1. Condition three years after operation.

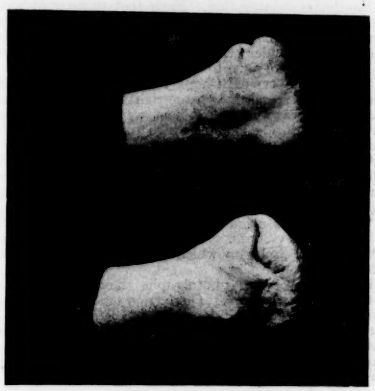

Fig. 2. Showing voluntary dorsal flexion.

Fig. 3. Showing voluntary plantar flexion.

elapsed since the operation and the result may be considered permanent.

Mrs. M., a woman of twenty-seven years, came under my care in March, 1900. She had been caught in a mountain blizzard one month before and obliged to remain all night in a deserted shanty; as a result both feet were frozen. When I saw her each foot was the seat of dry gangrene to a point a little behind the middle of the metatarsus. The gangrenous portion was black, the line of demarcation was well-formed, the two sides were nearly symmetrical. The tissue above the line of demarcation seemed to be healthy on each side.

Double amputation under ether at St. Luke's Hospital, March 17, 1900. On the right side disarticulation was made between the os calcis and scaphoid behind and the cuboid and cuneiform bones in front because here the anterior surface of the scaphoid was but slightly in advance of the anterior surface of the os calcis. On the left side there seemed to be a little more healthy tissue, so disarticulation was made between the cuboid and outer two metatarsal bones, sawing through the three cuneiform bones on a level with the anterior surface of the cuboid. On each side the tendo Achillis was divided and on the left side the anterior tendons were sewn to the face of the stump with chromicized catgut.

On each side the soft parts were divided pretty close to the line of demarcation. Each foot underwent moderate suppuration. On the right sides the flaps proved insufficient and the tarsal bones to the medio-tarsal joint were removed under ether ten days later. The anterior tendons were here sewn to the face of the stump.

This made a typical Chopart amputation on the left side and an atypical one on the right side where the scaphoid bone was left. Both feet were kept in marked dorsi-flexion during healing which took place largely by granulation.

At the end of five weeks both wounds were firm and a little later the patient began to get about, being instructed to massage and move the ankles morning and night. There was no posterior contraction. At the end of three months, aided by a cane she could walk fairly well in ordinary shoes. A little later she was provided with artificial limbs on which she gets about very well indeed.

The accompanying photographs show the condition at the end of two years. There is no tendency whatever to equinus. Voluntary dorsal flexion is excellent. Motion has somewhat increased during the past year. Function on the side on which the scaphoid was preserved is no better than in the stump from which it was removed.

I have no doubt that this woman's locomotion is easier than it would be with amputation at a higher point. She is pretty fat and is obliged to work about the house all day in caring for a large family of small children. She tells me that she can go up and down stairs pretty easily and that she can walk a long distance without fatigue.

On two other occasions I have made a single Chopart amputation. Neither case was followed long enough to judge of the end result, though in each instance the condition was satisfactory when the patient passed from observation. I believe that when the operation is made with a division of the tendo Achillis, suture of the anterior tendons to the face of the stump and placing of the remnant of the foot in marked dorsal flexion with careful attention to this position during healing, together with massage and ankle movements, especially those of dorsal flexion, afterward, the result in most instances should be as good as that presented here.

Medical Progress.

PROGRESS IN PATHOLOGY.

BY JOSEPH H. PRATT, M.D., BOSTON.

THE ETIOLOGY OF LEUKEMIA.

WALZ [1] has prepared a critical review of 223 articles upon leukemia which were published between 1894 and 1902. The section devoted to the etiology of the disease is especially interesting. The rapid course which acute leukemia runs certainly resembles that of an infectious disease. The tonsilitis which frequently accompanies acute leukemia or the ulcers in the intestine, described first by Askanazy,[2] might well serve as portals of entry for the infectious agent. Walz states that Cabot [3] has reported a case of apparently direct transmission of the disease from patient to nurse, and there is a similar oft-cited observation by Obrastzow.

Bacteriological studies and the earlier inoculation experiments yielded negative results. But by means of special staining methods Löwit [4] has demonstrated peculiar bodies in the blood resembling protozoa which he regards as the cause of the disease. He further supports his claim by the artificial production in animals of a disease resembling leukemia. As a specific stain he uses thionin, followed by Lugol's solution. In his latest paper Löwit [5] recommends that the blood be spread with a needle, as the leucocytes are injured when too thin a film is made.

Löwit found what he claims to be an ameba within the lymphocytes (*Hemameba leucemia magna*). In lymphatic leukemia he found metachromatic bodies. They were present in only two cases in the peripheral blood, but more frequently in the blood-forming organs. These also he regards as amebæ (*Hemameba leucemia parva sive vivax*). He describes with both hemamebæ various stages in the life-cycle — young parasites, crescent, sporulation and degeneration forms.

The views of Löwit have found a number of strong opponents, the most aggressive of whom is Türk,[6] who asserts that Löwit's bodies are artefacts derived from mast cell granules, and that he was able to produce forms not distinguishable from Löwit's parasites in non-leukemic blood. Vittadini [7] is the only one who claims to have confirmed Löwit's findings.

Pinkus [8] thinks it is questionable whether the bodies, even if they occurred exclusively in leukemic blood, are the cause of the disease, since *Hemameba magna* has been found in a case of lymphatic leukemia, and furthermore, in myclogenous leukemia the so-called parasites are not in

the myelocytes, but in the lymphocytes, which are the least characteristic cells in this form of the disease.

Türk has never succeeded in transmitting leukemia to animals. He states that the disease produced in rabbits by Löwit has nothing to do with myelogenous leukemia, as the same disease-picture can be produced by inoculating portions of organs from individuals that have died of other diseases. Türk asserts that *Hemameba parva* is nothing more than the nucleolus of the lymphocyte.

UNDIFFERENTIATED LYMPHOID CELLS IN MYELOGENOUS LEUKEMIA.

In every case of myelogenous leukemia the blood contains non-granular cells with a small amount of protoplasm. These cells are present in considerable number and are generally looked upon as lymphocytes. L. Michaelis,[9] however, regards them as undifferentiated lymphoid cells. They cannot be distinguished morphologically from lymphocytes. The undifferentiated lymphoid cells by further development become transformed into neutrophilic myelocytes, while the lymphocytes are adult cells. The undifferentiated lymphoid cell differs from Benda's myelogenic cell in that the former develops not only in the bone marrow but in other tissues.

Michaelis supports his view by a remarkable case of disease of the blood-forming organs which came under his observation. The total number of leucocytes in the peripheral circulation was only slightly increased, but 76% of the cells were lymphocytes and 7% myelocytes. The patient died after an illness of three months. The lymph-nodes were not swollen. The spleen was very large and soft and weighed 2,000 grams. The bone marrow was red and consisted almost entirely of lymphocytes and giant-cells. The spleen had the same histological structure.

LYMPHATIC LEUKEMIA WITHOUT ENLARGEMENT OF THE LYMPH NODES.

A careful histological study by Reed [10] supports the view of Walz and Pappenheim that in every case of leukemia the primary seat of the disease is in the bone marrow. The old theory that lymphatic leukemia is essentially a disease of the lymph nodes is still supported by Ehrlich. He bases his claim on the assertion that no lymphocytes occur normally in the bone marrow. This statement the writer calls in question, as in the bone marrow cells are found identical morphologically with the lymphocyte. There is no proof that the lymphocytes of the blood come from the lymph glands alone, and although it cannot be stated positively that they arise in the bone-marrow it is known that all other colorless cells of the adult blood originate in the bone marrow from lymphoid cells and that cells identical morphologically with the lymphocytes of the blood are found there.

The case upon which this study was based ran a rapid course. Hemorrhages, anemia and progressive weakness were the chief clinical features. A thorough study of the blood was not made during life. At autopsy neither spleen nor lymph nodes were enlarged. The bone marrow of the femur was homogeneous, a deep red and very soft. Microscopically the bone marrow consisted chiefly of lymphoid elements. The predominating cell was smaller than the red blood corpuscle and possessed a densely staining homogeneous round nucleus, and a small amount of clear protoplasm. There was another type of lymphoid cells varying in size which possessed a nucleus relatively large in respect to its protoplasm. The nucleus always showed a definite chromatin network. The cell is identical in structure with the lymphocytes of the blood of the lymph nodes. There was no indication of hyperplasia in either the spleen or lymph nodes.

This case is not unique. Six similar ones have been recorded within the last few years, and authorities are now nearly agreed that in lymphatic leukemia the blood changes do not occur until the bone marrow is involved. The writer states that no case of leukemia has come to autopsy in which the bone marrow was normal.

If leukemia is always a disease of the bone marrow it is manifestly incorrect to restrict the term myelogenous to one form of the disease. The writer suggests a new clinical classification based upon the blood picture. Three forms of leukemia are recognized, all due to myelogenous changes: the myelocytic, the lymphoid and the mixed cell varieties. Leukemia resembles an infectious disease. Possibly in leukemia a positive chemotaxis exerted by some poison in the body draws out certain cells from the bone marrow into the blood.

Reed has apparently overlooked the case of lymphatic leukemia reported by Dennig [11] from Liebermeister's clinic in which there was no swelling of the spleen or lymph-nodes and the bone marrow showed no microscopic alterations.

Blumer and Gordinier [12] studied a case of lymphatic leukemia of at least a year's duration in which the lymph nodes were not enlarged. The clinical picture was that of pernicious anemia. As in the similar cases of lymphatic leukemia without enlargement of the lymph nodes reported by Pappenheim and Reed, the striking feature of the pathological examination was the marked lymphoid change in the marrow of the long bones.

The predominating cell of the blood, although resembling the normal lymphocyte, presented points of difference of which the most important was the acidophilic character of its protoplasm. The writers regard this prevailing type of cell as identical with the predominating cell in Reed's case. They are inclined to accept the theory of Rubinstein that both lymphocytes and erythrocytes originate from a colorless mother cell in the bone marrow, and they regard the predominating white cell in the blood of their case as this mother cell. Arrest of development of this mother or ancestral cell would explain both the anemia and

[9] Zeitschr. für klin. Med., 1902, xlv, p. 86.

[12] Medical News, 1903, lxxxiii, p. 833.

the lack of typical lymphocytes noted in their case.

The writers hold that lymphocytes in adults are formed normally both in the lymph nodes and in the bone marrow. Theoretically, therefore, it would be possible to have lymphatic leukemia as a result of disease of the bone marrow, or of the lymph nodes, or of both. When lymphatic leukemia is of the ordinary type, that is, with enlargement of the lymph nodes, an increase of the typical lymphocyte occurs, whereas in the cases without enlargement of the lymph nodes the predominating cell differs from the ordinary lymphocyte and is formed in the bone marrow.

MYELOGENOUS LEUKEMIA WITH UNUSUAL FEATURES.

Ehrlich has asserted that in every case of myelogenous leukemia there is an increase of the absolute number of eosinophiles and this increase of eosinophiles is of great diagnostic value. This doctrine of Ehrlich has been repeatedly but unsuccessfully attacked. Simon,[13] however, reports a case in which throughout the course of the disease the eosinophiles were absent from the blood. He could find no similar observation in the literature, and he met with but one instance of leukemia in which the total number of eosinophiles was not increased.

The blood picture in Simon's case was remarkable in other respects. The percentage of mast cells was small, and early in the disease the absolute number was low. This is interesting in view of Ehrlich's doctrine that the mast cells show an absolute increase in all cases of myelogenous leukemia and that this increase of mast cells is of even greater diagnostic importance than the increase of eosinophiles. Shortly before death, however, the total number of mast cells became markedly increased.

Until near the end of the disease there was only slight enlargement of the spleen, and the total number of leucocytes scarcely exceeded the physiological limit. Myelocytes were present in the blood and the number increased with the advance of the disease. During the last six months of illness myelocytes formed from 30 to 50% of the leucocytes. This case and the one reported by L. Michaelis illustrate the fact that the appearance in the blood of myelocytes rather than an increase in the total number of leucocytes is the characteristic feature of the disease. Shortly before death the leucocyte count rose to 116,000.

Large mononuclear cells devoid of granules and distinctly different from the large mononuclear leucocytes of the blood appeared in large number toward the end of the illness when no less than 54% of all the leucocytes belonged to this type. Nägeli claims that these cells are found in the blood in every case of myelogenous leukemia and he noted also that they may in the later stages of the disease form the predominating leucocyte in the blood. Nägeli regards them as specific bone marrow cells and the antecedents of Ehrlich's myelocytes. For the study of the mononuclear non-granular elements in the blood the eosinate of methylene blue should be used, as Ehrlich's triple stain does not differentiate the lymphoid cells.

Reports of Societies.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

TWENTIETH ANNUAL MEETING, HELD AT WASHINGTON, D. C., MAY 12–14, 1903.

THE President, DR. NORMAN BRIDGE of Los Angeles, in the chair. Sixty-five members of the association were in attendance. The President in his opening address called attention to some of the dangers and duties of the association. First of all we usually make our generalizations, as to the effects of climate, by its apparent influence on the newcomer sick, rather than on the permanent resident population. This subjects us to several possibilities of error. The effects witnessed in the bodies of sojourners in a new climate might be fairly attributed to the influence of the latter if other things were equal, but other things never are equal or nearly so, nor can they be, and every one of these invalid newcomers is under conditions and subject to manifold influences that are markedly different from those that obtained at his home where the invalidism began. Dr. Bridge characterized the melancholy migration of patients hopelessly ill of tuberculosis to some distant and famous climate as one of the greatest tragedies of modern times. After citing three cases in which the unfortunate patient was sent thousands of miles for a climate when death was evidently near, Dr. Bridge discussed the border line cases in which there is a fair question as to the use of climatic treatment. We have created a widespread popular belief in certain curative effects of climate — those effects exist, but only for patients who still have fair physiologic forces, and it is our duty to try to prevent a blind faith in their power to raise the dead.

DR. SAMUEL A. FISK read

SOME NOTES ON NASSAU,

founded on a three months' residence during the past winter at that port. The picture of Nassau, as he witnessed it, was summer land in winter, roses in January, muslin gowns at Christmas, doors and windows open day and night, almost constant sunshine, snow and slush eliminated. It is reached by steamer in three and a half days from New York, or 160 miles from Miami, Fla. The island is about twice the size of Nantucket. The soil is dry, and rain does not stand in puddles. It is of coral formation, white lime rock, which can be quarried with the saw. There are more days of clear sunshine than the meteorological records indicate, as observations are taken only at 8 A.M. and 8 P.M. Thunder showers are rare

in winter. The effect of this tropical climate on any one from the latitude of New York is somewhat enervating and suggests the onset of malaria. Proper regulation of diet, exercise and arrangement of clothing goes far to mitigate the depression experienced at first. It does not do to eat and drink as one may in a colder climate. There is a disposition to do very little, and this little must not be done at mid-day. There is no sewer system and, for the most part, the privies are insufficient and inconvenient. The mainland supplies most of the food for tourists. Ice is manufactured at the hotels, but the town generally is supplied with ice from Maine. Milk is very expensive. Drinking water is obtained from cisterns, which collect the rain water or from wells which are impregnated with lime. Golf and bicycling are possible, but the climate does not favor the necessary activity. Piazza life is the main feature. There are commodious hotels with modern conveniences. This station is suitable for persons with Bright's disease, diabetes, neurasthenia and insomnia. The climate is unsuited for cases of tuberculosis. Nassau is soothing, not bracing; as a sanatorium for winter alone the Bahamas are, beyond all question, superior to any other health resort on the eastern coast of North America.

Dr. Guy Hinsdale presenfed a paper entitled

IMPRESSIONS OF CALIFORNIA RESORTS.

The paper was based on the experiences in connection with the recent visit of the association to California. Climatic details of Northern California, particularly in the vicinity of Mount Shasta, were given. The climate of San Francisco, Palo Alto, Santa Cruz, Monterey, Santa Barbara and other important stations was described. Dr. Hinsdale believes that sanatoria for tuberculous patients should be erected on the higher elevations on the Shasta route, at San Luis Obispo and Santa Barbara, excellent institutions having been already instituted at more southerly stations.

Dr. R. H. Babcock of Chicago read a paper entitled

SOME FURTHER REMARKS AND QUERIES CONCERNING THE INFLUENCE OF ALTITUDE ON HEART DISEASE.

Dr. Babcock mentioned three cases of mitral stenosis which were able to endure an altitude of 6,000 feet without discomfort; also a female without previously recognized disease of the heart who yet experienced an acute disturbance, which disappeared soon after reaching a lower level. A report of a minor who developed precordial pain and tachycardia after considerable exertion was given, his symptoms becoming relieved at the level of Chicago. Brief allusion was made to the development of uremic symptoms in some cases of chronic nephritis at the altitude of Denver. In chronic nephritis are symptoms referable to lowering of blood pressure or to increased metabolic activity? In the case of the miner, were the symptoms due to cardiac overstrain and not to the altitude *per se?* Could the effects in the other cases, good or bad, be attributed to lowered blood pressure incident to low atmospheric pressure? Or can any case of cardiac disease endure a moderately high altitude after having refrained from exercise until becoming acclimated? A consideration which seems to argue against a person's tolerance or intolerance of moderate altitude being due to the blood-pressure lies in the generally accepted statement that the pulse of the consumptive is one of low tension, and yet most of such patients are able to endure residence in Colorado at a mile or so elevation without serious cardiac embarrassment. Dr. Babcock showed that the danger of travel and residence at an altitude appears to be really greater in the case of apparently healthy hearts, since such individuals are likely to overdo and, therefore, get up a condition of cardiac overstrain, and that in all cases it is not so much the altitude itself which is to be feared as the ease with which the heart may be overstrained in the mountains. This strain is not due so much to the altitude as it is to the fact that in the higher regions the surface of the ground is uneven and hilly.

Dr. DeLancey Rochester of Buffalo read a paper on

THE ROLE OF LOCAL SANATORIA IN PREVENTING THE SPREAD OF TUBERCULOSIS.

Assuming that the best results in the treatment of this disease are obtained in closed sanatoria, and that patients once cured are no longer foci from which the disease can spread, the author advocated the establishment in every community of two sanatoria, one for advanced and one for incipient cases. This is necessary, because the treatment of the two classes of cases is decidedly different, and also because the constant presence of advanced cases and the occasional painful death of one or more patients have a decidedly depressing influence on the incipient cases. Dr. Rochester advocated compulsory notification in tuberculosis, and also the power to remove patients to the sanatorium for the good of the community.

Dr. Vincent Y. Bowditch of Boston read a paper on

SUBSEQUENT HISTORIES OF SEVENTY-NINE ARRESTED CASES TREATED AT THE SHARON SANITARIUM FROM 1891 TO 1902.

The results were obtained in a climate thought to be most unfavorable for consumptives, not far from the sea coast, and at an altitude of 200 to 300 feet above sea level. This sanitarium and that of Dr. Millet at East Bridgewater Mass., are under similar conditions in this respect, but the latter is for more well-to-do patients. During the eleven years in which the Sharon Sanitarium has been in existence, 182 patients have been treated. Of these, 18 are excluded, because they remained but a few days or were not cases of tuberculosis. Of the remaining

164 cases, 79 were recorded as arrested. Of these 79 there have died since leaving the institution after varying periods of comparative health only 12 persons, or 15.2%. These cases were all analyzed and the causes of death reported.

Among other cases reported as recovered was a woman who came in 1893 with tubercle bacilli and disease of the right lung. After fourteen months she left the sanitarium "a magnificent specimen of health, her cough having ceased several months before." She has remained perfectly well ever since — nine years; this result is a brilliant example of what can be done in a changeable, harsh climate not far from sea level. Dr. Bowditch believes, however, that in a better climate still better results, in general, will be obtained.

DR. E. O. OTIS of Boston read a paper on

DISPENSARIES FOR TUBERCULOSIS, WITH A DESCRIPTION OF THE TUBERCULOSIS DEPARTMENT OF THE BOSTON DISPENSARY.

After describing English and French dispensaries, and advocating special dispensaries for tuberculosis, an account was given of the Boston Dispensary. This affords treatment to all classes of patients, the daily visitors numbering from 250 to 300 and occasionally approaching 500. The department for the tuberculous is in the same building, and this arrangement provides an easy examination of the throat, ear, eye or other organ when desired. The clinic lasts from two to three hours daily. The sputum is examined and a report given at the time of the visit. The tuberculin test is employed successfully in out-patients and x-ray diagnosis is used. The routine examination covers every possible feature of a tuberculous case. The Boston Dispensary divides the city into districts and sends a physician daily, one for each district, to all cases of sickness among those who are too poor to pay a physician and are unable to visit the dispensary. Accompanying each physician is a trained nurse furnished by the Instructive District Nursing Association, a most valuable adjunct to the medical supervision. Food, if needed, is supplied from a diet kitchen. Patients in the incipient stage are sent to the State Hospital for Consumptives at Rutland, and for the destitute means are provided to pay the sum required, viz., $4 weekly. In many advanced cases admission is secured at the innumerable little boarding houses near Rutland, which have sprung up about the great sanitarium. In Boston notification in tuberculosis is compulsory. The dispensary also examines, when desired, patients who have been discharged from the Rutland Sanitarium or have taken the open air cure elsewhere. The dispensary affords clinical instruction to students and physicians in the examination of tuberculous patients.

DISCUSSION.

DR. LEONARD WEBER of New York thought that an effort should be made in all of the large cities, and particularly in New York, to equip dispensaries with every facility for the early diagnosis and treatment of tuberculosis, and that this object would be best obtained in the manner brought out by Dr. Otis' paper.

DR. DELANCEY ROCHESTER. I have been very much interested in Dr. Otis' statement regarding the dispensary treatment for pulmonary tuberculosis in Boston, for I made a very bad failure of an attempt to establish such a thing at home. The men who were in charge of the general medical clinic simply wouldn't stand for a clinic for tuberculosis alone, and we had great difficulty, in fact we absolutely failed, in establishing such a clinic. I see that, according to Dr. Otis' statement, he has enlarged his clinic to one for diseases of the lungs in order to finally accomplish the purpose.

DR. FREDERICK I. KNIGHT. Referring to the advent of the district nurse, I desire to state that any one who has visited the homes of the poor people since the introduction of the visiting nurse will agree in feeling that her visits to the homes of these patients is going to bring about great good.

DR. JUDSON DALAND. I wish to express my appreciation of Dr. Otis' paper, and to thank him for bringing out so thoroughly the uses to which a special dispensary service for this disease may be put, and more especially for his suggestions regarding the care of the patients so far as food is concerned. If we could put aside sufficient money for proper equipments, these cases that cannot go to sanatoria could be kept under close supervision, and I am perfectly certain that an enormous amount of good could be accomplished.

DR. J. E. STUBBERT of New York read a paper entitled

TENT LIFE FOR CONSUMPTIVES.

The results of sleeping in the open air were noted, and arrangements for moving the beds from the patients' room to a balcony or projecting the head of the bed through low windows were commented on. Dr. Stubbert advocated tent life as better suited to the majority of cases, and said that two tent colonies will be established during the summer at Liberty, New York, under his supervision. One for the richer patients is located on the side of a mountain, and is arranged in camps. The tents are large, with compartments for living room, toilet, etc. There will be sanitary plumbing and special attention to drainage. The camp will have telephone connections and other conveniences. The other camp is an extension of a boarding house, in connection with which individual tents for sleeping and living are rented. The expense in the latter camp is ten dollars weekly.

DR. FREDERICK I. KNIGHT. The economy of tents must be considered, which means that the air space and the facilities for its proper exchange will be limited, and I am therefore of

the opinion that barracks or cabins would serve the purpose much better. I am free to confess that the air in the few tents which I have been in seemed to me the worst possible for a consumptive to live in, and especially would this be true when artificial heating is necessary.

Dr. Samuel A. Fisk. I wish to endorse strongly the position taken in this matter with regard to the great necessity for fresh air. I think that the other considerations are of minor importance. The main thing that we are striving for is to provide an ample amount of fresh air and sunlight, and the kind of tent to be used is another thing. Food is likewise of prime importance. I know from my own experience on the frontier that persons can live in tents in mid-winter, and I know from living in a tent myself that when one has become accustomed to tent-life, and has lived and slept in a tent, he does not care to live in anything else.

Dr. J. Edward Stubbert. I agree with Dr. Knight in the statement regarding the poor ventilation often found in tents, but in citing that fact we must not overlook the other side of the question, namely, that the ventilation of the rooms in the majority of cases is much inferior to that found in the ordinary tent. I think the point that a person who has once lived in a tent will live in nothing else is true.

(To be continued.)

Recent Literature.

The Diagnosis of Surgical Diseases. By Dr. E. Albert, late Director and Professor of the First Surgical Clinic at the University of Vienna. Authorized translation from the eighth edition. By Robert T. Frank, A.M., M.D. 419 pages and 53 illustrations. New York: D. Appleton and Co. 1902.

This book is intended to present to practitioners and students the problems in diagnosis which actually confront them at the bedside. The subjects treated comprise only a part of the surgical lesions usually found in textbooks. They are the lesions of the different portions of the body which have especially attracted the attention of the writer in this connection. They are grouped according to their similarity of symptoms and points of general resemblance. In this way the advantages of clinical teaching are most nearly attained and by the presentation of a large number of clinical cases the value of this plan is further enhanced. Also, as the translator states, the fragmentary and disconnected instruction of clinical demonstrations, even under the most favorable circumstances, is more systematized. The subsequent reports of cases post-operative, and at times post-mortem, in confirmation or correction of diagnosis, is of great additional value to this system. It is unusual to meet a treatise on surgical diagnosis which is not an enumeration of a list of possible diseases, or in other words a systematic pathological-anatomical classification of surgical diseases. This latter method is not a characteristic feature of the present work. The author was a veteran teacher and a clinician of great experience. The wide circulation of the book in Europe is proof of the favor it has found there. The volume in a way suggests to one that classic of Milton's "Rest and Pain."

From the above description, however, one must not expect to find an ideal "up-to-date" treatise in this work. For since its author left it surgical science has advanced and new means of diagnosis have developed, *e. g.*, radiography, which are not herein described. Taken as a whole, however, the book has much to commend it and will both interest and instruct its readers.

Operative Surgery, by Herbert Wm. Allingham, F.R.C.S., Surgeon of the Household of His Majesty the King; Surgeon in Ordinary to His Royal Highness the Prince of Wales; Senior Assistant Surgeon and Lecturer on Operative Surgery at St. George's Hospital; Consulting Surgeon to the Surgical Aid Society; Late Surgeon to the Great Northern Hospital; Late Assistant Surgeon to St. Mark's Hospital for Diseases of the Rectum. New York: William Wood & Company. 1903.

This book consists of a brief account of the leading features of an operation. The author has tried to give memoranda which would serve to emphasize the important points concerning many operations and has given many hints which are based on his personal experience. The book has the distinct advantage of being a small volume and will serve as a useful guide to practitioners who desire to look up an operation.

The Practical Medicine Series of Year Books. Volume VII. Pediatrics, edited by Isaac A. Abt, M.D., Assistant Professor of Medicine (Pediatrics Department), Rush Medical College; Orthopedic Surgery, edited by John Ridlon, A.M., M.D., Professor of Orthopedic Surgery, Northwestern University Medical School. June, 1903. Chicago: The Year Book Publishers.

This little work gives a fairly complete review of the pediatric and orthopedic literature of the past year The abstracts are, as a rule, good. In some cases, however, they are not very clear: the wrong impression is given, or the relative values are not properly defined. The editor's notes are valuable.

Modern Materia Medica and Therapeutics. By A. A. Stevens, A.M., M.D., Lecturer on Physical Diagnosis in the University of Pennsylvania, etc. Third edition, entirely rewritten. W. B. Saunders & Co. 1903.

This is primarily a textbook and suitable chiefly for students. It does not differ essentially from many others of its class.

The Surgical Treatment of Gastric and Duodenal Ulcers. By B. G. A. MOYNIHAN, M.S. (Lond.) F. R. C. S. (Eng.), Senior Assistant Surgeon, Leeds General Infirmary, etc., etc. Illustrated. Philadelphia and New York: W. B. Saunders & Co. 1903.

This brochure of 83 pages is devoted to a discussion of the author's personal experience in the operative treatment of simple ulcer of the stomach and duodenum and includes a tabulation of his operative work.

The subject has been classified and considered as: (1) Perforation of Gastric and Duodenal Ulcers; (2) Hemorrhage; (3) Chronic Ulcer; (4) Hour-glass Stomach.

The work is well known, and the substance of the volume has already been presented to the profession through the reports of Mr. Moynihan's paper read at the meeting of the American Surgical Association in May, 1903. His views on this important subject are now available in a convenient form for those interested in this branch of surgery. The operative technique of his method of gastro-enterostomy is well described and illustrated. The tabulation of his clinical work is interesting and instructive, the date, age, sex, a résumé of the clinical history, the character of the operation, the condition found and finally the result, with the author's remarks being systematically and concisely given in each case. His paper was one which has attracted much attention.

The Office Treatment of Rectal Diseases. By RUFUS D. MASON, M.D., Professor of Rectal and Pelvic Surgery in the John A. Creighton Medical College, Surgeon to St. Joseph Hospital, etc., etc. Illustrated. Second edition. Lincoln, Neb.: The Review Press. 1902.

The author's description of this little book of 125 pages is that it is not intended to take the place of larger works devoted to this subject, but that it shall supplement them and cover many points that have been omitted and that it gives details which he as a teacher and specialist by many years of practical experience has found valuable. Diagnosis is very briefly discussed. Etiology, pathology, anatomy, vague theories and major operations are omitted. Treatment mainly is presented to the reader and in the most terse, practical manner possible.

The special conditions discussed are Constipation, Hemorrhoids, Abcess, Fistula, Ulceration, Prolapse and Cancer. The concluding chapters are devoted to rectal examination for life insurance and local anesthesia. The book is written in that bright, positive, concise style that is always attractive and which makes the reader feel after its perusal that henceforth the treatment of this class of disease will be simple and successful. This effect is apparently due to the fact that the description of methods of treatment form the greater part of the work and that only successful methods of treatment are presented.

The book certainly does, as its author claims, supplement other more complete treatises. It contains many valuable suggestions and practical details of treatment.

Surgical Emergencies; The Surgery of the Head. By BAYARD HOLMES, B.S., M.D., Professor of Surgery in the University of Illinois, etc. New York: D. Appleton & Co. 1903.

This book of 569 pages is one of a series describing the every-day surgery of the human body. The surgery of the eye, ear and other well-established specialties are not considered. The plan of the work is based on the author's experience in teaching surgery, and consultation work with many practitioners. In the Table of Contents one notes Congenital Malformations, Injuries to the Head and Face, Fractures of the Skull and Cerebral Injuries and Abscess, Otitis Media and its Brain Complications, Epilepsy, Meningitis, Diseases of the Parotid, Neuralgia, Tumors of the Face and Skull, Brain Tumors, Surgical Diseases of the Orbit, Cancer of the Tongue and other similar lesions. At the beginning of each chapter the subject described is defined, classified, its variations stated and concrete examples of the more important conditions requiring surgical attention enumerated. Care is taken to avoid undue prominence or emphasis of unusual conditions, but those of common occurrence are thoroughly discussed. Those unusual, but of such a character as to require immediate relief, are considered. Finally are described those conditions of uncommon occurrence, but of great theoretical importance. The writer has tried by a variety of means, graphic and otherwise, to present the different subjects in such a vivid manner that the impression on the reader is both distinct and permanent. Pathology, diagnosis and the " proper " methods of treatment are taught

Dr. Holmes believes that anatomy and pathology are best studied by inspection of actual specimens. That a subject should be studied from textbooks, the current literature relating to it, and carefully reported clinical observations of actual cases. The subjects treated in this volume are rather the emergencies of the average physician than those of the professional surgeon. The book is somewhat fragmentary, but the plan on which it is written has many features which are attractive and commend it. It contains much of interest and value. It is illustrated by nintey wood cuts and fourteen colored plates, some of which are quite instructive.

A Compend of Diseases of the Skin. By JAY F. SCHAMBERG. Third edition, revised and enlarged, with 106 illustrations. Philadelphia: P. Blakiston's Son & Co. 1903.

The third edition of this " Quiz-compend " has just been published. The text has been carefully re-read and various additions and revisions made.

THE BOSTON

Medical and Surgical Journal

THURSDAY, DECEMBER 17, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 Bromfield Street, Boston, Mass.

SCARLET FEVER.

At a meeting of the Boston Society of Medical Sciences held in the Harvard Medical School, Dec. 15, 1903, Dr. F. B. Mallory presented a paper on certain protozoön-like bodies which he had found in the skin in four cases of scarlet fever.

The bodies may be divided into two groups, of which the first comprises a series of sharply defined bodies varying in size from about two to seven microns in diameter. They are composed of a granular, finely meshed reticulum and frequently contain one or more vacuoles. The second group consists of radiate bodies varying in size from four to six microns in diameter. They contain a central body around which is arranged a varying number of segments (10 to 18), which in the earlier forms are merely indicated, but in the later forms are sharply defined laterally from each other. At a still later stage the segments are separated from each other but are still grouped more or less closely around the free central body.

The bodies of the first group stain lightly but sharply with methylene blue in the eosin-methylene blue method after fixation in Zenker's fluid. In the radiate bodies, or rosettes, however, the central body and the peripheral parts of the segments stain deeply with the same color.

The bodies of both groups occur in vacuoles in the epithelial cells of the epidermis, between these cells, and free in the superficial lymph vessels and spaces of the corium, but nowhere else.

It is difficult to explain these bodies as artefacts or as degenerations. On the other hand they closely resemble the different stages in the asexual development (schizogony) of the malarial parasites, but they are about twice as large as the latter when compared with them under similar conditions of fixation and staining.

It is impossible at present to say much in regard to the distribution of these bodies until favorable cases can be obtained for post mortem examination and the skin from various parts be carefully studied. In three cases dying within forty-eight hours after the first appearance of the eruption the bodies were numerous in two cases and few in the third, while in a case dying on the ninth day of the eruption occasional bodies could still be found. In all four cases the amount of skin saved for examination was very small. In bits of skin from several other early cases no bodies could be found.

In a recent paper Hektoen[1] places scarlet fever at the head of the list of those diseases of which the cause is absolutely unknown. The discovery of these peculiar and characteristic bodies in the skin of four cases may prove to be the first step in the unraveling of the cause of this disease.

Dr. Mallory concluded with the statement that while he personally believes that these bodies are protozoa and have an etiological relation to scarlet fever, he is far from claiming that such a relation has been proved.

The paper was illustrated with a microscope demonstration of sections of the skin and with a series of colored drawings and of lantern slide preparations of the scarlet fever bodies. For the sake of comparison a series of lantern slides of segmenting malarial parasites in fresh blood, and in the blood vessels of the brain and other organs from a fatal case of malaria, was also shown.

SANITARY SUPERVISION OF PUBLIC WATER SUPPLIES A PROTECTION TO PUBLIC HEALTH.

There can be no question that money invested in sanitary measures intended for the protection of the public health, and the consequent saving of human life, is well invested, and in the long run will yield profitable returns. Too often does it happen that the truth of the old proverb, "When the steed is stolen shut the stable door," is recognized only too late to prevent serious illness and loss of human life.

This principle is frequently illustrated in the indifference of many communities to the importance of providing every possible means of protection for public drinking water supplies.

[1] Hektoen. Recent Investigations Bearing on Infectious Diseases of Unknown Etiology. Journ. of the Am. Med. Ass'n, 1903, vol. xli, p. 405.

In Pennsylvania the people have paid dearly for this wanton neglect, as shown in the long-continued pollution of the water supply of Philadelphia, and the serious outbreaks of disease which have taken place at Plymouth and at Butler.

In Massachusetts the question of water pollution has been a subject of frequent discussion by legislatures, medical societies and social organizations for a third of a century, the result being the enactment of a general statute in 1886 placing all public water supplies under the supervision of the State Board of Health. Under the provisions of this act the work of introducing new supplies and of improving those already existing has gone rapidly forward until, at the present time, over 90% of the population of the state is supplied with public water, mostly of good and wholesome quality.

A valuable index of the purity of the water supplied to a community is the amount of typhoid fever prevalent among the people thus supplied, as shown either by the mean annual number of cases, or of deaths from this disease as compared with the existing population.

In Massachusetts during the years preceding the general introduction of public water supplies, for example, the ten years 1856–65, the death rate from typhoid fever throughout the state was high, at 9 or 10 out of each 10,000 inhabitants, but since such introduction it has rapidly fallen until in the last year (1902) the death rate from this cause was not over 2 per 10,000, or less than one-fourth of its former rate.

In the report of the State Board of Health for 1896 a diagram is published in which the death rate from typhoid fever and the percentage of persons not supplied with public water are shown in two parallel and descending lines, which are nearly coincident throughout the period of forty years. It is among this class of persons not supplied with public water that typhoid fever is most prevalent. What may be properly termed epidemics of such illness appear to be a thing of the past in Massachsetts. When, therefore, a limited outbreak occurs like that which was reported in Lowell in September last, or the occurrence of a dozen or more cases at Williamstown, public suspicion is unduly aroused, since even these limited outbreaks are of rare occurrence.

In Pennsylvania, however, the outbreak at Butler has assumed a seriously epidemic form, since here there were 1,200 cases in a population of 18,000, or more than 7%, a ratio exceeding any that have occurred in Massachusetts in recent years at least thirty-fold, and this is only a repetition of the severe epidemic which proved so disastrous at Plymouth in Pennsylvania a few years earlier. Recent advices from Butler show that the probable cause of the epidemic in that town was due to the existence of cases of typhoid fever upon the watershed of the public supply at a time when repairs were being made in the filtering plant, which allowed unfiltered water to be supplied to the inhabitants.

In the state of Vermont, with less than 350,000 inhabitants, the Legislature appropriates $10,000 a year for the use of its State Board of Health, while the Legislature of Pennsylvania, a state having a population of 6,000,000, makes a niggardly appropriation of $6,000 for all sanitary purposes.

In Massachusetts liberal provision is made for special work in the protection of the purity of public water supplies, and the State Board of Health is given general supervision of this work. By this means the Board is enabled to assume a careful oversight of all the water supplies in the state, both those of municipalities and those of private corporations. It makes regular and systematic examinations of the waters, provides rules and regulations for the sanitary protection of such supplies, gives advice to the authorities of cities and towns, gives warning of impending danger from pollution and from lead poisoning, and by these means affords a protection the value of which is far beyond the amount expended in carrying out the provisions of the law.

HARVARD OARSMEN.

DR. GEORGE L. MEYLAN of Columbia University recently read a paper before the Boston Physical Education Society on the subject, "The Study of Harvard University Oarsmen from 1852 to 1892, Inclusive." The general result of his very careful investigation was that certainly no injury is done to the individual by the exercise of rowing, even in races, which taxes physical endurance to the extremest limit. He found that during the forty years under investigation there had been 152 "varsity" oarsmen, of whom 32 had died. He was able to obtain interviews or get direct information regarding the remaining 120.

It was found in the first place that these men gave an insurance risk averaging seven and one-half years more than among ordinary persons. As regards general health, they were found to be

decidedly above the average. Nor were they found in any case wanting when studied by statistical tests. Only one of the 120 men thought that he might have been injured by college rowing, but the evidence even in his case was by no means conclusive that this was the fact. On the intellectual side it furthermore appears that the oarsmen have in general been successful in life, and on the whole have obtained more distinction than students generally, or even men belonging to the Phi Beta Kappa society.

Interesting as these observations are, it must be borne in mind that the men under discussion are picked individuals, who would not have been chosen as representative oarsmen had they not at the outset had unusual health. It must also be borne in mind that the publicity given athletes in various ways must be regarded as an element, at least, in their future worldly success. Admitting, however, this possibility of error, it is a matter of great interest, amply borne out by Dr. Meylan's investigation, that violent athletic sport does not seriously impair the constitution in later life, as sometimes stated. Investigations of this nature should certainly be prosecuted with relation to other violent forms of exercise, since by these means alone may we arrive at a fairly exact knowledge of the benefit or injury of modern athleticism.

MEDICAL NOTES.

A Five-year Medical Course. — The College of Physicians and Surgeons of the Province of Quebec is reported to have recently decided to lengthen the medical course to five years and furthermore voted that British licenses should no longer be recognized in that province. A more complete preliminary education as represented by the B.A. degree was also advocated for students of medicine.

Italian Hospital at Orange, N. J. — At a meeting held on Nov. 22, at Orange, N. J., a movement was set on foot for the establishment in that place of an Italian hospital, under the auspices of the Roman Catholic Church. It is proposed to rent a temporary building at once, and later to erect a substantial hospital building with complete modern appointments.

Remarkable Case of Skin Grafting. — A successful case which has attracted much attention has just been discharged from the Muhlenberg Hospital at Plainfield, N. J. The patient, who was chief clerk in the New York office of the United States Express Company, was one of the victims of the wreck on the New Jersey Central Railroad at Westfield last winter, and has been undergoing treatment since Jan. 27. He was scalded so severely with steam that one-third of the cuticle was destroyed. His case was at first regarded as entirely hopeless, but after he had lingered for several days it was determined to attempt skin grafting. The method of Thiersch was adopted, and over 4,200 grafts were employed, the material for which was generously furnished by two hundred Masonic brothers and employees of the express company.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Dec. 16, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 44, scarlatina 31, typhoid fever 12, measles 151, smallpox 0.

Compulsory Vaccination again Upheld. — It is stated that recently another claimant for damages because of compulsory vaccination has been non-suited in the Boston courts.

NEW YORK.

Report of Board of Health. — On Dec. 9 the President of the Board of Health transmitted to Mayor Low the report of the Department for the year 1902. In it, it is stated that the death-rate fell to 18.75 per thousand, as compared with 20 in 1901 and 20.57 in 1900. The total number of deaths was 68,085, as against 70,722 in 1901 and 70,872 in 1900. In the mortality from diarrheal diseases in children under two years of age there was a decrease of 858 from the preceding year. The death-rate in the section corresponding to the former City of New York (at present the Boroughs of Manhattan and the Bronx) was 19.49, which figure was not approached since 1814, when the low death-rate of 19.60 was recorded. In Brooklyn the death-rate, 17.88, is believed to be the lowest ever recorded, with the exception of the year 1866.

A Centenarian. — Isaac Mitnitsky died in the Williamsburgh District of Brooklyn, N. Y., on Nov. 28, at the reputed age of 109 years. He was born in Moscow, Russia, and the year of his birth, 1794, the family affirms, is recorded in the official records of that city. He did not come to this country until he was 92 years old, and since then he has made the journey back to Russia no less than four times.

DECISION IN FAVOR OF A HOSPITAL. — In an action brought by Mary H. Rice against Vassar Brothers' Hospital, Poughkeepsie, to recover $5,000 damages for injuries received by falling on the defendant's sidewalk, Judge Samuel T. Maddox, in the Supreme Court at Poughkeepsie on Nov. 24, non-suited the plaintiff on the ground that a charitable corporation is not liable for damages alleged to have been due to the negligence of the trustees. The decision was made on the application of the attorneys for the hospital, who brought forward the claim that to make a trust fund liable for damages might defeat the purpose of the trust by so depleting the funds as to make them inadequate.

DEATHS FROM VEHICLES. — Police Commissioner Greene has made public a statement in which he claims that the number of persons killed by vehicles in the streets of New York during 1902, 538, which was published a short time since, is too large. The correct figure, he says, is 375, and his statistics show that 172 deaths were caused by street cars, 146 by trucks, wagons, etc., 9 by automobiles, 7 by runaway horses and 2 by bicycles, while in 29 the exact cause was not reported. In his statement General Greene expressed the opinion that in order to reduce this evil there should be a more vigorous enforcement of the speed ordinances, and also the meting out of more adequate punishment to offenders.

AN APPEAL TO VANITY. — Last year 125,000 persons availed themselves of the privileges afforded by the permanent public baths, but of that number only 16,052 were women and girls. The Association for Improving the Condition of the Poor came to the conclusion that something would have to be done to increase the attendance of the latter, and after mature deliberation it was determined that an appeal to personal vanity would be more effective than one for the public welfare. Accordingly cards are now being handed out by agents of the society to girls and women in the neighborhood of the baths which bear this inscription: " For a soft, rosy complexion, a quick, graceful walk, and a healthy appetite, try a shower bath twice a week."

VACCINATION OF PUBLIC SCHOOL CHILDREN. — The Appellate Division of the New York Supreme Court for the Second Department, sitting in Brooklyn, handed down a decision on Nov. 20, upholding the constitutionality of the statute enforcing the vaccination of public school children. The decision was given in the case of Edmund C. Viemeister of the borough of Queens, who sought to compel the Board of Education and the principal of Public School No. 12 in Queens to admit his child to school, admission having been denied because the child had not been vaccinated. It was urged on behalf of Viemeister that the statute was void, being contrary to the provisions of the Constitution. In the prevailing opinion Justice Woodward declares that the statute does not violate the Constitution, as it operates equally upon every person who is or may desire to become a pupil in the public schools, and affords equal protection to all. He then adds: " However willing we might be to agree with the appellant that the practice of vaccination is attended with dangers, and that its efficacy is a matter of uncertainty, these are matters which should be properly addressed to the legislative department, rather than to the courts." Justice Hirschberg also wrote an opinion sustaining the statute, declaring that it constituted a legitimate exercise of the police power of the state.

Miscellany.

RETIREMENT OF DR. EDWARD COWLES FROM THE McLEAN HOSPITAL.

AT a meeting of the Trustees of the Massachusetts General Hospital, held on Friday, Dec. 11, 1903, the following votes relating to the retirement of Dr. Edward Cowles of the McLean Hospital were placed upon their records:

Voted: That the Trustees of the Massachusetts General Hospital, in grateful recognition of the long and successful administration of the McLean Hospital by Dr. Cowles, place this minute upon their records. Dr. Cowles entered the service of the Hospital as Superintendent of the McLean Asylum on Dec. 11, 1879, and is the first of its officers to take advantage of the scheme of retiring allowances adopted by this Board on July 14, 1903. He came to the institution a well-trained and successful hospital administrator. During the twenty-four years of his devoted and efficient service the Asylum has been transformed into a hospital; the attractive and admirably planned establishment at Waverly has taken the place of the unsatisfactory and outworn quarters at Somerville; valuable researches into the nature and treatment of the most terrible of human ailments have been made; and improvements in the care of the insane have been made possible by the knowledge so acquired. At all times he has been the patient and persuasive advisor of the Board and its trusted and efficient agent.

Voted: That a Board of Consulting Physicians for the McLean Hospital is hereby created.

Voted: That Dr. Edward Cowles be appointed a member of the Board of Consulting Physicians for the McLean Hospital.

Correspondence.

NOTE ON THE USE OF THE FLUOROMETER TO ESTIMATE THE PROPORTIONS OF BETA AND GAMMA RAYS GIVEN OFF FROM RADIUM SALTS.

BOSTON, Dec. 11, 1903.

MR. EDITOR: In the fluorometer described in the third edition of "The Roentgen Rays in Medicine and Surgery," pages 640 to 642, the fluorescence of a specimen of radium is used as a standard with which to compare the fluorescence produced by different vacuum tubes on a tungstate of calcium screen. The fluorescence which a specimen of radium may excite on a tungstate of calcium or on a barium platino-cyanide screen may also be used as a standard, but this method was not chosen because these screens might deteriorate by continuous excitation, especially the barium platino-cyanide screen. To compare the fluorescence produced by different specimens of radium or by the different rays emitted by a given specimen of radium, the fluorescence excited on the barium platino-cyanide screen of the fluorometer by the radium may be a more convenient standard than the fluorescence of the radium itself.

Recently, in order to compare the amount of fluorescence produced by a specimen of radium chloride of about 7,000 activity, contained in a glass tube, with a specimen of pure radium bromide, I placed the first specimen below and in contact with one part of a barium platino-cyanide screen and the specimen of pure radium bromide below the other portion of the screen, the first part of the screen spoken of being protected from the rays of the pure radium by a sheet of lead placed below the radium of 7,000 activity. Experiment showed that in order to have the two portions of the screen equally brilliant, it was necessary to hold the screen 4½ inches (11.25 cm.) from the pure radium bromide. If, however, the Beta rays given off by this specimen of radium were cut off by interposing a plate of aluminum of suitable thickness between it and the screen the two portions of the screen were equally illuminated when the screen was held 1 inch (2.5 cm.) from the radium bromide. Judging by this experiment it would seem that the Gamma rays of pure radium bromide were only about one-twentieth as abundant as the Beta rays. I did not attempt to estimate the amount of Alpha rays; they were presumably cut off by the mica covering of the metal box which contained the radium bromide. This mica may have cut off also some of the Beta rays. I determined the thickness of the aluminum plate necessary for cutting off the Beta rays by first deviating them by a magnet and then interposing successive sheets of aluminum until no fluorescence was produced on a screen; this thickness of aluminum did not diminish to any noticeable extent the Gamma rays.

To diminish even slightly the Gamma rays I found it was necessary to interpose in their path an aluminum plate about five times as thick as that required to cut off the Beta rays so that for the purposes of the practitioner the thickness of aluminum about one-seventh of an inch, which cut off the Beta rays completely, would not affect the Gamma rays.

I am not studying the therapeutic effects produced by the Beta and Gamma rays together, on the one hand, and the Gamma rays alone, on the other. Thus far my observations indicate that healing can be produced in both ways, but if the Beta and Gamma rays are both used there is much more danger of a burn than if the Gamma rays are used alone. I am investigating this subject with a view to determining the method that should be followed in order to obtain the most good with the least danger to the patient. At present, however, I merely desire to direct attention to a method of estimating the amount of these rays given off by radium.

Very truly yours,
FRANCIS H. WILLIAMS.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, DEC. 5, 1903.

Deaths reported, 3,111; under five years of age, 792; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 677, acute lung diseases 546, consumption 343, scarlet fever 30, whooping cough 6, cerebrospinal meningitis 5, smallpox 16, erysipelas 6, puerperal fever 5, measles 10, typhoid fever 50, diarrheal diseases 87, diphtheria and croup 119.

From whooping cough, Chicago, Baltimore, Boston, Fall River, Lawrence and Holyoke 1 each. From smallpox, New York 1, Philadelphia 15. From cerebrospinal meningitis, New York 3, Somerville 2.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Nov. 21 the death-rate was 17.4. Deaths reported, 5,037; acute diseases of the respiratory organs (London) 165, whooping cough 59, diphtheria 73, measles 106, smallpox 2, scarlet fever 46.

The death-rate ranged from 7.1 in East Ham to 29.3 in York. London 16.6, West Ham 16.6, Brighton 9.6, Southampton 9.5, Plymouth 24.7, Bristol 15.5, Birmingham 20.6, Leicester 16.8, Nottingham 15.7, Liverpool 20.1, Bolton 15.9, Manchester 18.7, Salford 22.3, Bradford 18.8, Leeds 18.5, Hull 17.5, Cardiff 17.8, Rhondda 18.3, Merthyr Tydfil 21.8, Hornsay 9.3, Warrington 21.2.

METEOROLOGICAL REGORD.

For the week ending Dec. 5, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING DEC. 10, 1903.

BROOKS, S. D., surgeon. To proceed to Brunswick, Ga., and assume temporary command of station. Dec. 8, 1903.

MCMULLEN, JOHN, passed assistant surgeon. Relieved from duty at Hongkong, China, and directed to proceed to San Francisco, Cal., and report arrival by wire. Dec. 3, 1903.

PARKER, H. B., passed assistant surgeon. To proceed to New York, N. Y., and report to Surgeon G. W. Stoner, Immigration Depot, for duty. Dec. 7, 1903.

WHITE, M. J., passed assistant surgeon. Relieved from duty at Honolulu, T. H., and directed to proceed to Hongkong, China, for duty. Dec. 2, 1903.

RICHARDSON, T. F., assistant surgeon. Granted leave of absence for seven days from Dec. 6, 1903, under paragraph 191 of the regulations.

AMESSE, J. W., assistant surgeon. To proceed to Seattle, Wash., and assume command of the service at that port. Dec. 5, 1903. Granted leave of absence for one day. Dec. 5, 1903.

BERRY, T. D., assistant surgeon. Detailed as inspector of unserviceable property at Cleveland, Ohio. Dec. 5, 1903. To proceed to Cairo, Ill., and assume temporary command of service at that port during absence of Surgeon G. M. Guiteras. Dec. 10, 1903.

EBERSOLE, R. E., assistant surgeon. Relieved from duty at Gulf quarantine station, and directed to proceed to Tampa Bay quarantine station and assume command. Dec. 7, 1903.

EBERT, H. G., assistant surgeon. Granted leave of absence for four days from Nov. 28, 1903, under paragraph 191 of the regulations.

SMITH, E. G., assistant surgeon. To proceed to Santa Clara, N. Y., for special temporary duty to examine aliens. Dec. 10, 1903.

BREADY, J. E., acting assistant surgeon. Granted leave of absence for two days from Dec. 15. Dec. 8, 1903.

GREGORY, G. A., acting assistant surgeon. Granted leave of absence for seven days from Dec. 5. Dec. 4, 1903.

RYDER, L. W., pharmacist. Granted leave of absence for fifteen days from Dec. 10. Dec. 9, 1903.

CASUALTY.

Acting Assistant Surgeon Hugh Burford died at Brunswick, Georgia, Dec. 7, 1903.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING DEC. 12, 1903.

W. M. WHEELER, surgeon. Ordered to the Navy Yard, Puget Sound, Washington, and also on board the "Nipsic."

J. C. THOMPSON, P. A. Surgeon. Detached from the Navy Yard, Puget Sound, Washington, and ordered to the "Albatross."

C. S. BUTLER, assistant surgeon. Detached from the "Albatross" and ordered home to wait orders.

C. S. PECK, assistant surgeon. Detached from the "Iris" and ordered home to wait orders.

H. T. PERCY, surgeon. Detached from the "Indiana" and ordered to the "Iowa."

P. F. JENNESS, assistant surgeon. Detached from the "Indiana" and ordered to the "Iowa."

C. D. W. BROWNELL, surgeon. Ordered to the "Amphitrite," with additional duty at the Naval Station, Guantanamo, Cuba.

G. PICKRELL, surgeon. Ordered to additional duty in charge of the Naval Hospital, San Juan, P. R.

W. N. MCDONNELL, acting assistant surgeon. Detached from the Naval Academy and ordered to the "Glacier."

SOCIETY NOTICE.

LECTURES ON ALCOHOL AND OPIUM INEBRIETY.—Dr. T. D. Crothers of Hartford, Conn., Prof. of Mental and Nervous Diseases at the New York School of Clinical Medicine, will deliver a course of four lectures on "Inebriety from Alcohol, Opium and other Narcotics," Jan. 5th and 6th, 1904, at 4 P. M. and 8 P. M., in the hall of this school, 328 West Forty-second street, between 8th and 9th Ave., New York City. The public are cordially invited to attend.

M. STERN, M.D., Secretary.

THE next meeting of The New England Hospital Medical Society will be held at Hotel Nottingham, Dec. 17, 1903. The scientific programme is—"The Mutation Theory" by Dr. H. E. Lothrop.—"Modern Bacteriological Methods" by Dr. M. E. V. Frazer. Report of a case by Dr. E. C. Upham. Presentation of specimens by Dr. Mabel Austin.

MARION NUTE, M.D., Secretary *pro tem.*
32 Mill St., Dorchester.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT—A meeting of the society will be held in Sprague Hall, Medical Library Building, on Monday, Dec. 21st, at 8.15 P. M. Papers—Dr. George G. Sears will read a paper on Prognosis in Acute Pleuritis. Dr. Robert W. Lovett will read on the Treatment of Severe Cases of Lateral Curvature. Discussion by Dr. Bradford and Dr. Goldthwait.

ARTHUR K. STONE, M.D., Secretary,
543 Boylston St.

THE HENRY PHIPPS INSTITUTE LECTURES.

THE third lecture in the course established by the Henry Phipps Institute will be given in the auditorium of the Witherspoon Hall, Philadelphia, on Tuesday, Dec. 29th, at 8.30 o'clock P. M., by Dr. G. Sims Woodhead, Professor of Pathology at Cambridge University, England. Subject "The Paths of Infection in Tuberculosis." This lecture will be illustrated by slides projected on a screen. The profession, in general, is cordially invited. A reception to Professor Woodhead will follow the lecture.

MAZYCK P. RAVEALL, Assistant Medical Director.

RECENT DEATHS.

EDWARD FRIDENBERG, M.D., of New York, a well-known specialist in diseases of the eye and ear, died on Dec. 9, from cerebral apoplexy. He was born in New York City in 1855, and was graduated from the College of Physicians and Surgeons in 1878. He served as interne at the Charity Hospital, Blackwell's Island, and was afterwards on the medical staff of Mount Sinai Hospital. Later he spent a considerable time in Germany in the study of ophthalmology and otology. He was formerly President of the Harlem Medical Association and at the time of his death was ophthalmic and aural surgeon to the German Hospital and Dispensary.

ELISHA HALL BRIDGES, M.D., of Ogdensburg, St. Lawrence County, N. Y., one of the leading physicians in the northern part of the state, died from acute Bright's disease on Dec. 9, at the age of sixty-two years.

WILLIAM H. HOLMES, M.D., for many years a prominent physician and surgeon of Orange, N. J., died recently from chronic kidney and heart disease. He was sixty-nine years old and during the Civil War he served as an assistant surgeon in the navy.

BOOKS AND PAMPHLETS RECEIVED.

Quiz-Compends, No. 19. Compend of Diseases of the Ear, Nose and Throat. By John Johnson Kyle, B.S., M.D. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1903.

A Non-Surgical Treatise on Diseases of the Prostate Gland and Adnexa. By George Whitefield Overall, A.B., M.D. Illustrated. Chicago: Rowe Publishing Co., 1903.

Elements of Surgical Diagnosis. By A. Pearce Gould, M.S. (Lond.), F.R.C.S. (Eng.). Third Edition. Revised and enlarged. Chicago: W. T. Keener & Co. 1903.

Address.

THE RESPONSIBILITY OF THE MEDICAL EXAMINER.[1]

BY HERBERT PARKER, ESQ.,

Attorney-General of the State of Massachusetts.

Mr. President and Gentlemen of the Society:

He who addresses medical examiners has need to speak carefully, even ingratiatingly; he must appeal to your kind consideration, for it is certain that to the medical examiner, of all men, we must look for the truth to be spoken of us, after we are dead; and there is grave significance in this.

You have probably, you younger medical examiners, examined the statute to see the material origin of your authority. You older men have long since forgotten to look for any such assurance as statutory authority because you draw it now, rightfully, from your experience. You would have been surprised to find that the statutes of the medical examiner are different than what you have found with relation to the appointment of any other executive judicial examiner of the Commonwealth.

You will learn, have learned, to your great satisfaction, that the requirements for your appointment as medical examiners are, first, that you shall be discreet men, and second, that you shall be profoundly learned in the science of medicine. It is to this field of your responsibility that I would call your attention now.

You are assumed to be, and you must be, discreet men before you are qualified to enter on the discharge of duties of the most profound importance to the community. You stand, gentlemen, upon that debatable ground over which there hangs always something of the atmosphere and shadow of doubt. The line between the medical and legal profession is the line between the medical and legal issue.

Only as you are enlightened by profound learning, only as you are guided by soundest discretion, can you pass upon the first and vital question of your requirements. I say that these questions are of profound importance to the community, for they concern not only the public interest that involves inquiry into the perpetration of the possible crime, but here again is the grave responsibility that rests upon every physician to whom of necessity is entrusted the tenderest care of the sentiments of numerous persons with whom you are concerned.

You are called by some hysterical neighbor or friend to come and view the body of some one suddenly stricken to death. The frightened relatives or neighbors know not from what source that bolt came, from where it fell. They know only that for the moment they stand awe-stricken in the presence of the awful mystery of death. You, gentlemen, are required to preserve, in that atmosphere of doubt and alarm and excitement, the full possession of your mental faculties. It may be that what we human beings call accident caused that death. It may be that there was some lesion of some organ when the death occurred. We can no more tell than we can tell what causes the lofty trees of the forest to fall, and you can hear the plaint and fierce ravages that shall come and tear the forests. It may be that death came from that source, and we know who alone is to be invoked for such source. It may be that death came from violence — and I use violence in its statutory sense; not that some blow was stricken and death followed, but that violence that means intervention of some power, — whether death came from a sudden incisive blow, or the instantaneous effects of a poison perhaps caused that death. In either case it is a violent death, and this violent death for your consideration and investigation should be any death not immediately explainable from the surroundings that come to your attention.

Now, then, you have been called upon to consider, maybe, the result of any one of these causes. It may have been caused by the voluntary taking of some poison instigated by the voluntary wish of the victim, so that he or she should be relieved all of a sudden of the anxiety of life.

You will not and you do not, and it is to the eternal credit of your profession and to your personal character that you do not, hastily draw conclusions. You should not hastily draw the conclusion that death was through the voluntary act of the woman or man who has died, for you are to consider the effect of a hastily spoken word of judgment by the physician, upon whose utterance the stricken family and friends and community wait, as they would wait the utterance of an oracle. You are not hastily to conclude that death was caused by suicide, even though it is the easiest avenue through which you can escape from your doubt, for that means, if it be erroneous in its conclusion, that you not only have too hastily passed upon a medical and pathological question, but too hastily you have assumed to judge of the conduct of a fellow human being. And your words are not lightly spoken, for they carry the weight of the learning of your great profession. They carry the weight of that confidence which has come to you through your living and moving and being with and advising those who come to rely upon you.

You are not too hastily to conclude, and you do not, that the death was caused by the lawless act of some other, for the too hasty conclusion upon these lines is a twofold error. It would tend to fix suspicion first, upon some one who does not deserve such suspicion, and it sticks always, and years of righteous living cannot wholly obliterate the stain. It is a double error, because the too hasty conclusion of yours may lead to lines of investigation by the prosecuting officer or officers and they are shut off on other lines of inquiry through which and by which the truth might be ascertained. Far better not to pass upon it until the fullest and most exacting

[1] Address at the Annual Meeting of the Massachusetts Medico-Legal Society, June 9, 1903.

investigation can and shall have been made by you.

The statute requires of you in the performance of your duty what is not ordinarily required of any other officers, because their lines of duty are pretty clearly circumscribed and do not go from one field of inquiry or from one field of responsibility to another; the medical field is one, the judicial another, and so on through the complex departments of our government and administration of government. But you, gentlemen, are required to make, not merely such examination as will enable you to make a report precisely and exactly, as has been made by Dr. Twitchell here to-day, an example of medical precision, in the autopsy of the Bitzer homicide, — and I need not call attention to the other papers which enlighten and which gives me great satisfaction as an officer of the Commonwealth; — in the consummation and the purpose of these inquiries by medical examiners you are required not merely to inquire what the anatomical results are, but the statutes require of you that you shall make examination into the cause and conditions and circumstances concerning the finding of the body, that you are to call the attention of those persons who are supposed to have been in its presence, and who may be there, as to the position in which it lies, all of those things which to your mind may be significant, which explain the mystery which you are investigating.

Now, why are all these things required? They are, first, because of the general responsibility that rests with you by reason of the very subject, by your study and determination. They are further required of you because one of the primary functions of the medical examiner is the investigation of crime and the fixing of guilt where it belongs, and I need not tell you men, who are engaged with us prosecuting officers, that the end of the prosecution of every crime is not simply the fixing of guilt upon the guilty and securing punishment to those who can restore no life. It would be but a futile and discouraging effort that we are making. But this is not the ultimate end of prosecution and investigation of crime. What we seek is, and that is what all law seeks, the protection and security of human life, and every conviction secured righteously, as all must be in our Commonwealth. Every offender who has taken human life, who is apprehended in his crime, should be punished, and must know the power of our law; and the effect on others, who may be likewise tempted, is to know that a certain hand of the law, guided by human agency, will mete out and apprehend, and that the power of punishment is in this law, upon which ultimate security can rest, until by the grace of God and the efforts of men there are changes in the criminal law that have never yet come.

Now, therefore, when you are called to inquire into the death of some one supposed to have died from violence, you are to steady yourselves, bring yourselves into that receptive, responsible state of mind that shall set your every faculty into keenest activity, that shall constantly invoke the senses and ample responsibility that is in you. Be mindful of those whose interests are put into your keeping, the feelings of those who may be cast down by your word, but more than all you are to remember that wherever this ultimate purpose of the criminal law shall be appertained, the protection of human life shall depend upon the closeness of your observation and material opinion, and on the sentiments and inferences that you draw from those conditions, for you all know that the powers of the government first take their form and direction from the intimation that the medical examiner makes from the inferences that he draws from his examination.

Remember that the report on the autopsy that you make may be substantially the only material in which you may rely when the case may turn into a real case of homicide in court. The brain, preserved as this one we have here to-day, may not be brought before the court and jury by the physician, who may be called upon one side or the other to advise the court or the jury. It might all turn on the fact of this demonstration. The vindication of the law may all turn on the accuracy which you may have made and reported in your autopsy. You may have overlooked some detail that only momentarily attracted your attention. It may be that, by passing that door, you have gone by the avenue through which you could have passed very absolutely the question demonstrative of the cause of death.

I am saying to you these things which have occurred to every one of you. I am teaching you nothing. I am speaking to you of these things of which we all are reminded, and for us, we shall never forget that we will not discharge our duty if we suffer ourselves for a moment to be diverted from the absolute concentration on that which lies before us. Inferences one way or the other may be drawn from a statement, not absolutely verified by the autopsy. Or, if you make in your report of your autopsy suggestions that investigation might have made demonstrations rather than suggestions, the true inferences seen in the one case in the other are eliminated. Omit nothing that the closest scrutiny could suggest. Remember that the day is coming, gentlemen, when you are not to be confronted only by those persons who know nothing where you are wholly wise. The laymen who stand about, waiting for what you may tell them, contribute little to what you may tell, but rely on your manifesto. A case occurs, when your every conclusion is going to be disputed, when the inferences of guilt that you have drawn are unfounded. You cannot meet this attack that will be made upon you by counsel and by physicians, whose duty it will be to draw inferences, if there be any reason, differing from those that you have drawn.

The only method is by the absolute certainty so far as anything human can be of your original investigation and your report. It cannot be

met, believe me, gentlemen, by any ingenuity and reasoning, by any manifold duty and resentment of counsel. No ingenuity of convincing or manifold reasoning will permit you to meet this issue that you have got to meet.

Prepare yourselves by assuring yourselves that nothing in suggestion to your brain or mind has escaped this investigation. Then the case will be presented in court beyond a question of dispute of what the autopsy did reveal, leaving only legitimate elimination of the inferences that can be drawn from them.

This is the responsibility of the medical examiner briefly stated by one who is interested as you are in seeing to it that the beneficent purposes of our law, framed in our statutes, find its realization in the courts of justice, which are the places where human injuries manifest themselves, and the effort to make our human system of law follow along so far as we are able, to preserve them, and transform them to the divine law, under which we live and must ultimately go.

Original Articles.

DIFFUSE (COMBINED) DEGENERATION OF THE SPINAL CORD.

BY E. W. TAYLOR, M.D., AND G. A. WATERMAN, M.D., BOSTON.

(From the Department of Neurology, Long Island Hospital, Boston Harbor.)

THE following cases are reported as a further contribution to the subject of the combined lesions of the spinal cord. The confusion in the classification of these cases is still very great, and many further clinical and pathological reports are necessary before a satisfactory basis can be reached.

CASE I. DIFFUSE (COMBINED) DEGENERATION WITHOUT ANEMIA OR OTHER CACHEXIA.

C. G., unmarried, forty-nine years of age, was admitted to the Long Island Hospital June 8, 1901. Nothing of his family history bearing on the present condition was obtained. He had had typhoid fever when a young man and in 1882 syphilis, for which he was treated with apparent success. Since 1888 he had taken alcohol in excess.

About three years before entrance to the hospital he noticed a dull, constant pain which occupied small areas at the front of the abdomen at the level of the umbilicus. He did not notice any pain in his back. He had no nausea. He took medicine which seemed to improve the condition but led to a facial eruption. At the end of a year he was relieved of this pain, but in the summer of 1898 he noticed a cold area about the size of a hand just below both knees. This gradually enlarged and a feeling of numbness supervened in the cold areas. His feet became involved in the sensory disorder and he felt as though "walking on a thick carpet." In the winter of 1899 paresthesia of the legs developed, and his knees felt as though "in a vise." These disorders of sensation involved the legs from below upwards. During this period and up to April, 1900, he was able to walk steadily, whether in light or dark, and had no disorder either with his sight or handwriting. Since that time, however, his eyesight had gradually failed, so that at the time of entrance to the hospital he was wholly unable to read. His fingers had also begun to feel clumsy and cold, but there was no paresthesia or numbness of the arms. His handwriting became much impaired.

In February, 1901, he noticed a feeling of cold which gradually extended from the legs up to the level of the nipple. Up to six months before entrance he was able to walk, then gradually lost power in his legs until they were practically totally helpless. He had no disturbance of deglutition or articulation.

Physical examination showed a poor reaction on the part of the pupils both to light and with accommodation. His vision was poor. He could not count fingers at a distance of ten feet, nor could he read ordinary type. Lungs and heart were normal. A slight fibrillary twitching was noted over the pectoral region and in the muscles of the upper arm. His hand grasp was good, but there was general disturbance of temperature sense over the body and arms. His legs and toes could be moved very slightly. His legs took a semi-flexed position. Knee jerks were very much increased, ankle clonus and Babinski reaction were present. The tactile sense also showed some impairment. Later a marked disturbance in control of the sphincters came on and a certain mental failure became apparent. The Hgb. was 60%, whites, 12,800; reds, 5,284,000.

On June 28, 1901, it was noted that the patient was progressively failing both physically and mentally. He had become emaciated, was dirty in his habits and practically helpless. He died July 8, 1901.

Autopsy (01.71 lv,) by Dr. G. B. Magrath, July 9, 1901, twenty-one hours post mortem. There was slight sclerosis of the coronary arteries and some old fibrous adhesions in the pleural cavities, but beyond this, outside of the nervous system, nothing noteworthy. The brain showed slight edema, weighed 1,300 gms., and there was apparently slight atrophy of the first two frontal convolutions. The arteries at the base of the brain, circle of Willis and the vertebrals, showed a high degree of arteriosclerosis. All the vessels showed alterations of the lumen, irregular thickenings of the walls, and hypertrophy of vessels upon which depended the establishment of collateral circulation. The vertebral arteries were very unequal in size; the continuation of the basilar into the posterior cerebrals was practically interrupted at the bifurcation, the circulation in the distribution of the posterior cerebrals being effected by the posterior communicating

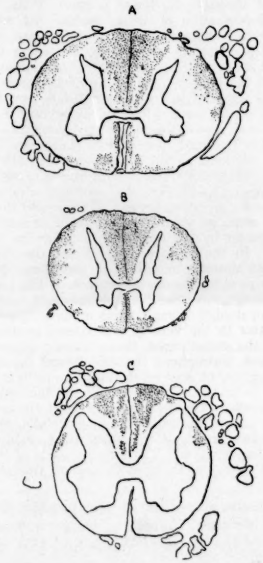

FIG. 1. Case I. A, cervical; B, thoracic; C, lumbar, showing diffuse lesions in a case without anemia. Accurate tracings, Edinger drawing apparatus.

arteries from the middle cerebrals. The communicating arteries were much hypertrophied in consequence. Alterations of the ventral branches of the circle of Willis were less marked, though showing similar changes in the walls to the dorsal branches.

Sectioned frontally, the brain showed, especially in the region of the internal capsules and in the lenticular nuclei, a very marked tendency to the formation of small cysts, most of them less than one mm. in diameter. This condition was much less marked in the white matter and no such cysts were observed in the cortex. The cerebellum gave slight evidence of arteriosclerotic change.

Examination of the spinal cord in gross showed some diffuse degeneration in the dorsal and lateral columns.

Microscopic examination. Sections from the brain cortex, capsule, pons, oblongata, optic nerve and spinal cord were cut and stained by the usual methods. The *cerebral cortex* from the right frontal region and the paracentral lobule showed no striking alterations. The pia varied somewhat in thickness at various points and in places showed considerable infiltration with blood; there was no general atrophy of the cortex, and the blood vessels showed no evidence of endarteriitis, or of hyaline or other degeneration, though the walls were generally thick. The *optic nerves* (Marchi) gave no evidence of myeline degeneration.

The *internal capsule* showed a high degree of general arteriosclerotic change, very much more marked than in the cortex, where the blood vessel lesions, as stated, were slight.

The *pons* was normal except for vascular changes, less in degree than in the capsule, but yet very apparent.

Beyond a very decided thickening of the arterial walls, the *oblongata* presented nothing abnormal. Especially to be noted was the complete absence of the type of degenerative change seen in the cord.

Cord. In general the lesions of the cord corresponded to those frequently described in diffuse, combined degeneration, in being most marked in the cervical and thoracic regions with degenerations in the dorsal, lateral and ventral tracts, and diminishing markedly in the lumbar region with a more definite limitation to the dorsal columns. At a level through the lower portion of the pyramidal crossing degeneration of white matter did not appear. In the cervical enlargement the lesions were pronounced and of characteristic appearance, involving the dorsal columns, particularly in their central portions, the lateral portions of the cord in the regions of the cerebellar tracts and to less degree of the pyramidal tracts, and the area on either side of the ventral fissure but beyond the limits of the uncrossed motor tracts. The degeneration here, as elsewhere in the cord, was of two characters, — a dense neuroglia sclerosis, most evident in the columns of Goll, and a degeneration with small overgrowth of neuroglia and the formation of vacuoles. Fat granule cells were abundant in the degenerating areas.[1] The lesions in the thoracic region were, in general, similar in distribution though slightly greater in extent than in the cervical portions of the cord. In the lumbar enlargement the degeneration was limited almost exclusively to the dorsal tracts, with narrow strips along the dorsal septum. The areas adjoining the dorsal commissure and the root zones spared. There were doubtful small areas of disintegration of the white matter in the ventral and lateral portions of the cord. In the sacral region there were no alterations.

Nerve roots throughout the spinal cord showed no sign of degeneration at any level studied, nor was there evidence of myeline or cell degeneration in the ventral horns.

Blood vessels. The vessels throughout the cord showed in certain places somewhat thickened walls, which could not be shown to stand in causal relationship with the areas of degeneration. The larger vessels of the pia and the ventral artery of the cord showed no alterations.

The essential points in the pathological anatomy of this case, therefore, were marked arteriosclerosis of the circle of Willis and the arteries of the internal portions of the brain — internal capsule; diffuse quasi-systemic degeneration of the cord involving dorsal and lateral tracts, most extreme in the thoracic region; freedom from degeneration of nerve roots and gray matter; these lesions occurring in a patient who had not suffered from pernicious or grave secondary anemia, and who, so far as known, was not the victim of a cachexia of any sort.

The clinical history of this case is sufficiently explained by the pathological alterations. Syphilis and alcohol may have had some bearing on the widespread alterations of the vessels, but cannot be brought into direct causal relation with the main lesions in the cord. The early disturbance of sensibility is in accord with the usual history of these cases, followed by increase of deep reflexes and increasing incoördination, gradually leading to a condition of complete paraplegia. The marked increase of knee jerk in spite of predominant lesions in the dorsal tracts is worthy of mention. Disturbance in vision was, no doubt, due to refractive error rather than to optic nerve atrophy, as shown by the microscopic study of the nerve. The case, in general, is a perfectly typical one of diffuse combined degeneration associated with arteriosclerosis in a person not suffering from pernicious or secondary anemia, or so far as discovered from any other wasting or debilitating disease. It is of interest in comparison with the following case in which pernicious anemia was a conspicuous feature of the clinical picture, and in which similar though somewhat more circumscribed lesions were found, and also as pointing to the fact that this general type of disease may and no doubt frequently does occur as a primary cord lesion, irrespective of accompanying conditions, with which it has usually been associated.

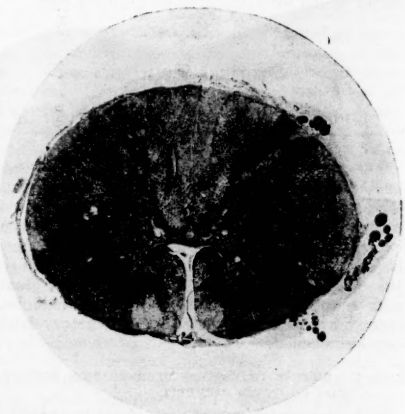

FIG. 2. Case I. Lower cervical region. The diffuse, non-systemic character of the degeneration is evident; areas about ventral fissure suggest focal vascular lesions; nerve roots normal.

[1] For details of this peculiar alteration see Putnam and Taylor: Journ. Nerv. and Ment. Dis., xxviii, 1, 1901. This lesion had also been previously described by others, with a somewhat different interpretation.

CASE II. DIFFUSE (COMBINED) DEGENERATION WITH PERNICIOUS ANEMIA.

H. R. (Massachusetts General Hospital, O. P. D. No. 20213), a women sixty years old, unmarried, a seamstress, was well up to the spring of 1900 except for occasional attacks of rheumatism. She then began to have sensations of numbness in the fingers, but not affecting the body or the arms. In spite of the fact that her fingers felt as if "asleep," she was able to sew and make highly coördinated movements. In July she began to have similar sensations in her toes, which gradually spread until in October the whole of both legs was involved. Excepting for the numbness she considered herself perfectly well. There was no disturbance in walking. Her appetite was good and her bowels regular; nothing of importance was learned regarding her family history. Seen Oct. 8, 1900, she had an anemic appearance, and her gait was slightly ataxic. Heart and pupils showed no abnormality. The knee jerks were slight.

A *blood examination* Nov. 20 gave the following results: — Hgb. 25%; red cells, 1,850,000. Differential count of 500 white cells; — polymorphonuclear neutrophiles, 71.8%; basophiles, small 25.2%; basophiles, large 1.6%; cosinophiles 1.4%. In the white count two megaloblasts and four normoblasts were seen. There was considerable poikilocytosis; many oval forms; an excess of macrocytes; some microcytes.

On Dec. 5 a note was made that the legs were very rapidly becoming weak and ataxic so that the patient was able to walk but a few steps at a time and very unsteadily. Dec. 18 she entered the New England Hospital, remaining until April 29. During that period, under general tonic and hygienic treatment she improved considerably.

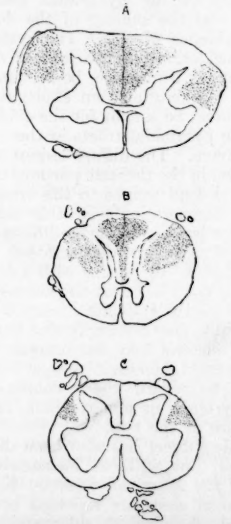

FIG. 3. Case II. A, cervical; B, thoracic; C, lumbar, showing somewhat circumscribed lesions in a case with pernicious anemia. Accurate tracings, Edinger drawing apparatus.

A second blood examination showed a still further reduction in the red cells with poikilocytosis, Hgb. 45%, and 14,000 white cells.

After leaving the hospital she began again to fail, although her appetite remained good. She became more ataxic and by the middle of July could not move her legs while in bed, and very imperfectly when sitting in a chair. She could not stand alone. Her bowels were very constipated, with about one movement a week, in spite of attempts at catharsis. Aug. 15 without warning she fell, was taken up unconscious and remained so for several hours. She was then delirious and helpless; vomited once or twice and had excessive diarrhea for several days. She failed rapidly and died Aug. 30, without recovering complete consciousness.[2]

Autopsy Sept. 1, 1901, by Dr. E. E. Southard. Examination of patient limited to the spinal cord. Extradural plexuses not injected; fat-tissue edematous. *Dura*, normal above, swollen to twice its size below by a movable mass of clear colorless fluid. Intradural attachments of cord, normal. *Pia*, pale, moist, of normal appearance, except in lower third, which shows the usual injection of post mortem origin. On section of the cord, microscopic evidence of lesion doubtful. No striking alterations of horns in size or shape. Gray matter soft and slightly retractile on section. No apparent alteration in distribution or amount of white matter. Color and consistency normal, except in lower dorsal region and upper portion of lumbar enlargement, where, in the dorsal columns, there is a vaguely limited area, 2 by 3 mm. in diameter, oval in cross-section, and bisected by the middle third of the dorsal septum, showing pinkish-gray color with slight if any loss of consistency. *Nerve roots*, normal.

Bulk of cord preserved in 4% formaldehyde solution. Specimens from each of three levels preserved in 95% alcohol, in Zenker's and in Mueller's fluids.

Microscopic examination. The spinal cord was stained by the usual appropriate methods and gave the following series of changes: — In the cervical region degenerations of white matter were sharply limited to the dorsal and lateral tracts, occupying a central area in the dorsal columns, including the columns of Goll and a part of the columns of Burdach, except at the dorsal periphery, where undegenerated fibers were interposed. The lesions were of the two characters frequently described, a fairly dense neuroglia sclerosis toward the centers of the degenerated areas, bounded by areas containing many vacuoles, and unproliferated neuroglia, with numerous fat granule cells, presumably being a more recent stage of the process than

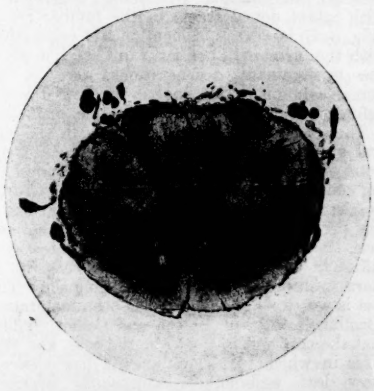

FIG. 4. Case II. Thoracic region, quasi-systemic degenerations of dorsal and lateral tracts in pernicious anemia; dorsal nerve roots normal. The apparent ventral degenerations are due to slight defects in staining, exaggerated in the reproduction.

the denser portions. The degenerations were not limited to neurone systems in any portion of the cord involved. In various portions of the thoracic region the lesions of the white matter were the same in general distribution, the more complete sclerosis being in the columns of Goll and in the crossed pyramidal tracts. The lesions in the lumbar enlargement were noteworthy from the fact that they were confined to the crossed pyramidal tracts, and had all the appearances of a simple secondary degeneration. (Fig. 3, C.) The far more usual degenerations in the dorsal columns (see previous case, Fig. 1) were wholly lacking.

[2] For many of the facts in this case we are indebted to Dr. Annie Hamilton.

The *gray matter* showed no noteworthy alterations, other than hyperpigmentation of cell bodies.

The *nerve roots* throughout the cord were normal, both ventral and dorsal.

Blood vessels external to the cord in the pia showed no abnormality. The vessels in the cord were for the most part distended with blood, but beyond a possible slight thickening of the walls were normal. There were no signs of inflammatory reaction in the neighborhood of vessels. A definite relationship between lesions of the white matter and vessels could not be demonstrated by the histological appearances.

The points of chief pathological interest in this case were:

Lesions of the spinal cord in a person dying presumably of pernicious anemia, sharply limited to dorsal and lateral columns of the cord, but not anatomically confined to neurone systems; no noteworthy alterations of nerve cells of ventral horns; no general changes in the blood vessels either without or within the cord; no degeneration of nerve roots.

On the clinical side the case presented the type of symptoms often seen; vague at first, chiefly characterized by paresthesiæ, gradually leading up to a very considerable degree of ataxia, with final inability to stand, due, no doubt, to the combined dorsal and lateral cord lesion — ataxic paraplegia. It is to be observed that during the course of her illness of something over a year there was at no time a sharp exacerbation of symptoms. Slight knee jerks in the presence of marked pyramidal degeneration with intact dorsal tracts in the lumbar region (Fig. 3, C) is worthy of mention and comparison with the increased knee jerks in Case I, in which the predominant degenerations were in the dorsal columns. The final collapse two weeks before death, however, remains unexplained.

These two cases evidently belong in the general group of the diffuse (combined) degenerations of the cord, the most striking accompanying condition in the first case being general arteriosclerosis and in the second a fatal anemia of the pernicious type. The lesions of the first case, though in general similar, were much more diffuse in character than those in the second, and more widespread, though less compact. This fact is worth noting since it has been maintained (Bastianelli, Russell, Batten and Collier, Spiller) that the converse is apt to be the case, and that cases in which pernicious anemia has occurred show less well-defined, apparently systemic alterations. The association of arteriosclerosis with the lesions of combined degeneration has not been frequently reported and its occurrence in this case is no doubt to be regarded as a coincidence rather than a causal relationship, particularly since the vessel changes were much more conspicuous in the brain than in the cord, whereas the diffuse nerve lesions were, as is usual, practically limited to the cord. In general we are strongly inclined to the view expressed by Russell, Batten and Collier that anemia, arteriosclerosis and the various other concomitant conditions associated with this now well-defined type of nerve degeneration are not etiologically significant, and that a common but as yet unknown cause lies behind, which, recognizing the vagueness of the term, we may call a toxemia.

Since the publication in 1901 by Putnam and Taylor[3] of a paper on "Diffuse Degeneration of the Spinal Cord," containing a general though by no means exhaustive review of our knowledge of these lesions, a considerable number of articles have appeared bearing directly on the subject. In a carefully reported case, Pickett[4] discusses various matters pertaining to the general questions involved in the combined degenerations, criticises the term "diffuse degeneration," used in a previous article,[5] as inadequate, and insists that the process is, at least, partly systemic, and that we have to do with two processes, one systemic and the other diffuse, a view also held by Russell, Batten and Collier. This is evidently merely a matter of terminology. A process must be either systemic or non-systemic as we use the term "system," as applied to neurones, and not merely to circumscribed areas in the cord. There is not sufficient evidence, as yet, to show that in these conditions the pyramidal tracts or the peripheral sensory neurones are degenerated as independent systems, although the superficial appearances are often suggestive of such limited lesions. The usual abrupt ending of the degeneration of the pyramidal tracts in the oblongata and the sparing of the dorsal nerve roots is evidence of this. The systemic character of the lesions in the lumbar or thoracic regions may, in a measure, be accounted for by secondary degenerations, an explanation which, no doubt, must be sought for the evident alterations in the pyramidal tracts in the second case reported above. The diffuse lesions are usually most marked in the thoracic portions of the cord, which would lend weight to this supposition of secondary degeneration. In this sense, therefore, that the lesions are partly diffuse and partly the result of secondary degeneration, it may be admitted that we are dealing with a double process, but it is not clear that the lesions are partly diffuse and partly systemic in any other sense. This, naturally, does not imply that true systemic combined sclerosis may not exist in which the diffuse element is lacking. A safer basis for the present is to regard these combined lesions either as systemic or non-systemic, rather than as a mixture of the two.

The whole subject has also been discussed in much detail, but with an inexcusable neglect of much of the American work by Kattwinkel.[6] Eight personal cases are reported both on the clinical and pathological side, and a further observation of Kremer's is added. The cases are of the general type of combined degeneration, for the most part without sharp limitation to recognized fiber tracts, and the author takes occasion to discuss at length the difficulties of diagnosis when both dorsal and lateral tracts are involved, and the frequency of symptoms point-

ing toward tabes in spite of degenerations beyond the sensory systems. On the etiological side Kattwinkel lays much stress upon the work of Marie regarding the vascular arrangement in the cord, and also upon the less known work of Guillain and others in determining the course and relations of the lymph channels. From this investigation it appears that the arrangement of the lymph spaces in relation to the meninges and blood vessels is such that a stasis of lymph takes place with greater readiness in some parts of the cord than in others, in the presence of alterations of the blood vessels, or in certain instances even in the absence of visible vascular changes. This combination of dilatation of lymph spaces and consequent lymph stasis and vessel changes, he holds responsible for the alterations observed in the diffuse combined lesions of the cord. The two findings were practically constant in the cases cited. So far as we know, this conception of the function of the lymph system in producing these degenerations has not been maintained by other writers. It needs further verification before being generally accepted.

A case has also been reported by Rheinboldt [7] from Hitzig's clinic, of so-called " combined system disease," in which the literature is again reviewed in great detail, but imperfectly, and conclusions drawn which add little of significance to our knowledge of the subject. The distinction made that cases with slight anemia are particularly associated with diffuse sclerosis of systematic distribution, as contrasted with the more irregular distribution of the lesions in fatal anemia, does not conform to our experience. We have in the examination of such cords found absolutely no changes which can be regarded as distinguishing the various types of cases.

Frank Billings, in the Shattuck Lecture [8] before the Massachusetts Medical Society for 1902, presented an important contribution to our knowledge of the cord and oblongata lesions following or associated with pernicious anemia. Billings is inclined to accept the term " diffuse degeneration " as a sufficiently exact pathological statement of the conditions found, and regards it as highly probable that in cases of pernicious anemia the hemolysis and the diffuse cord degenerations are due to the same toxin.

Burr, in conjunction with McCarthy, has reentered the discussion of the " postero-lateral scleroses " with a report of eight additional cases,[9] and makes a classification of these lesions into eight groups, which he thinks may for clinical and laboratory purposes be sufficiently differentiated. Such a classification seems to us rather more elaborate than our present knowledge warrants; it is, at least, apparent that the transitional forms of disease of this type are so numerous that sharp categories are to be maintained only with great reservations. An essential distinction, if it can be demonstrated, is between true combined parenchymatous neurone degenerations and lesions from the outset diffuse in character. Burr and McCarthy are apparently of the opinion that such a distinction may be made even excluding Friedreich's ataxia and the combined lesions occurring in dementia paralytica. Their group 8 seems to come in this first category, whereas under group 6 are included those cases in which in our experience a much larger proportion of all the combined lesions are found. Oppenheim still maintains the existence of a true combined systemic neurone disease and is inclined to place in a distinct category the type of case described by Russell, Batten and Collier.[10]

In general, so far as we have followed the work done since the publication of the former paper alluded to, there seems no sufficient reason for altering the statement then made that no fundamental characteristics of the lesion have been found depending on different causes, and that for the present the term " diffuse " or, to be more specific, " diffuse combined degeneration," is a sufficiently exact designation of the usual anatomical alterations. This naturally excludes the cases, in the post-mortem study of which we have as yet had no experience apart from Freidreich's disease and dementia paralytica, in which true systemic degenerations of lateral and dorsal tracts may take place.

Finally certain evidence appears to be accumulating that cases which present during life a high degree of spasticity with slight ataxia, implying extreme degeneration of the lateral tracts are more chronic in their course than those with early and marked ataxic symptoms. A number of cases recently observed by us clinically and after post-mortem study, as well as the experience of others bears out this supposition.

HISTORICAL NOTES ON THE LAWS GOVERNING CIVIL MALPRACTICE IN THE ANCIENT TIMES AND THE MIDDLE AGES.[1]

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

THE question of civil malpractice is of interest to both the medical and legal professions, and of recent years many rather unusual cases involving medical liability have been tried in various courts of the United States. That the physician or surgeon have been held liable for their actions by the courts of justice is as old as law, and it occurred to the writer that publishing a few scattered notes he had made on the history of this subject might not be without interest, although he must concede that the question consigned in the following pages is only superfically discussed.

Among the Egyptians the law punished very fully any too imprudent or audacious physician, and in the seventh volume of his " *Histoire de la Legislation* " De Pastoret says that " general

[1] Read by invitation at the Annual Meeting of the Massachusetts Medico-Legal Society, June 9, 1903.

rules had been established for the treatment of patients. These were the result of carefully made observations which were guarded by the priests in books that were so respected that they were solemnly carried in the processions taking place on days of public fête. An absolute prohibition did not exist preventing a physician from applying a new truth, but if, far from obtaining the salutary effects that he expected to procure he caused the death of his patient, he was obliged to pay his tribute for the misfortune or the boldness of having sacrificed the life of a citizen, by being beheaded. On the other hand, he was never liable to a patient confided to his care when he followed the rules laid down in the sacred books."

The same authority says that the Greeks also admitted medical liability, and Tourdes quotes an example related by Plutarch of a certain physician of Ephesis, by name Glaucus, who, having left his patient to go to the theater, was condemned by Alexander to be put to the cross, because the patient, having imprudently eaten during his absence, died.

In Roman law the principle of medical liability was admitted, and this is proof positive since it is so formally stated in the old texts. This can easily be understood, since at Rome any one could practice medicine who so wished, and, generally speaking, the slaves practiced the healing art, which was a source of large income for their masters. These physicians, or perhaps it were better said empirical practitioners, had no other end than the gain of money, and there was, consequently, a double motive for making them liable for mistakes committed in the exercise of their practice. On the one hand, there was no guarantee offered by a diploma attesting to serious studies and a certain science, while on the other, there was a complete lack of devotion and scientific disinterestedness.

A physician who gave his services to a patient was responsible to the master if the latter were a slave, and he fell under the jurisdiction of a suit *lege Aquilia*, or under the application of suit for the hire of labor. The first clause of the law Aquilia covered in point of fact by those cases where another's slave had been killed without right. It was quite sufficient that a slave had been mortally wounded. The physician who, after having operated upon a slave, abandoned the after care and allowed him to die was at fault according to the terms of the law which ran as follows: " Præterea si medicus qui servum tuum secuit, dereliquerit curationem, atque ob id mortuus fuerit servus, culpæ reus est." [2]

There was also error on the part of a physician who by ignorance killed his patient by administering a medicine *mal à propos* and which caused the latter's death, as the following text shows: " Imperitia quoque culpæ admuneratur; veluti si medicus ideo servum tuum occiderit quod cum male secuerit aut perperam ei medicamentum dederit." [3]

Wounds which were not fatal but which were sufficiently serious to be damaging to the master of the slave were comprised in the third clause of the law Aquilia. The direct application of the law Aquilia was only allowed when the detriment resulting was caused *corpore corpori*, for example, when it was applied to a physician who had wounded or killed a slave by the performance of an operation upon the latter. But it was not applicable to the one who had only been the cause of the detriment, and who had not caused it by his proper body, as, for example, a physician who had prescribed a medicine *mal à propos*. In this case the *juris consulis* gave the application to the law, that is to say, introduced by interpretation, following the example of that of the law and procuring by the manner in which it was drawn up by the pretor the same results.

According to Accarias the professional services of a physician could become the object of a hire of labor when it was a question of a slave, and Proculus declared that a physician who had badly cared for a slave could be sued either *ex lege Aquilia* or *ex locato*. The following is the exact text: " Proculus æit, si medicus servum imperite secuerit, vel ex locato vel ex lege Aquilia competeri actionem." [4]

The direct application of the law Aquilia could not be applied to a physician when the victim was a free man, and Ulpien says that " a man has not the right of ownership of his limbs." Now, in order to obtain a direct application of the law Aquilia, it was necessary that the person injured should have also his patrimony involved. But a free man who had become the victim of errors committed by a physician could have the direct application of the law Aquilia accorded by the pretor who procured the same effects, excepting in that which concerned the pecuniary reparation of the injury. In the latter case the value of human personality was not considered. The reparation could only include the tort resulting from expenses involved for the cure, from incapacity to work and, lastly, the funeral expenses.

Now, although the texts are perfectly affirmative regarding the admission of the principle of medical liability in Rome, it is more difficult to say whether or not it was frequently applied, and it would appear that the contrary was more likely the case if one considered with what violent indignation Pliny affirmed that in Rome a physician enjoyed the most complete impunity as he states in the 29th book of his " Natural History," as follows: " Nulla præterea lex, quæ puniat inscritian; capitale nullum exemplum vindictæ. Discunt periculis nostris, et experimenta per mortes agunt: medicoque tantum hominem occidisse impuniter summa est. Quin imo transit convicium et intemperantia culpatur: ultroque qui periere arguuntur."

The Roman laws were not, however, as severe as Montesquieu has upheld in his immortal work entitled " *Esprit des Lois*," in which he says " that the people were desirous of having physicians punished for their negligence or their ignorance. In this case they condemned a physician who

[2] Instit. Liv., iv, tit. iii, § vi.
[3] Instit. Liv., iv, tit. iii, § vii.
[4] D. Liv., ix, tit. ii, vii, § viii.

occupied a certain social position to exile, while death was the sentence applied to the one occupying a lower social condition." This great writer committed an error, for the law to which he makes allusion,[5] "*Ad legem Corneliam de Sicariis* . . .," did not punish negligence, ignorance or lack of attention, but the *crime*, the grave mistake committed with the criminal intention of producing death.

Medical liability was rigorously followed out in the ancient Germanic law, to such an extent that before undertaking the cure of a patient the physician was obliged to give a security in order to guarantee the indemnity in case he was unsuccessful. A physician who while bleeding a free man wounded him, was obliged to pay his family a compensation of one hundred and fifty ducats in gold. In case of the death of the patient, the physician became the property of the family, who could use its right of vengeance as it saw fit. ' Si quis medicus, dum fleotomiam exercet, ingenuum debilitaverit. CL solidos coactus exolvat; si vero servum hujusmodi servum restituat (in lege Ervigiana post exolvat leguntur: si vero mortuus fuerit proprinquis continuo tradendus est ut quod de eo facere voluerint habeant protestatem."

A physician could not bleed a free woman unless her husband or some of her near relations were present, because the law said: " Difficillium non est sub tali occasione ludibrium interdum adscrescat."

In Beugnot's edition of the " *Assises de Jérusalem*" will be found many important remarks regarding the liability of physicians in the middle ages.[6] A physician called to attend a serf, and by his ignorance causing the death of his patient, was condemned to pay the value of the serf and was obliged to leave the city, and I here quote an interesting paragraph:

" C'il avient par aucune mésaventure que je naffre un mien serf ou serve, ou aucune autre personne le naffre, et je i amène un meige et celui meige s'accorde o mei a pris noumé et me dit au tier jor, puisqu'il ot bien veu la plaie, que bien le garet sans faille; et il aveint puisque il le tailla malement ou por ce que ne devet étre taillé et il le tailla et porce il mourut et porce que it devet tailler la blaie par la levure et l'apostème donc et il le tailla de travers et por ce mourut: la raison juge et commande en ci a juger que celui meige doit amender le serf ou la serve par droit tant comme il valait au jour qu'il fut naffré, ou tant comme l'acheta celui de qu'il estait car c'est dreit et raison par l'assise. Et deit la cort celui meige congeer de la vile ou it fist cele mauvaise megerie."

According to this text the physician after having seen the wound promised to cure the patient, but following a badly conducted operation which resulted in the death of the patient, the physician was declared liable for this unfortunate occurrence. The text then goes on so as to cover those cases in which a wound became gangrenous because the physician did not give the patient daily attendance, and it declares the former liable for this accident. In the same way it holds the physician liable for any imprudence committed by the patient, because he did not indicate in what ways the patient should care for himself. And, lastly, the text speaks of damages due in case the victim was a serf. The physician, after having promised to cure him, employed bad drugs and did not succeed in his object. The patient was maimed forever. The physician was obliged to take the serf for himself and to pay to his master the sum that the serf had cost him. In case the physician could not pay the entire sum, he was obliged to leave the serf with his master and only pay " celui serf ou cele serve vaura de mains por ce qu'il est mahaignes par sa coulpe."

When the victim was a free man the liability of the physician was very much greater. If it were a question of simple wounds or of bad treatment which did not cause death, not only the physician had no right to demand any fee but he had his right hand cut off. In case of death of the patient the physician was condemned to the gallows: " Mais se il avet se mahaign fait a un crestien ou a une crestienne, la raison juge qu'il det predre le poing destre et ne det plus estre damages for tant que c'il avet rien pris de celui por le meger si est tenus dou rendre par dreit. . . . Et se celui miege avet anci malement mege come est dit dessus aucun franc home ou aucune franche femme et elle en moret la raison juge que celuy meige det estre pendus et . . . it a det estre dou seignor par dreit. Mais ce il avait riens receu dou mort si det estre rendu as parens dou mort des choses dou meige car ce est raison et dreit."

The text adds that before being put to death the physician should be taken through the streets of the city in order to serve as an example to his colleagues.

It happened that, on account of fear regarding their liability, physicians refused their services to patients, or if they gave them they demanded a guarantee releasing them from any responsibility should the case terminate unfavorably. Guillaume de Tyr tells us that Amaury I, feeling that his strength was leaving him, demanded medicines from some Syrian physicians. These they refused, and he was only able to obtain them from the Latin physicians after he had given his promise that they need not be disturbed, no matter what issue the disease might take.

In the ancient French law the liability of physicians and surgeons was distinctly held. Denizart established a hierarchic difference between physicians and surgeons, and declared that the latter were subordinate to physicians. He admitted the liability of surgeons and declared them held for tort towards those they might maim by their ignorance, and attributes to physicians the power of examining the facts of the case in order to ascertain whether the surgeon was repre-

[5] D. iv, iii.

[6] The ideal type of feudal law is that so graphically depicted in the works which pass under the title of the Assises de Jérusalem, and which profess to describe the usages of that curious product of the Crusades, the Latin Kingdoms of Palestine.

hensible or not. He goes on to say that: " When a surgeon has conducted the case according to the rules of his art, he should be paid for his operations and for his care and dressings, although the patient may have not been cured, even if one was obliged at a later date to do an amputation of some fractured limb, the cure of which the surgeon had undertaken."

Efforts were made in France by Charles VI, Henry IV, Charles VII and Louis XIV to formulate laws to control the practice of surgery, but these were apparently only partially successful. It is not without some interest perhaps to add that, as far as I have been able to discover, Henry IV of France was the first to create what would at the present time be called a medico-legal expert. These experts were selected from among the most capable surgeons. It is also positive that about the middle of the sixteenth century certain cities appointed what might be termed expert surgeons, for the purpose of examining the wounds of patients seriously injured, and to see that the attending surgeon treated the case properly; for otherwise the patients could bring suit for tort should it be shown that there had been malpractice. That this is a fact will be found from the following quotation that I make from the treatise on surgery by Felix Wurtz, a noted surgeon of Basel, whose fame was widespread at about 1560:

" Un Chirurgien ne doit point permettre à un chqun de voir, ou mettre la main aux blessures de ses patiens, ce que neantomoins plusieurs ont accoustumé de jure. Ce n'est pas que je oeuille blasmer la couterme de plusieurs Villes bien policées, où les Magistrats font ordinairement visiter une jois, ou deux, touttes les blessures considerables, par les Chirurgiens jurez; au contraire, je soustient qu'elle est extremement necessaire et qu'elle se devroit establis par tout, enfin que si quelqe'un est malpensé, ainsi qu'il arrive assez souvent, il en puisse pacie ses plaintes à la Justice."

The mistakes committed in the rules of practice should be appreciated by men engaged in that profession, and Denizart quotes a judgment which acquitted a surgeon who was accused of having given bad treatment, only after having heard the testimony of expert surgeons. The case was as follows: A surgeon sued a patient, who had a broken arm, for the payment of his fee. The arm had either been set badly or too early and, having been inconsiderately moved by the patient gangrene appeared. The patient refused to pay the bill. The court then ordered some expert surgeons to examine the question as to how the accused had acted and if the operation and his dressings were in conformity to the rule of his art. After having heard the declarations made by both the surgeon and the patient, they returned a verdict in favor of the surgeon, and as a final consequence the court ordered the patient to pay the surgeon's fees. This same writer mentions another case where the surgeon was sued in the criminal court and was condemned to pay fifteen thousand pounds damage and interest, because the ignorance of the surgeon was proven by the findings of the experts called in on the case.

Charondas, a well-known lawyer who flourished in the middle of the sixteenth century, said that a surgeon was liable for accidents which might occur to his patients if they came from his mistake. He mentions a case of a surgeon who was taking care of a patient afflicted with a venereal ulcer, but an accident occurred during the treatment which caused the death of the patient. For this mishap the surgeon was brought to justice as having been the cause of the death. Charondas during the trial held that since neither deceit nor ignorance on the part of the surgeon could be shown in the treatment employed for the cure of the ulcer, the surgeon could not be held responsible for the accident which occurred later.

Papon, a well-known judge who lived during the regency of Catharine de Medicis, says, that although a patient may die, the physician should not be held liable unless he was found ignorant or too hardy in his treatment, and that consequently a legal examination should be held in order to ascertain the true circumstances of the case, and if the physician is found to have committed a mistake he should be punished by the courts. This same author then relates the case of a physician who gave a potion to a patient which was either capable of killing him or saving him in a very short time, and the patient died from its effects. The physician was, however, easily acquitted, but he was admonished by the court never to repeat the same treatment again under penalty of being severely punished.

Jean Duret, a physician of some note who lived during the last half of the sixteenth century, declared that a physician was liable if he showed himself an idiot in both the theory and practice, or if he showed himself too audacious, and Raymond de l'Eglise upheld that a physician was liable not only for his temerity and his neglect of a patient but also forhis ignorance as well. Brillon, whose classical dictionary was published in 1711, also upheld that physicians were liable for their acts. He based his opinion on Papon and another writer, who declared that a physician was liable either for a slight mistake or a very slight mistake, and he relates several judgments in which the principle of medical liability is upheld.

The public was far better protected against nostrums and quacks a few hundred years ago than it is at the present time, as will be seen from the following: In the reign of Edward VI, Grigg, a poulterer in Surrey, was put in the pillory at Croydon and again in Southwark, for cheating people out of their money by pretending to cure them by charms, or by looking at them, or by casting their water. Many other quacks have at various times been subjected to punishment. Anthony was punished for his Aurum Potabile; Arthur Dee for advertising medicines to cure all diseases; Foster for selling a powder for the cure of chlorosis; Tenant, a urine caster, who sold pills at six pounds apiece; Aires, for selling purging

sugar plums; Hunt for putting up bills for the cure of diseases in the streets. The council in the reign of James I dispatched a warrant to the magistrates of the city of London to arrest all reputed empirics, and cause them to be examined by the censors of the Royal College of Physicians. Several were arrested and acknowledged their ignorance. In the reign of King William a certain Fairfax was fined and imprisoned for injuring persons by his Aqua Cœlestis, while in Stow's chronicle it is recorded that a water caster was punished for exercising his quackery. He was set on horseback with his face to the horse's tail, which he held in his hand, with a collar of urinals about his neck, led by the hangman through the city, and was whipped, branded and then banished.

The old French jurisprudence felt some hesitation in pronouncing for or against medical liability, and Merlin believed that suits brought against physicians were rarely successful. He mentions a number of judgments which acquitted the physician. The parliament of Paris in 1696 gave the following judgment in one case, the court saying: " That surgeons are not liable for their remedies as long as they have showed no evidence of ignorance or rashness in their practice." And in summing up the case on which the court had rendered judgment, the Advocate-General Portail said: " There is only one case where suit can be brought against the medical profession, and that is when deceit had been practiced, in which case it is a true crime."

In 1596 the children of a surgeon, who had wounded a patient while bleeding him, were condemned to pay 150 pounds damages by the Parliament of Bordeaux, and in another case a surgeon was condemned, because he cut a child for stone in the bladder without the advice of a physician, to pay damages amounting to 60 pounds, with the injunction of the court never in the future to cut another patient for stone without the consent of some physician who was approved by, and who had been received by, the faculty of medicine.

Many other cases could be cited, but I think from what has been said in this short paper that medical liability has been sustained by all the courts of former times. The question of criminal malpractice I have entirely left aside hoping at a future date to discuss the history of this important subject.

THE BITZER HOMICIDES.[1]

BY GEORGE P. TWITCHELL, M.D.

Medical Examiner, Greenfield, Mass.

Louis Bitzer, thirty-six years of age, a jeweler by trade, in 1901 lived in Turners Falls. His place of business was on the main street of the village, and he lived on a side street a short distance from his store. His family consisted of his mother, his wife and three children, Anna, fifteen years of age, Caroline ten, and Louis Martin, five.

Ida Columbe, seventeen years of age, worked in the store for Bitzer as clerk or saleswomen. On the morning of Dec. 31, 1901, Ida went to the post-office to get the ten o'clock mail; when she got back they started to put away the Christmas goods in the back room. Bitzer had two revolvers, one of 32 and the other of 38 caliber, lying on a table in this room. Ida told him to put them away as she was afraid of them.

He opened one to see if it was all right and when he closed it it accidentally went off and shot the girl. When he saw that he had shot the girl he felt that he could not bear to be pointed out by people as one who had done a crime but had rather be dead himself, yet he did not want to die and leave his children, so he went home to take them with him and kill himself. Before leaving the store he wrote a statement of the accident on a large sheet of brown paper. What he subsequently did he does not remember, but he did go to his house and shot his wife, his two daughters, and his son; the boy, who was in bed recovering from an attack of measles, was killed and the others more or less seriously wounded; all recovered. He was disarmed by his wife, sister-in-law and mother and shortly afterward was arrested. He told his mother that he had shot Ida Columbe. At the station house he gave to one of the officers the statement he had written at the store. It was as follows:

> Starting in to work, Ida and myself putting goods away which were left over from Christmas, I put away my revolver which I have taken home with me nights to protect myself and Ida late at night. Looking it over and closing it up it went off accidentally and killed the poor little girl. For Heaven's sake don't blame me about it. The moment it went off I thought by myself what will become of my dear wife and children, so I do not want to be looked upon as a man thinking that he committed a crime, so I will die for it, and I cannot die without having my poor children with me. Take us all to church and sing our last farewell, 'Nearer my God to Thee.' Farewell to those who have loved us. Have John Gould take care of our bodies. My business affairs, write to Mr. Wm. S. Dana and J. Aschin, 43 Maiden lane, and the two gentlemen will look after my business affairs. Everything I leave behind will be for my dear old mother and Martin.
>
> I for my last words, sitting here and write this pitiful letter, wish you all good luck. This is a sorrowful thing but it must be done, and O My God don't blame me for it.
>
> I wish my dear old mother and brothers good-by.
>
> Your beloved Louis Bitzer.

About 12 o'clock I first viewed the body of Ida Columbe. In the back room of Louis Bitzer's store I found her, lying on the floor on her back, the legs fully extended, the feet about three inches apart and resting on the heels, the forearms flexed and the hands resting on the chest. Her head was slightly turned towards the right and rested on a man's ulster, which was arranged as a pillow. She was fully dressed, without her outer garments; the clothing was all in good order, the skirts covering the tops of her shoes and fully extended under her body; her underclothing orderly arranged. Blood was about her mouth and nostrils, smearing the side of her face and neck and upper part of her blouse and

[1] Read at the Annual Meeting of the Massachusetts Medico-Legal Society, June 9, 1903.

a little on the ulster. A penetrating wound was in the head, in the hairy scalp, just in front of the left ear. Lying on the floor, on the left side of the body near the knee, was a hairpin with a velvet knot on it. One hair ribbon was on the head and another was found under the buttocks when the body was removed.

The body lay in the comparatively narrow space between the table and safe, with the feet about one foot from the front of the sink. This was an iron sink, open underneath, and from about six inches under the sink, extending nearly to the heels of the body, were two nearly parallel marks or scratches on the floor. There was a mirror hanging over the sink on the wall, and a comb lying in it. Her hat, outer garments and chatelaine bag were on the table.

The autopsy showed a well nourished young woman, 4 feet 11½ inches in height, weighing probably about 115 pounds. Blood was about the mouth, nostrils, left side of the face and in the hair on the left side of the head. One inch anterior to the highest point of the left ear was a penetrating wound, the edges of which were blackened and burned. The hair around the wound was singed and brain substance oozed from the wound.

On removing the brain the course of the bullet was found to be on a line parallel with the horizon; the bullet passed entirely through the brain and was reflected back and was found in the right lateral ventricle. The organs of chest, abdomen and pelvis were normal. Her hymen was intact.

Autopsy on Louis Martin showed that the bullet entered through an opening in the left parietal bone, bordering on the coronal suture and two inches from the union of the coronal and sagittal sutures, passed superficially through both hemispheres and broke out a triangular piece of bone from the parietal bone on the right side at its eminence. The bullet was found in the substance of the brain directly under this loose fragment of bone.

Both lobes of the left lung and the lower lobe of the right lung were congested. Pleuritic adhesions were in the left thorax. All the other organs were normal.

After an indictment for murder had been found by the grand jury against Bitzer, the district attorney requested Dr. Frank W. Draper to conduct experiments to determine at what distance the revolver must have been held to singe and burn the hair and scalp. I had the pleasure of being present at these experiments.

The same revolver and similar ammunition were used, namely, the one of 32 caliber. The targets were various places on the hairy scalp of cadavers. At a distance of 6 inches the hair was not singed; between 3 and 4 inches the results were similar to what I saw on the head of Ida Columbe. I understand experts, employed by the defense, found they could singe hair at a very much greater distance. They used wigs as targets and the question arises as to whether that might make a difference in the results.

Bitzer was examined by experts as to his mental condition. The case never came to trial. The plea of murder in the second degree was offered and accepted by the government.

MALARIA AND MOSQUITOES OF WORCESTER. A YEAR'S OBSERVATIONS ON THE HABITS OF CULEX AND ANOPHELES.

BY WILLIAM W. MCKIBBEN, M.D., WORCESTER, MASS.,

Assistant Resident Physician, South Department, Boston City Hospital.

(Concluded from No. 25, p. 669.)

IN another puddle close by a few anopheles larvæ were found, lying like sticks flat on the surface with the two short respiratory syphons where the ears ought to be. By the aid of a lens they were seen to create a current towards the mouth by means of brushes, rejecting sticks and other débris. Their food probably consists of algæ and protozoa. There were no culex in this pool with the anopheles. In fact it is more strictly true with the larvæ than with the adults that anopheles and culex do not get along well together. The culex, being so prolific, soon kill out anopheles. This was seen time and again in the laboratory. Close by on the edge of a " dump " in some organic refuse, maggots were seen in countless numbers, the adult flies swarming about them. The ashes on this Southbridge street " dump," as is the case with at least four other large dumping grounds of Worcester, were graded on a level with the street. It would have been just as easy to have spread the ashes one quarter the depth, and over four times the area; that would have done away with the whole bog which now furnishes malaria to a section of the city called " the Island."

About six o'clock the bell-jar which had been pretty well shaken up riding over the cobble stones, drowning quite a number of larvæ, was seen to contain about fifty adult mosquitoes which had hatched out from the pupal stage. Whereas at five o'clock there had been about 75% larvæ and 25% pupæ, now there were about 25% larvæ and 75% pupæ. The pupæ are exceedingly active to escape fish which regard them as choice morsels of food. When the lecture began at eight o'clock, by placing an incandescent light back of the bell-jar, the audience was enabled to see at least 500 adult culex flying in the upper half of the jar and innumerable " wiggletails " in the water. In a separate bottle containing some of these " wrigglers " a few drops of kerosene or light fuel oil were added. A very thin film of oil spread over the surface, which the larvæ in vain tried to pierce with their breathing tubes. After sucking the oil into these tubes they wiggled violently to the bottom, turning on themselves hoop-like, trying desperately to suck the oil free from the tube. Several attempts of this kind generally resulted in death in a few minutes; sometimes, however, convulsive movements were seen even at the end of an hour.

Another experiment was shown of adding a minnow, a stickle-back and a goldfish to a bell-jar of water containing a large number of mosquito "wrigglers." It was laughable to see how greedily all the fish devoured these larvæ. Soon their little bellies stuck out quite perceptibly. After starving the adults in the original bell-jar for a week and losing a considerable number of them, a quarter of a banana hung to a string was dropped into the jar. In less than five minutes every available space on the banana was occupied by a ravenous mosquito, the proboscis deeply imbedded into the soft juicy pulp. Another instance, resembling the one of the bell-jar jolting over the cobble-stones, illustrates how nature makes an effort to propagate the species in time of danger by rapid changes from larval to pupal and from pupal to adult stages: in the dry weather of May the same puddle, where the original larvæ were obtained, began to dry up and the "wrigglers" were driven into a smaller and smaller space, until finally there was nothing left but a soft black ooze. It was at this period that the rapid change from stage to stage was seen in the hot sun — adults being born in large numbers. After four days in this mud the larvæ were passive and probably could not have survived much longer without food, when a welcomed shower came and again the puddle was formed and again the surface was seen covered with little rings, which represented the ends of the breathing tubes protruding for air.

Light fuel oil proportioned at the rate of one ounce to fifteen square feet of surface was spread on the water by means of a child's watering can, purchased at the ten-cent store. Returning in twenty-four hours, all the "wiggletails" were found dead in the mud at the bottom, while many adult females were caught while attempting to deposite their rafts, consisting of about four hundred eggs each.

In Peat meadow there is a drainage ditch about four feet deep and three feet wide. In some places the ditch is completely bridged over with grass, under which adults were very thick. The water is just the kind anopheles prefers, *i. e.*, slow-moving and clear. Culex, not being so particular, will breed in any kind of standing water except that having a scum over it, such as from algæ, duckweed, etc. In the little inlets or recesses in the banks, generally where there was sunshine, the anopheles larvæ were scooped off the surface with a dipper having a white enameled lining. This small ditch is one source of Beaver brook, the banks of which for two hundred to three hundred yards on either side are covered with cases of malaria for a distance of two or three miles.

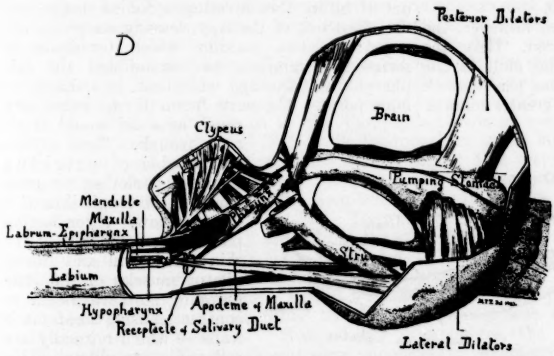

*Figure D is the head section simplified, showing the pump with its two posterior dilators attached to the dorsal plate and the five lateral dilators attached to the lateral plate; the complicated musculature which binds the anterior end of this pump to vertex, frons and the hollow struts which strengthen the head; the pharynx with its complicated musculature; and below, the muscles from base and head of the strut that retract the cutting lancet or maxilla, and the muscles from the head of the strut and the base of the labium which are attached to the posterior end of the apodeme of the maxilla and probably serve for protractors of this organ, *i. e.*, the maxilla.

It is very rare that anopheles larvæ are found in accidental receptacles, such as the tin cans on these "dumps" where culex breeds so profusely. They prefer natural bodies of water. Lake Quinsigamond was sterile of larvæ in the main body of water owing to the winds, waves, currents and fish. But anopheles larvæ were found in the "Sanctuary," a grassy stream leading back from the lake, where, after passing under the boulevard, it opens into a large grassy marsh. Just south of "The Sanctuary" are thick woods of tall trees, favorite camping grounds of the Worcester people. Owing to the protection from the wind the mosquitoes collect there in swarms. Many cases of malaria can be traced to these woods, the boys of St. John's Brigade being a striking example. In July three boys from Plantation street camped in tents there for two nights, and then went home because they could not sleep for the mosquitoes. Plantation street is situated on a hill, where neither anopheles nor malaria is to be found. In eleven days after returning home all three of the boys came down with periodic chills and fever, the second attack occurring exactly at an interval of forty-seven hours from the first. One of the boys had severe abdominal pain, finally becoming localized to the splenic region. Examination of fresh blood, and specimens stained with Ehrlich's and Wright's stains, showed the tertian parasite filling completely the red blood corpuscle, which was swollen and pale; actively motile, fine black granules of digested hemoglobin occupied the center of the

*Figures D and E are from the original laboratory drawings made and kindly furnished by Mr. M. T. Thompson, Clark University, Worcester. These will be published in more detail by him later.

plasmodium, which in the fresh specimen showed ameboid movement. At maturity each nucleus of pigment had gathered some protoplasm around itself until the amebula had subdivided into about twenty or thirty spores. With the rupture of the corpuscle simultaneously with the chill these young gametes were freed into the blood serum. Four hours before the next attack was due the plasmodia were seen to be segmenting again, so twenty grs. of quinine bisulphate were administered in capsule form. The attack which followed was lighter than the preceding one in each case, and proved to be the last paroxysm. However, another twenty grs. were administered four hours before the third attack was due, and after that prophylactic doses of two grs. three times a day were given for three weeks. This was combined with a tonic consisting of iron, arsenic and strychnia, in tablet form, as the hemoglobin averaged only 70% and the corpuscles in one case had diminished from 4,700,000 to 3,000,000.

Among the Italian authorities, however, the method of Sydenham is preferred. Here the quinine is administered after the chill in the sweating stage, because at this time the stomach is more retentive and there is a greater number

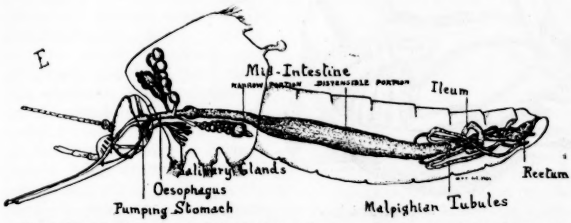

Figure E shows the general relations of the alimentary canal to the body; the pharynx and pumping-stomach followed by the esophagus with its three "air"-filled diverticula; the elongate digestive or mid-intestine whose distensible portion serves (in our species at least) to contain the ingested blood; then the five malpighian tubules, ileum and the rectum with the six conical "glands."

of young ameboid forms swimming free in the blood, in which form they cannot resist the disinfecting properties of the alkaloid, as the organism can when enclosed within a red blood corpuscle. Ferguson[1] recommends the bihydrobromate of quinine, 3 gr. hypodermically. He claims that it is non-irritating in solution, is ten times more effective than by mouth, and that six doses will cure. Italian observers have fully demonstrated that the only certain path of entrance of malarial infection is through the skin; that water taken through the stomach is not the vehicle; the epidemiological data prove it; a long series of experiments confirm it. Marshy water taken from intensely malarial places both in the summer and autumn, ingested in quantities up to three liters a day, failed to produce the disease in more than sixty persons experimented upon by various authors. It is of interest to study the exact method of this infection by the skin; and in this connection to study also the head and mouth parts of the mosquito in order to see in just what manner she punctures the skin, sucks the blood containing gametes, infects herself and finally gives subcutaneous injections of sporozoites or blasts to uninfected persons.

Mr. M. T. Thompson, one of the students in biology at Clark University, succeeded in getting a longitudinal section exactly through the median line of a culex stimulans, showing beautifully the musculature of the head. The slide was shown under the microscope at the June meeting of the Boston Society of Medical Sciences, to demonstrate the pumping stomach with its five lateral and two dorsal dilaters, the pharynx, the salivary duct, etc. Two excellent drawings of the mouth parts of culex (dissected) and anopheles (not dissected) were made from the microscope by another student — Mr. Roy Cushman. The biting apparatus is hidden within a sheath which terminates in an olivary body. In the act of biting this covering is folded down over the chest out of the way, leaving six pieces exposed: the two maxillæ which terminate in serrated extremities, two mandibles, the epipharynx and the lips, which end in a sharp oblique point. The parts fit on to each other very much as a lid would fit on to a trough. These stylets are capable of pricking through clothes or even through the tough skin of a horse or cow. After having pierced the capillaries of the skin the lateral and dorsal dilator muscles of the little pumping stomach begin to contract, causing the stomach walls — which normally are collapsed — to dilate. This creates a vacuum and the blood fills the stomach from the suction produced. In the ordinary tertian parasite, such as is seen in Worcester, the cycle in the human ends in about forty-eight hours with the liberated spores entering new red blood cells. Some, however, die and are assimilated by leucocytes. But should any of these free-swimming gametes be taken from the human body they undergo a further cycle of development — the sexual. A part grow larger in size, while others protrude long filamentous processes called flagella which separate from the parent body to fuse with the female or receptive forms. These flagellating forms were sometimes seen in fresh specimens of blood — after standing a half-hour under a 1-12th oil immersion lens — taken from cases which had newly entered the Worcester City Hospital. Ordinarily the process of development stops here. But if this union of the sexes takes place in the anopheles' stomach the fertilized females work through the mucous, inner muscular and outer muscular coating of the stomach, entering the esophageal diverticulum. As they enlarge, short dark lines quickly sur-

[1] Progressive Med., December, 1902.

round clear spaces on the surfaces. The clear spaces are known as centremeres, and the lines as blasts. The latter, which are really spindle-shaped cells, enlarge until they burst the mother cell (Zygotes), and being very motile soon find themselves free in the connective tissue supporting the salivary glands. From here it is an easy matter for those so-called sporozoites to reach the tubules of the salivary glands and become inoculated with the saliva in the act of biting. They then enter the red blood corpuscles and thus the original cycle in the human is started all over again. Since the Italians demonstrated this complete biological victory four years ago, it has been verified by scientific observers the world over. But not satisfied with the life history of the parasite alone, practical demonstrations were made. One hundred and four persons in a thickly malarious region were carefully protected at night from the bites of anopheles by screens and mosquito bars, and although practically everybody around them developed malaria, they themselves were free from it the whole season.

Drs. Cambon and Low, of the London School of Tropical Medicine, lived during the whole summer of 1900 next to an old canal in one of the worst malarial swamps in the Campagna. The doors and windows of their little five-room house were most carefully protected by screens, and they were always indoors before sunset, from where they could see the anopheles collecting on the wire screens outside. They were exposed to the mist which arose from the stagnant water at night, but were unaffected by malaria even during the wet season when all the peasants were suffering. Beside these two, a check experiment is described by Dr. L. O. Howard in his book on "Mosquitoes." The Italian authority Bastianelli sent some anopheles mosquitoes which had been fed on the blood of a patient suffering from malaria in Rome, to Dr. Patrick Manson in London. Dr. Manson's son, who had not been in a malarious country since a child, allowed himself to be bitten and in due time came down with double tertian malaria, microscopical examination demonstrating the parasites in the blood. It was Dr. Manson who, twenty years ago, after proving that the parasitic worms, filaria, could be demonstrated at night in the blood of persons suffering from elephantiasis, had the happy thought that as mosquitoes were nocturnal in their habits they might be concerned in the transmission of this dreaded disease. To-day we are positive that the embryos of these filaria Bancroftii are inoculated into man by the beaks of a species of culex, commonly seen around the houses in Australia.

And now comes under the date of Aug. 15, 1903, a command — from Brig.-Gen. Grant of the War department, at the Headquarters Department of Texas, at San Antonio — to screen all barracks, manholes, ventilator openings, barrels, etc., containing standing water, to prevent the spread of yellow fever from Mexico into the United States by means of the Stegomyia or brindle mosquito. The police officers of each port are to be held personally responsible for the proper drainage, filling or protection by oiling of all accumulation of water outside of premises, for the removal of all possible receptacles, such as old cans, crockery, etc., and for the proper condition of surface drainage. The command concludes with, "Two mosquito-proof rooms with wire gauze ceiling, seven feet from the floor, should be prepared at or near the hospital, the one for the reception of suspicious cases, and the other for the treatment of yellow fever cases."

In 1895 the unsanitary condition of Havana, Cuba, was appalling. Water from the houses was allowed to flow out into the streets and settle there. Mosquitoes bred freely. During the year there were 551 cases of yellow fever in the city. In 1896 with the arrival of crowds of non-immune immigrants from the United States and elsewhere the number of cases shot up to 1,278. In 1897 there were 828 cases. But in 1898 when the sanitary laws became more rigid, the streets were cleaned up, better drainage established, etc., the number dropped to 138, and to 102 in 1899. In 1900 the arrival of hundreds of non-immunes again brought the number up to 406. It was in the summer and fall of that year that the conclusive experiments were carried on in and around Havana to demonstrate that the Stegomyia mosquito was the carrier of yellow fever, although it was not then known that the disease itself was caused by a protozoön.

Following the methods now about to be used in Texas, of destroying the breeding places of mosquitoes and of screening the hospitals and houses, the number of cases dropped in 1901 to seventeen. Since that time there have been only five cases in Havana. In spite of all this evidence of satisfactory mosquito extermination, Worcester still remains inactive, although interested, as is shown by the fact that fifteen different clubs listened to lectures on the subject last winter. All of the daily papers contained articles — one covering three pages.

An editorial in the *Evening Gazette* severely criticised the Common Council for recommending a loan of $25,000 to be expended in improving the filtration beds and refusing to donate the $1,200 which the Board of Health, at the suggestion of the Worcester District Medical Society, recommended to fight mosquitoes and malaria. The mayor, while admitting the necessity of combating malaria, considered that the tuberculosis hospital was more important in spite of the great expense attached to it. Consequently, anopheles flourishes, not through the mayor's friendship (as is the case with the Common Council) but through his indifference. The writer on a visit south this summer found the laity of New Orleans actually opposing measures for mosquito extermination — about to be taken by the board of health backed by the medical profession — on the grounds that

the mosquito was put there for a purpose which was known to the Lord (and he alone); that they probably destroyed certain impurities in the air and ought to be befriended. Considering the system of shallow cisterns in New Orleans, they will get all the chances to befriend they wish. It remains to be seen what will be the attitude of the Worcester city authorities as the scourge of malaria increases and as the evidence of successful mosquito extermination accumulates elsewhere as it has at Brookline under Dr. H. Lincoln Chase and Dr. J. Albert C. Nyhen. The conditions are certainly most deplorable in Worcester at present (September, 1903).

We've fought our way up from the Gulf
By that loud-ringing blade "Quin. Sulph.,"
And now are we to sit here dumb,
And let Anopheles "go hum"?
No! Fight him with Petroleum!
Purveyor of Plasmodium,
Anopheles Mosquito.

Envoi.

To me will come an awful ease
When thou art gone, Anopheles!
My Plasm freed from Odium,
When thou art dead, Plasmodium!

Medical Progress.

PROGRESS IN PATHOLOGY.

BY JOSEPH H. PRATT, M.D., BOSTON.

(Concluded from No. 25, p. 682.)

LEUKEMIA REGARDED AS A TUMOR FORMATION.

LEUKEMIA, according to Weber,[14] is the result of a neoplastic activity of the leucocyte-producing organs in which the tumor cells gain entrance into the blood stream. Hence the disease, according to this theory, should be grouped with the new growths. If the less differentiated cells of the type of the large lymphocyte are drawn from the lymph-nodes or from the bone marrow lymphatic leukemia is the result. In the acute cases the blood usually contains more of the large than of the small lymphocytes. If the more differentiated cells, that is, the granular cells of the bone marrow, are concerned chiefly in the tumor formation, the pathological picture of myelogeneous leukemia is produced. According to this theory lymphatic leukemia is a tumor arising from the proliferation of a more embryonic cell-type than myelogenous leukemia, and this agrees with the fact that in its development and course lymphatic leukemia is generally more rapid. Leucocytosis or lymphocytosis is simply the expression of a tissue reaction while leukemia is always due to the emigration of tumor cells from a hyperplastic neoplasm in the leucocyte producing tissues. If the organism attempts the rapid formation of myelocytes there may not be sufficient time for the development of granules in the cell protoplasm, and as a result unripe cells are thrown into the circulation. These unripe cells resemble the large and small lymphocytes and not the typical myelocytes. The writer holds that cells of the myelocytic type, found in the spleen and lymph nodes in cases of myelogenous leukemia, may be formed *in situ* out of the undifferentiated large lymphocyte.

Weber[14] reports a case of acute leukemia of two months' duration, in which the blood picture was that of a mixed cell leukemia (Reed's terminology). In a spread of the heart's blood 93% of the white cells were lymphocytes and 6% myelocytes. The liver, spleen and lymph nodes were enlarged. Great numbers both of lymphoid cells and eosinophilic myelocytes were found in the internal organs. Professor Muir of Glasgow, who examined the sections, regarded the case as one of lymphatic leukemia, although he had never seen such numbers of eosinophiles in that disease.

The theory advanced by Weber is not wholly new. Türk[15] was the first to regard lymphatic leukemia as belonging in the neoplastic series.

A FERMENT IN THE BLOOD IN MYELOGENOUS LEUKEMIA.

Brandenburg[16] in 1900 called attention to the fact that the blood in myelogenous leukemia without the addition of $H_2 O_2$ or turpentine oil would color guaiac tincture blue. This held true even when very small amounts of blood were used. Bone marrow from a case of myelogenous leukemia gave the reaction, but the structures rich in lymphocytes, as the spleen, thymus and lymph nodes, as well as the other organs of the same individual, yielded negative results.

Meyer[17] found the reaction did not occur when the blood and bone marrow from a case of lymphatic leukemia were tested. He confirmed Brandenburg's results in two cases of myelogenous leukemia and modified the technique. The following simple method of applying the test is recommended: Two or three drops of leukemic blood are collected in a test-tube and mixed with a large amount of water, so much, in fact, that no color of blood remains. The fluid becomes a deep blood on the addition of guaiac tincture.

Under Prof. Friedrich Müller's direction a study of this property of myelocytic blood was made. The reaction was found to depend upon an oxidizing ferment present in the myelocytes. The same ferment was demonstrable in pus cells and in the completely normal neutrophilic leucocytes, but not in the lymphocytes.

The author believes that the conception of an acute lymphatic leukemia as a distinct variety of the disease is correct, and that it should be sharply differentiated from the myelogenous form.

Rosin and Bibergeil have shown that the nucleus of dead leucocytes is colored by neutral red, while the nucleus of living leucocytes is not. The cytoplasm of both living and dead leucocytes takes this stain.

[14] Virchow's Archiv, 1903, clxxiv, p. 324.

[17] Loc. cit., 1903, I, p. 1489.

Meyer found in a case of leukemia that a relatively large number of nuclei were stained at the time when the excretion of uric acid was greatest. Hence he concludes that the destruction of leucocytes can be estimated not only by the uric acid output, as is well known, but by the number of leucocytes in a blood smear taking the nuclear stain with neutral red.

ACUTE MYELOGENOUS LEUKEMIA.

Until recently all cases of acute leukemia were regarded as belonging to the lymphatic type of the disease. Frænkel, who made a careful study of the literature up to 1895, did not admit the existence of an acute myelogenous leukemia. Pinkus, in his article in Nothnagel's "System," published in 1901, was not able to record a single case. Billings and Capps [18] give the details of an undoubted case of acute myelogenous leukemia observed by them and the analysis of seven cases collected from the literature. The duration of the disease in their case was two months. The number of leucocytes varied from 540,000 to 374,000 per cm. When first examined the blood showed 30% of myelocytes and 39% of large mononuclears. Later the percentage of myelocytes increased to 54.

The onset in most of the recorded cases was sudden. Four cases had an inflammation of the throat, and necrosis of the jaw or palate occurred in three instances. The lymph nodes were usually somewhat swollen, and the spleen was always palpable, although in only two instances greatly enlarged. The anemia in every case was severe and progressive. The number of leucocytes ranged from 16,000 to 540,000. The average count was much lower than usually found in the chronic myelogenous leukemia. There was difficulty in separating the mononuclears and the myelocytes, due to the fact that many transitional cells with faint indistinct granules occurred. The myeloid cell has usually an eccentrically placed nucleus, which is often oval and the protoplasm is frequently faintly granular.

When the large mononuclears are associated with a considerable number of myelocytes of the same size, and when many of the mononuclears show indistinct granules, the writers believe it is safe to regard them as myeloid cells.

In the recorded cases of acute myelogenous leukemia the large mononuclear never formed less than 15% of the leucocytes in the blood, while the myelocytes varied from 8 to 60%. Eosinophiles, mast cells and nucleated red corpuscles were present in varying number in some cases and absent in others.

Billings and Capps do not refer to the striking case of acute myelogenous leukemia observed by Kraus.[19] The patient was a woman of the age of twenty-seven. The onset was sudden, and apparently the entire course of the disease embraced only seven days. There was fever, and hemorrhages occurred into the gums, skin and uterus. The blood contained 40% of hemoglobin. The myelocyte was the predominating cellular element. There were almost no lymphocytes and no normoblasts. Türk [20] demonstrated last spring at a meeting of the Vienna Society of Internal Medicine the anatomical and microscopical preparations from a case of acute myelogenous leukemia. The clinical picture was that of pernicious anemia, and the blood findings were remarkable. The anemia was profound. There were 1,060,000 erythrocytes and 19% of hemoglobin. The marked alterations of the red blood corpuscles which occur in pernicious anemia were absent. No erythroblasts were seen. The leucocytes numbered 42,200, and of these 47% were myelocytes, 32% polynuclear leucocytes and 14% lymphocytes. Eosinophiles were rare and no mast cells were found.

At section the bone marrow of the vertebræ, ribs and sternum and the proximal parts of both femora was homogeneous and of a grass green color. Microscopically, the marrow was composed almost exclusively of neutrophilic myelocytes.

TOXEMIA IN ACUTE LEUKEMIA.

Hayem and Bensaude [21] have shown that the toxemia of purpura hemorrhagica resembles that produced by injecting into the blood-stream of one animal the blood or serum of another species. In the list of maladies of this type they include, in addition to purpura hemorrhagica, pernicious anemia, variola hemorrhagica and acute hemorrhagic leukemia.

They report a case of acute hemorrhagic leukemia with the blood picture of lymphatic leukemia in which the spleen, liver and lymph-nodes were not enlarged. The duration was three months. At the close there was severe hematuria, associated with cutaneous and visceral hemorrhages, epistaxis, and metrorrhagia.

CHANGE IN TYPE FROM MYELOGENOUS TO LYMPHATIC LEUKEMIA.

Wilkinson [22] reports a case of chronic leukemia with great enlargement of the spleen and complete absence of lymphatic envolvement. A blood examination toward the close of life showed myclocytes and lymphocytes in about equal number. The white count was 560,000 per cm. During the week following this first examination the blood picture changed to that of a typical lymphemia, though an occasional myclocyte was present.

Klein [24] has observed 41 cases of leukemia during the past twelve years; 23 of these were of the lymphatic type and 7 ran an acute course. In one of the acute cases, in which 99% of the 360,000 leucocytes per cm. were lymphocytes, not a single enlarged lymph-node was found during life or at autopsy, and the spleen was barely palpable. Acute cases with only slight enlargement of the lymph nodes were not rare. In

these cases three symptoms are of diagnostic importance: — the alterations of the buccal mucous membranes, the hemorrhagic tendency and the anemia. Without a blood examination some cases of acute lymphatic leukemia could not be distinguished from scorbutus or others from Werlhof's disease.

Klein maintains that in the diagnosis of lymphatic leukemia the increased percentage of lymphocytes rather than the total number of leucocytes is the essential thing. In one of his cases the leucocyte count ranged from 5,800 to 75,000. The percentage of lymphocytes was 54.8 when the total number of leucocytes per cm. was as low as 7,400.

ERRORS IN DIAGNOSIS OF ACUTE LEUKEMIA.

Melland [23] truly observes that in the acute form of leukemia "there is frequently nothing either in the size of the spleen or the lymph nodes to suggest the true nature of the disease or the advisability of estimating the numbers of leucocytes, and so, in the absence of a routine blood examination in all cases of severe anemia, a diagnosis of pernicious anemia, of purpura hemorrhagica, of scurvy, or even of severe chlorosis may be made. Indeed, in the thirty-two years from 1857, when Friedreich described his first case, to 1889, Ebstein was only able to collect 17 cases in the medical literature, whilst in the last ten years, during which systematic blood examination has become the rule, some 40-odd cases have been added to the list." Melland reports a case in which the anemia was intense and hemorrhages frequent. No enlargement of the spleen or lymph-nodes occurred and the post-mortem findings were almost negative. Smears of the bone-marrow showed a lymphoid degeneration; both large and small lymphocytes were present, but the former largely predominated.

THE ORIGIN OF LYMPHOMA.

Glénski [25] studied a case of lymphatic leukemia in which there were multiple lymphomata on the meninges and ribs and a leukemic infiltration of the tissues of the orbit causing exophthalmos. The author believes that the so-called heteroplastic lymphoma may arise *in loco* from pre-existing lymphoid tissue or may be due to the proliferation of lymphocytes which have left the blood stream. He states he has often seen lymphocytes in the various coats of the vessel wall from the sub-endothelial layer to the adventitia. These lymphocytes pass from the blood through the vessel wall to the surrounding tissue, where they multiply and give rise to lymphoma. Glénski does not believe the lymphocytes have an independent movement.

TRAUMA A CAUSE OF LEUKEMIA.

Reckzeh [26] reports interesting observations on a series of leukemic cases which occurred in Kraus's Berlin clinic. He thinks that injuries are important predisposing factors in the causation of the disease. As men are more exposed to trauma than women, it is not surprising that leukemia is more frequent among men. All his patients were males. This theory of the causal relation of trauma to leukemia is supported by several of the cases studied.

Shortness of breath was frequently noted. This may be the result of some complication such as pneumonia or pleurisy, but is usually due to pressure from the enlargement of the thoracic lymph-nodes. In three cases there was much pain in the sternum. In every case the blood showed a definite poikilocytosis. Granular degeneration of the erythrocytes was observed in only one instance. The blood-plates were frequently very numerous. The author accepts the view of Pappenheim and others that every leukemia is of myelogenous origin and divides the cases into the mixed-cell and lymphoid varieties. Experiments undertaken to throw light on the active movements of the lymphocytes yielded negative results.

One case presented the clinical features of pernicious anemia as well as of leukemia. Similar instances have been reported by Strauss, Grawitz and others. There was marked poikilocytosis and polychromatophilia and extensive granular degeneration. Numerous microcytes and megalocytes occurred. Megaloblasts were present in great number. The number of erythrocytes ranged from 1,850,000 to 3,750,000 and the hemoglobin from 40 to 55%. The leucocyte count varied from 302,000 to 102,000. Myelocytes formed from 5 to 27% of the white cells. Toward the close the eosinophiles vanished from the blood. Reckzeh regards the pernicious anemia as secondary and due to profuse hemorrhages which occurred during the course of the leukemia.

LYMPHATIC LEUKEMIA WITHOUT MACROSCOPIC ALTERATIONS OF THE BONE MARROW.

In the brief allusion to Dennig's case on page 681, an unfortunate typographic error makes 'macroscopic" read "microscopic." There were no gross morbid changes of this case, but a smear from the bone marrow showed a decided increase of lymphocytes. In all the other recorded cases visible alterations in the bone marrow have been present. The author states that Walz, who performed the autopsy and who is well known through his studies of leukemia, will make the histological report.

FIRST AID BY RAILWAY EMPLOYEES.

THE trainmen of the Chicago and Eastern Illinois road are to be given a course of instruction regarding the best method of giving aid to the injured in case of railway wrecks. The plan is to establish schools in the various division headquarters and require the trainmen to attend the lectures and demonstrations which will be given on the subject. — *Med. Record.*

Reports of Societies.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twentieth Annual Meeting, Held at Washington, D. C., May 12–14, 1903.

(Concluded from No. 25, p. 685.)

Dr. R. A. Cleemann of Philadelphia described

A CABIN FOR OPEN-AIR TREATMENT.

Plans were shown of a cabin, the sides of which let down and afford free circulation of air. The cabin rests on posts which form the four corners and rise to eleven feet in height. Horizontal beams extend between these posts at a distance of two feet above the ground, and on these the floor of the cabin is laid. The walls of the cabin, made of ⅛-inch planking, are eight feet high; three of the walls are hinged along their lower edge so that they may open outwardly and downward. Posts are placed at a suitable distance outside the cabin to prevent their descent below the plane of the floor. When the sides are drawn up they fit snugly into grooves or rabbiting. The walls are let down and raised by pulleys attached to the upper beams. These movable walls are the important feature.

Dr. W. C. Glasgow of St. Louis read a paper entitled

SOME EXPERIMENTS IN THE TREATMENT OF PULMONARY AND LARYNGEAL TUBERCULOSIS BY MEANS OF THE ELECTRIC LIGHT.

The treatment gave satisfactory results.

Dr. Rochester of Buffalo stated that he had been experimenting for the last two years on the consumptives of the Erie County Hospital, using the actinic rays, and that he had obtained absolutely no beneficial results thereby.

Dr. Thomas D. Coleman of Augusta, Ga., read a paper on the

SUSCEPTIBILITY OF THE NEGRO TO TUBERCULOSIS.

It was shown that the present condition of the negro has been growing worse since he has been left to his own devices. The natural susceptibility to tuberculosis in the colored race is accentuated by bad environment, bad habits, improper food and poor clothing. There is a racial predisposition to the disease. Evidence was adduced to show that the negro was comparatively healthy in slavery times. Now the death-rate from tuberculosis is about twice as great in the colored as in the white race, as shown by statistics from Charleston, S. C., Atlanta and Augusta, Ga., and New Orleans, La. Since the abolition of slavery the negro has left the plantations in large numbers and has sought the cities. Dr. Coleman suggested the usual remedies, viz., moral education, fresh air and disinfection. In Augusta the ratio of deaths from tuberculosis to total mortality for the last five years has been for whites 1 in 11.36; for colored 1 in 6.11; in other words, though the colored population is from 10 to 16% less than the white, in five years tuberculosis caused the death of 147 white persons and 448 colored. In round numbers, allowing for the discrepancy in population, about twice as many colored people die annually from tuberculosis as in the white race. In Atlanta the ratio is 1 to 10.90 for whites and 1 to 8.12 for colored; in New Orleans, 1 in 8.95 white, and 1 in 6.64 colored.

DISCUSSION.

Dr. Sanger Brown thought that much of the discussion that we see in the press, societies and elsewhere relative to tuberculosis misses the main point — the importance of pure air and proper ventilation. In the British Army we know that barracks were maintained throughout the civilized world in every climate, and before the subject of ventilation was properly presented in relation to tuberculosis we know that the death-rate was something frightful from tuberculosis, and when those same men, under the same conditions, same food, habits, etc., were given large barracks and the ventilation was looked to the disease almost disappeared from among them, and yet here we go on talking about spitting on the floor and the influence of civilization and a great many other things, losing sight of those demonstrations.

Dr. Edward R. Baldwin. I am convinced that such a racial weakness exists, and I think that this is amply illustrated by the susceptibility shown by various races toward certain of the infectious diseases. Racial susceptibility is still a recognized factor, and I agree fully with Dr. Coleman in this particular.

Dr. Thomas J. Mays. About four or five years ago I undertook to investigate the relation between consumption and insanity in the negro. I communicated with eminent medical men in the South, and was informed that, for example, in the state of Georgia, there were before the Civil War or before the emancipation of the negro, about forty insane negroes, and that pulmonary tuberculosis was practically unknown in that state. The same testimony came from North Carolina and also from Mississippi and Virginia, namely, that tuberculosis was practically unknown in these states. The results of my investigation led me to believe that insanity comes first amongst the negroes, then probably syphilis, or possibly syphilis precedes insanity and then comes tuberculosis.

Dr. Beverley Robinson of New York opened the discussion on

THE COMMUNITY AND TUBERCULOSIS.

After discussing the uses of sanatoria for the well-to-do and the poor, Dr. Robinson spoke of home treatment, which, for the vast number, is the only available treatment. The day of specifics is passing. Hygiene in its broadest and best sense is, after all, our main reliance. Statistics based on other means, no matter how favorably interpreted by their warm advocates,

meet with little response from those who have learned by long experience to become properly skeptical. We are looking forward to the bright day when, perhaps, a really efficacious anti-tubercle serum shall be discovered or, better still, an immunizing serum. Dr. Trudeau's work in this line was referred to, and encouraged us to believe that the day is not far distant. Dr. Robinson referred with gratification to the excellent results of Dr. John F. Russell of New York, reached by improving the resistance of the patient by administering fats in assimilable form.

Dr. Robinson hoped that while seeking to improve or abolish the nests of disease we will not lose sight of the broadest humanity for the sufferer. Don't make him a social outcast! Don't add to his misery. Tuberculosis is not contagious in the ordinary sense of this word and in the same way as the eruptive fevers, for example, are contagious, through a third person or through the air of the patient's room. One may be as safe in the room of a phthisical patient as anywhere else, provided, of course, every rational and important precaution and observance be upheld to prevent infection. The disease is infectious and communicable, but not contagious. Dr. Robinson noted the growing repugnance found at summer resorts to tuberculous persons. But in an experience of thirteen years in the Out-door Department of the New York Hospital where patients coughed, expectorated and where frequently tuberculous sputa reached the floor, dried up and were later wafted freely to the respiratory tract of all present, no case of consequent infection was noted. Dr. Robinson advocated tent life and took, in general, a broad humanitarian and rational view of the whole subject.

DR. FREDERICK I. KNIGHT. While sanatorium physicians are perhaps the proper ones with their statistics to defend the sanatorium treatment, there is no doubt but that tuberculous patients may recover under all conditions whether treated or not treated; many of them have recovered in my practice under the most disadvantageous circumstances, with no proper hygiene or care of any kind. Of course, those cases are comparatively few. Others have recovered under old-fashioned treatment, but I do not hesitate to say that far more, very many more, have recovered under the proper modern treatment, which we call sanatorium treatment. It isn't necessary for a person to be in a public institution, but it is very important for him to be away from home, if possible, particularly if he lives in a rigorous climate. He can be away from home, for instance, in a private house at Asheville or at Saranac lake and be treated practically on the sanatorium plan; but he must be away from home, and I have always advised a patient even if living in a good climate to go out of his own home if he wished to be treated to the best possible advantage. That is very much more true, though, in the case of a rigorous climate. It is impossible in New England to make a patient live on the piazza, to live out of doors all day long as they do in the Adirondacks for instance. He will do it there because everybody else does it. But it is different in New England; it necessitates his being alone all day long, and he won't do it; he runs into the furnace or stove or whatever it may be, because the rest of his family is there. So I say that the home treatment cannot be carried out as satisfactorily in a cold climate. Now, in regard to tents. I never saw a tent that was comfortable in summer; it is too hot with the heat of the sun, and in the winter the air must be foul. I don't see how we can well heat and ventilate a tent in cold weather so that the patient has pure air.

DR. E. O. OTIS. Dr. Robinson seems to disparage, I might say, the private sanatorium for paying patients. There are two points I think that it is well to bear in mind in this connection with regard to private sanatorium. Dr. Knight has just referred to one; that is, the control of the patient. You may have a patient who could command any amount of money who lives in the country, who can turn his whole house into a special sanatorium, and still you may not be able to control that patient, which is one of the most important points in the sanatorium treatment. I had an experience of that sort this very last year: the patient was wealthy, the house was in the country, it was on a hill, had verandas on all sides, and every condition so far as material resources were concerned for good treatment, but the husband of the lady declared that she could never be properly controlled under those circumstances, and she was consequently sent to a paying sanatorium where she is recovering. The second point I desire to make is this: the educative influences of the sanatorium treatment. We know that in Massachusetts we are experiencing the great value of the teachings of the cured patients, the graduates of Rutland, upon the community. Is it not as important that these paying patients should give us that influence upon the class of people with which they are brought in contact? It is a very valuable and important matter to be kept in mind. One thing further. Dr. Robinson has referred to the cruel and inhumane treatment accorded in many cases by the unreasoning fear of others in regard to this disease. I think that the profession itself is largely to blame for this. I do not know of any other one thing that has done more perhaps to create that undue fear than the signs which we put up in all of our street cars and at our stations and many other places, against spitting. That is all right, but it seems to me at least inconsistent to have a large sign with regard to spitting on our street cars and not to pay any attention to the matter of pure air and ventilation.

DR. THOMAS J. MAYS of Philadelphia read a paper on the

DEATH RATE OF ACUTE PNEUMONIA.

He noted its increasing prevalence and its rank

as the most frequent cause of death in the great cities in the United States, outranking pulmonary tuberculosis in nearly every instance. While statistics are more or less incorrect, still he believes that on the whole they are in respect to mortality reasonably accurate and useful. Dr. Mays' presented charts covering a period of twenty-five years, showing the mortality from acute pneumonia in fourteen of the cities in the United States, including Rhode Island and New Jersey and representing a total of over eleven million inhabitants. The lines showed the deaths from pneumonia, pulmonary tuberculosis and heart disease and the gradual ascendancy of the pneumonia curve. In Chicago the greatest increase in the mortality from pneumonia was observed, amounting in forty-two years to over 350%. The deaths from heart disease increased 450% in the same period. Dr. Mays said there is no good reason for believing that pneumonia has gradually sprung into such prominence as to cause present or future alarm, for its highest death rate occurred before 1896, and since that time it has declined 21.17%. The conclusion is that deaths from pneumonia are decreasing; that deaths from disease of the heart are increasing and that deaths from phthisis decreased until five years ago, but have markedly increased since that time.

Dr. Thomas D. Coleman of Augusta, Ga., read a paper entitled

SOME COMPLICATIONS OF PNEUMONIA, WITH REPORT OF CASES.

Dr. Coleman assumed that the mortality of pneumonia was about 21.8%, taking the world over and taking statistics as they are presented. The most common complication is pleurisy, so common that it may almost be considered a part of the disease, for it occurs in all cases where pneumonic consolidation reaches the surface of the lung. Endocarditis and pericarditis and gangrene of the lungs are formidable complications.

Dr. Glentworth R. Butler of Brooklyn read a paper on the

TREATMENT OF LOBAR PNEUMONIA.

Dr. Butler noted the absence of any specific treatment of the disease, but looks for it in the discovery of an antitoxin which will counteract the toxemia of the disease. The possibility that the disease is not a bacteriological unity and that it may be caused by other pathogenic organisms than the pneumococcus of Fraenkel would indicate the necessity in this case of suitable mixed antitoxins.

DISCUSSION.

Dr. Judson Daland, Philadelphia: I am of the opinion that the high mortalities quoted for pneumonia are from hospital and not private practice. There is one simple point in regard to pneumonia and that is that frequently in severe cases death occurs through the heart as mentioned by Dr. Rochester.

Dr. Egbert Lefevre, New York: In regard to the treatment of the so-called cardiac failure, I have made some study of cases of pneumonia brought to the hospital and also in private practice in relation to the blood pressure in these cases and the question of drugs used to control the same. I find that these cases may be divided into two great classes, namely, those in which we have a true failure of the heart where the heart muscle weakens, and those cases where the apparent failure of the heart is in reality due to vasomotor paralysis and dilatation of the blood vessels. This collapse in the general vascular system is probably caused by the direct action of the toxins on the vasomotor center. The intravascular blood pressure shows this very distinctly when taken by the Gaertner or Riva-Rocci instruments. The vessels are widely dilated, and as a result we have a rapid and irregular heart and a loss of tension in the whole arterial system. The first sound of the heart loses its distinct character and becomes very similar to the second sound. These cases react quickly to drugs that act upon the medullary centers. In the other class where the heart itself is primarily affected, I find that stimulants which act directly upon the heart produce the best results, such as the digitalis group, for instance, or preferably strophanthus. In regard to the other cardiac stimulants, I have largely discarded the alcoholic and substituted therefor the liquor ammonii acetatis.

Dr. H. L. Elsner, Syracuse, N. Y.: It is a well-known fact that the pneumococcus toxin paralyzes the spinal centers, and that a vasomotor paralysis results. In cases in which nitroglycerine and the nitrites have been indiscriminately used much harm results. If the resistance of the peripheral blood vessels is far removed you add insult to injury, and I believe there is an enormous amount of extra work thus thrown upon the right heart. There are cases of arterial sclerosis in elderly people with pneumonia with tense arteries, where the arterial wall offers monstrous resistance to the heart with extremely high arterial tension, where I believe nitroglycerine does much good. But these are exceptional cases. The truth of the matter is that the indication which we must always keep in mind is toward stimulating the right heart. One remedy not mentioned here to-day is spartein, which I believe to be one of the best remedies for this purpose, not in small but in large doses of, say, 1 or 2,gr. administered every two or three hours. Then, too, adrenalin or suprarenal extract is useful. Those of us who have recently used the sphygmomanometer to test blood pressure I believe can bear testimony to the efficiency of adrenalin and suprarenal extract in this condition. I believe that we have in suprarenal extract and its adrenalin the very best heart tonic which we can use, and I believe that all of these cases ought to be given suprarenal extract or adrenalin from the beginning as a food and not a medicine. Pneumonia justifies polypharmacy, and persistent effort on the part

of the doctor and nurse at every moment in the illness of these patients will often bring its reward in the unexpected and brilliant results.

DR. E. FLETCHER INGALLS of Chicago presented a paper on

THIOCOL IN THE TREATMENT OF CROUPOUS PNEUMONIA.

He showed that thiocol may be given to pneumonia patients in large doses without disturbance of the digestive tract and without apparent harm. In no case did he observe that it affected the temperature, pulse, respiration or physical signs because in these cases where these factors indicated improvement the natural course of the disease would have been expected to cause a similar change. Dr. Ingalls suggests 5 gr. as an initial dose, rapidly increasing to 30 gr.

DR. G. R. BUTLER, Brooklyn, N. Y.: I have perhaps seemed to insist a little too strongly on the importance of treatment in pneumonia, but it was written while still under the impression got from certain consultation cases. The physicians in attendance were therapeutic nihilists, and to my mind their patients were being left to drift to death without a finger lifted to prevent. Under proper therapeutic treatment recovery took place, and it was while laboring under a very vivid recollection of these cases that I wrote the paper.

DR. S. E. SOLLY of Colorado Springs reported a case of

TUBERCULOUS BRONCHIECTASIS.

The patient was a woman aged forty-eight, who had a tendency to colds and came to Colorado from western New York in July, 1902. She had fever, loss of weight, rapid pulse and a scanty, watery sputum containing staphylococci and streptococci, but no tubercle bacilli. There was a small area of consolidation of the right middle lobe. There was a leucocytosis of 13,800. Tubercle bacilli appeared in the sputum in rather large numbers. The expectoration was fetid and reached sixteen ounces in twenty-four hours. As the sputum became scanty the temperature rose; as it discharged the temperature fell. At no time was there evidence of a cavity. Skiagraphs showed what appeared to be a dilated bronchus. Recovery seems to be assured at the time of the report.

Dr. Solly said that tuberculosis may occur as a complication of bronchiectasis, but that practically bronchiectasis of large areas never arises as a complication of tuberculosis. Nevertheless it is admitted that small bronchiectacic areas, without special clinical importance, are not infrequent, also that large areas sometimes occur in the tuberculous in cases in which there have been circumscribed processes in the apices, or a tendency to recovery by subsequent fibrosis, and only under such circumstances.

DR. RICHARD C. NEWTON of Montclair, N. J., read a paper on

DEEP BREATHING.

Dr. Newton advocated deep breathing so that, by the increase of respiratory capacity, the action of the heart and blood vessels will be strengthened and the oxygenation of the blood will be increased, with the result that all the tissues will be better nourished, metabolism will be better carried on and secretion and elimination will be more perfectly accomplished. Every bodily function will be better performed and the improvement will be more manifest than in digestion and the assimilation of food. Few people breathe properly and they know very little of this important physiologic process. Textbooks have little to say on this point. The abnormal respiratory conditions in obese subjects, for instance, should be studied. Indolent and shallow breathing causes suboxidation with resulting obesity, and obesity is a prominent cause of dyspnea on exertion. Children should be taught deep breathing early and it should have a place in the physical exercises of all schools. Dr. Newton quoted Dr. Edward Hitchcock, who has said that "There is no doubt that if as much care were bestowed on our young in seeing that this particular part (the thorax) was developed with that care that the brain receives, tuberculosis would almost disappear."

DR. D. H. BENGEY of the Laboratory of Hygiene, University of Pennsylvania, presented a paper entitled

NEGLECTED PROPHYLACTIC MEASURES AGAINST DISEASES OF THE RESPIRATORY TRACT.

The paper showed the bad effects of dust, especially in cities where electric cars and smooth pavement are found. He advocates greater efforts to flush and cleanse the streets. Defective ventilation in the schools is another cause of respiratory affections. Neglect of proper ventilation is a cause of untold suffering.

DR. C. L. MINOR of Asheville, N. C., read a paper on

THE CYRTOMETER, A NEGLECTED INSTRUMENT OF PULMONARY DIAGNOSIS AND PROGNOSIS.

The following officers were elected: President, JAMES C. WILSON, M.D., of Philadelphia; Vice-Presidents, DR. THOMAS DARLINGTON, JR., of New York; DR. THOMAS D. COLEMAN of Augusta, Ga.; Secretary, DR. GUY HINSDALE of Philadelphia.

The twenty-first annual meeting will occur June 2, 3, 4, 1904, at Philadelphia.

Recent Literature.

The Medical Epitome Series: Anatomy. A Manual for Students and Practitioners. By HENRY E. HALE, A.M., M.D. Series edited by V. C. PEDERSEN, A.M., M.D. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1903.

This volume purports to be more than the mere essentials of human anatomy. It goes somewhat beyond the scope of the ordinary quiz-compend, and contains in compact form the important points of anatomical knowledge. Questions are appended to some of the chapters.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 24, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS

THE FORMATION OF BILIARY CALCULI ELSEWHERE THAN IN THE GALL-BLADDER.

AT a recent meeting of the Surgical Section of the Suffolk District Medical Society the question was discussed whether or not calculi formed in the liver after cholecystectomy. It would appear from the chemistry and pathology of biliary calculi that, should they be met with after removal of the gall bladder, they in all probability were there before the operation and had simply remained undiscovered at the time.

The theory that biliary calculi originate from concentration of the bile has long since been laid aside and given place to the view that cholesterin and calcium bilirubinate, which are essential for the formation of calculi, collect about débris of one sort or another which has accumulated in the gall bladder and there become precipitated or slowly crystalize.

The experimental work of Dochmann, which consisted in the ligation of the cystic duct, showed that when obstruction to the exit of bile existed the percentage of calcium in the bile of the gall-bladder increased as compared with that of the liver; and since an increased percentage in the calcium signifies a decrease of solubility of cholesterin, as well as bilirubin, it would be quite rational to conclude that an obstruction to the flow of bile cannot be excluded as an etiological factor in the formation of calculi.

The experiments of Naunyn, however, showed that an increase of the calcium salts of the bile in amounts obtained in Dochmann's experiments were not sufficient to cause the precipitation of calcium bilirubinate to take place. On the other hand, it seems well proven by the experiments of Jankau and Rey that food does not influence the percentage of calcium salts in the bile. When salts of calcium have been absorbed they are secreted again, more especially in the colon. It would also appear that the percentage of cholesterin in the bile is quite independent of the blood in health and disease.

The question of gallstone formation has been treated by Naunyn in a masterly manner and his conclusions must be considered valid at the present day. He demonstrated that a catarrhal process, an angiocholitis desquamativa, is the fundamental cause for the formation of biliary calculi, a view upheld by all to-day.

The epithelial débris which have been cast off consist mainly of cholesterin and lime salts and serve as nuclei for calculi; bilirubin and cholesterin being deposited on these, the calculi continue their growth. The entrance of pathogenic bacteria from the intestine, such as the B. coli or typhosus, are also etiological factors, inasmuch as they give rise to cholecystitis, provided an obobstruction takes place. An injection of the B. coli into the gall bladder will only set up a cholecystitis when the cystic duct has been ligated.

The etiology of cholelithiasis may be summed up as follows: A desquamative catarrh, due to the entrance of pathogenic bacteria from the intestine, followed by an obstruction to the flow of bile.

It is quite evident that theoretically, biliary calculi can form wherever bile is present, therefore they may be developed in the liver, cystic duct and gall-bladder. These are authentic observations proving that calculi may primarily form in the intrahepatic cystic ducts. This, however, must be of most infrequent occurrence, as can naturally be surmised if one considers that in a patent cystic duct the bile current would carry down any nuclei that might be forming and since the cystic duct system becomes broader as its final exit from the liver is approached, it consequently must happen that small calculi originating in the finer branches of the hepatic duct must also be washed down by the bile current passing onward into the choledochus and into the intestine.

Not infrequently calculi have been met with in the hepatic cystic ducts when an obstruction of some duration has been present in the choledochus. In a case operated on by Riedel, which came to autopsy, numerous calculi were found in the hepatic cystic ducts, the cystic and choledochus being obstructed by a large calculus

sending ramifications into each. Other similar cases have been recorded.

As with the intrahepatic ducts, calculi exceptionally form in the hepatic duct and choledochus and a case is reported by Niemer in which he believes that a calculus originated in the hepatic duct. The gall-bladder and cystic duct, as well as the choledochus and hepatic ducts, were full of stones, those in the hepatic being tightly imbedded in the hepatic parenchyma. The intrahepatic cystic ducts contained numerous calculi and bile-stained pus. It is, however, probable that the calculi found in the hepatic duct formed there after the choledochus became occluded by a stone. Other similar cases have been recorded, but it is more than probable that the obstruction of the main ducts was the original cause. It therefore appears that primary formation of calculi in the cystic duct, if occurring at all, is most infrequent. They are usually secondary to obstruction of the choledochus from a calculus coming from the gall-bladder or from pressure without.

REPORT OF THE SURGEON-GENERAL OF THE UNITED STATES NAVY.

THE annual report of the Surgeon-General of the United States Navy for the year 1903 has recently appeared. Many recommendations and suggestions for the improvement of the service are made, and the report, as usual, contains many facts of interest. It appears that since the passage of the law increasing the medical corps up to 150 members, 16 applicants have been successful in meeting the requirements, and there are now but 11 vacancies, which it is hoped may be filled before the expiration of the calendar year. In spite of this increase, it became necessary to increase the medical service by the appointment of acting surgeons for temporary service. In making these appointments particular care was taken to select men fitted, both physically and mentally, for the service, with prospect of promotion to the regular service.

An excellent suggestion is made that the present titles in use by the medical corps are somewhat derogatory to the dignity of their office. It is, therefore, recommended that Congressional action be taken to permit the renaming of the different grades of the medical corps, using, for example, the term surgeon-admiral instead of surgeon-general, surgeon-captain instead of medical director, surgeon-lieutenant in place of past assistant surgeon. Such a change certainly seems in accordance with the dignity which should be invested in men of this branch of the service.

Regarding the matter of hospital ships, certain interesting facts are stated. This country was the first to provide such vessels for active service, but since the recent war with Spain it has fallen behind other nations in this respect. At the last international medical congress the inspector-general of the British Navy's medical corps stated that the British Navy is the only one at present which has a hospital ship permanently in commission. He also stated that eight more ships of this type were being planned, each with a capacity for 200 patients. The need of such permanent ships in the United States Navy is becoming more and more apparent, particularly owing to the policy of the department in carrying on extensive drill operations at distant stations. At recent manœuvres at San Juan, P. R., it is stated that one vessel was unable to take part in the drill, owing to the widespread prevalence of malaria among the crew. This might, it is believed, have been avoided had a hospital ship been available. In general, it is the opinion of the admiral of the navy that for a fleet and base having together a force of 10,000 men, a hospital ship should be provided.

For those interested in the details of the medical management of the Navy, the report should be of much interest. It contains the usual statistical tables and individual reports from the various stations and vessels in active service.

THE RETIREMENT OF DR. EDWARD COWLES.

IN the retirement of Dr. Cowles from active service as superintendent of the McLean Hospital, the branch of medicine which he represents loses an indefatigable worker and a most able executive. His service at the hospital has been long and honorable, dating from Dec. 11, 1879, when he assumed the superintendency of what was then the McLean Asylum. He has therefore been contemporaneous with the striking advances which the last two decades have seen in the study and care of the insane and in the development of the science of psychiatry in its wider bearings. During this eventful epoch, which is surely destined to be but the beginning of a period of continued progress, the institution of which he is the head has unvaryingly been a leader and not a passive follower in the onward movement. There has been no hesitation in accepting the teachings of what has come to be known as the Kraepelin school, and of putting into active practice in this

country the plan of study of mental disease which Kraepelin has done so much to further.

Not the least of Dr. Cowles' services to the profession and to the community has been the unfailing insistence upon the abolition of old methods and the introduction of the new. His influence may be seen in the substitution of the word " hospital " for " asylum," in the development of training schools for nurses in institutions for the insane, and in his capacity to draw to his assistance men of distinguished ability in the various fields of psychiatric research. In his retirement from active service he has the somewhat unusual satisfaction of realizing that he has been closely identified with a movement for the betterment of the insane, in the inception of which he was a participator, and in the consummation of which he has been a constant factor.

Although retiring from the active duties of the superintendency, he becomes a member of the Board of Consulting Physicians, and in this capacity will, no doubt, for many years to come render the hospital a further and peculiarly valuable service.

MEDICAL NOTES.

A Medical Press Exhibit at the St. Louis World's Fair. — An effort is being made to organize a collective and comprehensive exhibit at the St. Louis Exposition of the medical and scientific publications of America. Those interested may communicate with Dr. Charles Wood Fassett, St. Joseph, Mo.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Dec. 23, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 80, scarlatina 47, typhoid fever 11, measles 158, smallpox 0.

Centenarian. — Mrs. Honoretta Marshall of Webster, Mass., died in Worcester Insane Hospital, Saturday, Dec. 19, at the reputed age of 105 years 4 months and 12 days.

Sanitary Conferences for the Health Officials of Connecticut. — The Connecticut Board of Health has inaugurated sanitary conferences, to include all the health officials of the state, encouraged thereto by the favorable experiences of such assemblings in neighboring states. The proposed subjects for consideration at these conferences are of an eminently practical character and such as relate to the daily official functions of local health officers.

Bequests to Hospitals. — By the will of the late George W. Boyd the following institutions are benefited, among many others: The Perkins Institution for the Blind, $5,000; Maine General Hospital at Portland, for free beds, $12,500; Maine General Homeopathic Hospital at Portland, for a like purpose, $12,500; Memorial Hospital for Women and Children at Brooklyn, N. Y., for free beds, $5,000; the Children's Hospital, Boston, $5,000. A reversionary interest of $35,000 is also given to the Massachusetts Homeopathic Hospital, and $25,000 to the Massachusetts General Hospital upon the termination of certain trusts.

NEW YORK.

Lincoln Hospital. — The graduating exercises of the training school for nurses of the Lincoln Hospital and Home were held Dec. 12 at the New York Academy of Medicine, when diplomas were awarded to a class of twelve young negro women and an address was made by Booker T. Washington. This institution, which was formerly situated at 65th Street and First Avenue, where it was known as the Colored Home and Hospital, has, since its removal to the Bronx, developed into a full-fledged hospital, with ambulance service, etc.

Appointments, Columbia University. — Among the appointments announced at the monthly meeting of the Trustees of Columbia University held on Dec. 7 were the following: Dr. Thomas B. Morgan, at present Professor of Biology at Bryn Mawr College, to be Professor of Experimental Zoology; Professor Hugo Münsterberg of Harvard University, to be non-resident Lecturer in Psychology for the current academic year.

Suppression of the Mosquito. — A convention, called at the suggestion of the Governor of New Jersey, of scientific men and others interested in the suppression of the mosquito, was held in New York on Dec. 17. Robert W. de Forest, president of the Tenement House Commission and of the Charity Organization Society, was elected permanent chairman, and resolutions were adopted recommending the appointment of a provisional committee to consider the formation of a central organization of national character with which local bodies might co-operate in conducting a general mosquito crusade.

INCREASED WATER SUPPLY. — The completed details of the recommendations of the commission appointed to investigate the most feasible sources for an increased water supply for the city, whose preliminary report in November was recently noticed in the JOURNAL, were submitted by Mayor Low to the Board of Estimate and Apportionment on Dec. 18. With the report of the commission he presented a letter in which he showed the ability of the city, from a financial point of view, to take immediate steps toward the consummation of the desired end, and stated his conviction that the professed new system would eventually be more than self-supporting. He also urged that the incoming administration, upon whom this responsibility will devolve, should give immediate consideration to the great work that has now been outlined.

SMALLPOX. — In view of the prevalence of smallpox in Philadelphia and other Pennsylvania cities, the Board of Health is taking vigorous measures to prevent an outbreak of the disease in New York, and sixty-four new inspectors have been appointed to co-operate with the regular vaccinating corps. In Manhattan but one case of smallpox has thus far been found, that of a Pullman car porter, but there have been several cases in Brooklyn. Investigation showed that they originated with laborers at the Navy Yard, and a dozen inspectors were promptly dispatched to the yard, with orders to vaccinate all the sailors, marines and workmen who did not object. As less than one-tenth of the men (numbering over five thousand) are willing, the Secretary of the Navy has been requested to issue instructions requiring the remainder to submit to vaccination The Pennsylvania Railroad Company has set a good example by ordering all its employees to be vaccinated.

COTTAGE COLONY FOR AGED AND INFIRM. — The Commissioner of Public Charities has awarded a contract for the erection of the first three cottages of a new cottage colony for the aged and infirm poor of the city, which is to be established on Staten Island. Two of them are for women, accommodating thirty each, and one is for aged couples, accommodating twenty couples. The present policy of the Charities Department is to erect all additional almshouse accommodations as this new cottage colony. The almshouses (now known as Homes for the Aged and Infirm) on Blackwell's Island and at Flatbush, Brooklyn, are taxed to their utmost capacity during the winter season, and, with the normal increase in the number of inmates, will soon be quite inadequate to the demands upon them. At neither of these institutions is there any opportunity for outdoor employment for such of the inmates as are able to work a part or all of the day. To the new colony will be assigned the more able-bodied class of inmates; while the infirm and helpless will be left in their present quarters. Each cottage will have attached to it a plot of ground on which the inmates may be employed, according to their various tastes and capacities, and the outdoor life will, no doubt, be of material physical benefit to them.

A CENTENARIAN. — Isaac Price, a native of New York City, died of apoplexy in Greenpoint, Brooklyn, on Dec. 11, in his one hundred and second year. It is stated that he was a total abstainer as regards alcohol, but that he was an inveterate chewer of tobacco, and that it was to its use during practically his whole life he attributed the excellent health which he always enjoyed.

BEQUESTS TO HOSPITALS. — By the will of James King Gracie, the uncle of President Roosevelt, $25,000 is left to the New York Orthopedic Dispensary and Hospital, to be known as the Anna Bulloch-Gracie Endowment Fund, and an additional $5,000 for the endowment of a bed in perpetuity, to be known as the Esther Gracie Ogden bed.

Obituary.

IN MEMORIAM. GEORGE J. ENGELMANN.

AT the December meeting of the Obstetrical Society of Boston the following resolutions was passed:

In the death of Dr. George J. Engelmann the Obstetrical Society of Boston desires to place on record its sense of loss.

For seven years he was a faithful and devoted attendant at its meetings and contributed to their success by his discussions and writings.

He served the society faithfully as president and corresponding secretary.

A man of wide scholarship, kindly, hospitable and courteous, he left many pleasant memories for which he will long be remembered by his fellow members.

Miscellany.

REPORT OF NEW YORK'S TENEMENT HOUSE DEPARTMENT.

ROBERT W. DE FOREST, the Tenement House Commissioner of New York City, has transmitted

to Mayor Low the first report of New York's new Tenement House Department. In it he says:

"On Jan. 1, 1902, a new department of the city government, known as the Tenement House Department, was created. Since that time all the tenement houses in New York have been examined and their condition ascertained.

"The cleansing of the Augean stables was a small task compared to the cleansing of New York's 82,000 tenement houses, occupied by nearly 3,000,000 of people, representing every nationality and every degree in the social scale. The task that confronted the department was not, however, limited to this. Without organization, without employees, with all its problems before it, it was on the very day that it came into existence confronted with an organized and vigorous attack in the legislature upon the fundamental principles of the law for whose enforcement it was created.

"Without previous records, with almost no information in regard to the condition of the existing tenement houses, it was called upon to carry out an important and far-reaching scheme for their improvement, involving the structural alteration of over 40,000 buildings.

"In the period under consideration in this report a new branch of the city government has been organized, its machinery created and a force of about 400 employees trained, disciplined and educated; far-reaching and important advances in legislation have been secured as a result of the department's action, and radical and vicious attempts to break down the tenement laws defeated.

"The existing tenement houses have been frequently and systematically inspected; foul cellars have had the accumulated filth of years removed; defective and unsanitary plumbing which has apparently existed for long periods has been remedied; houses unfit for human habitation vacated; hundreds of houses have been radically reconstructed and improved; light has been let into dark rooms; vile yard privies and privy sinks have been removed and the whole sanitary condition of the city raised to a higher standard. The results of this work are clearly reflected in the reduced death-rate, which in 1902 was 18.7 as compared with 20.0 in 1901, and in the first eight months of 1903 has been reduced to 18.0.

"To those who have borne the burden of the organization of the new department what has been done seems but a beginning — a first step in the endless fight against disease and death."

The report is the most comprehensive report on this subject that has ever been made by a city department, and will shortly be printed, in two volumes, of about 1,000 pages. It will contain many photographs, plans and other illustrations. One of the leading features of the report is a series of colored maps, showing population, density of population and the nationality and the number of families living in each block throughout the tenement districts of the Borough of Manhattan.

RECORD OF MORTALITY

Deaths reported, 3,377; under five years of age, 771; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 729, acute lung diseases 677, consumption 392, scarlet fever 20, whooping cough 11, cerebrospinal meningitis 10, smallpox 24, erysipelas 5, puerperal fever 12, measles 17, typhoid fever 63, diarrheal diseases 73, diphtheria and croup 102.

From whooping cough, New York 4, Pittsburg 2, and Chicago, Philadelphia, Baltimore, Boston and Woburn 1 each. From smallpox, Philadelphia 16, Pittsburg 8. From cerebrospinal meningitis, New York 7, Baltimore 1, Lynn 1, Woburn 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Nov. 28 the death-rate was 17.6. Deaths reported, 5,092; acute diseases of the respiratory organs (London) 200, whooping cough 92, diphtheria 49, measles 114, smallpox 4, scarlet fever 30.

The death-rate ranged from 8.0 in Hornsey to 29.6 in Sunderland. London 17.4, West Ham 17.4, Brighton 13.3, Southampton 18.9, Plymouth 19.5, Bristol 16.8, Birmingham 17.6, Leicester 15.4, Nottingham 19.1, Liverpool 21.7, Bolton 17.4, Manchester 20.6, Salford 20.5, Bradford 16.6, Leeds 20.2, Hull 16.7, Cardiff 16.0, Rhondda 14.4, Merthyr Tydfil 21.1, East Ham 12.3, Warrington 23.6, York, 24.7.

METEOROLOGICAL RECORD.

For the week ending Dec. 12, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION.

At the last meeting of the Surgical Section the members voted to leave the details of the arrangement of future meetings to the chairman and secretary. It has seemed best to Dr. Harrington and myself to arrange for four meetings, to take place on the first Wednesdays of January, February, March and April. At the next meeting we are going to discuss the question of early operation in diseases of the stomach, but the subjects for the other three meetings have not been decided upon. The subjects for these discussions will, however, be announced at the next meeting, so that members may have an opportunity to look up the results of cases they have operated upon.

It is hoped that the Surgical Section may, this year, be rather a meeting for the discussion of mooted questions in everyday surgical practice than an opportunity of reporting rare cases, or of presenting digests of the papers of foreign operators. Interesting pathological subjects, or the patients themselves, may be shown at the first of the meeting, but the bulk of the evening will be devoted to discussion rather than to the reading of papers. Meetings will be held around the table in the reception room of the library, and smoking will be permitted, if so voted at each meeting by the members present. The Section proposes to send invitations to attend the meetings this winter to surgeons of the smaller hospitals in the suburbs and surrounding towns. Members of the Massachusetts Medical Society who wish to have notification postals sent them before each meeting may send their names to the Secretary.

On the next notification postal the following questions will be printed, as of especial interest in the discussion:

How often is persistent stasis of the stomach contents due to a purely functional condition?

Should exploration be advised as a routine in cases of marked stasis of the stomach contents?

Comparative results of medical and surgical treatment in cases of stasis?

E. A. CODMAN, M.D., Secretary.

RECENT DEATHS.

CORNELIUS M. O'LEARY, M.D., of Manhattanville, New York City, was killed by a motor train in Brooklyn on Dec. 12. He was born in Ireland sixty-four years ago and was a graduate of the College of Montreal. In 1862 he was graduated from the Medical Department of the University of the City of New York, and upon the death of his father, in 1864, succeeded him as professor of philosophy and classics in Manhattan College. He retained his chair up to the time of his death, but also conducted an extensive medical practice. In 1870 he was appointed an inspector in the New York Health Department and in 1871 was made a commissioner of pharmacy. Dr. O'Leary was also a writer of some note, especially on evolution and allied subjects, and was an ardent disciple of Herbert Spencer.

FRANCIS W. HIGGINS, M.D., of Cortland, N. Y., died suddenly of cardiac disease on Dec 18, at the age of forty-six years. He had been president of the Third District Branch of the New York State Medical Association and a vice-president of that society.

SAMUEL FOSTER QUIMBY, M.D., M.N.S.S., died in Salem, Mass., Monday, Dec. 21, at the age of sixty-three years. He was a member of the staff of the Salem Hospital, and had practised his profession in Salem for nearly forty years. Dr. Quimby was a graduate of the Harvard Medical School, and a member of the Massachusetts Medical Society and of the Harvard Medical Alumni Association.

ERRATUM.

IN the first line of the last paragraph of Dr. F. H. Williams' letter on radium salts, in the last issue of the JOURNAL, for "I am *not* studying the therapeutic effects," read: "I am *now* studying," etc.

BOOKS AND PAMPHLETS RECEIVED.

The Nature of Man. Studies in Optimistic Philosophy. By Elie Metchnikoff. The English Translation edited by P. Chalmers Mitchell, M.A., D. Sc. (Oxon.) Illustrated. New York and London: G. P. Putnam's Sons. 1903.

TYPHOID FEVER IN CHILDREN.[1]

BY ADOLF BAGINSKY, M.D., BERLIN, GERMANY.

Professor of Children's Diseases, University of Berlin; Director of "Kaiser und Kaiserin Friedrich Kinderkrankenhaus."

Typhoid fever of children, although known and often mentioned by the older authors, was considered to be a rare disease until the latter part of the nineteenth century, but progress and rich experience since then have taught us that it is frequent and a disease of great interest to the practitioner.

In his "Historical Study and Pathological Anatomy of Typhoid Fever of Children," V. Szokalski [2] states that Roederer and Wagner, in an essay entitled "De Morbo Mucoso," mention that this disease does occur; on the contrary, Petit and Serres describe under the name "Febris Entero Mesenterica," what they consider merely a disease of adults. Typhoid has since been known under other names, as, *e. g.*, "Entero Folliculosa," "Febris Typhoides," "Typhus Fever" and "Nerve Fever." We find, however, from Abercrombie,[3] in his monograph, "Diseases of the Digestive Canal," in the chapter, "Diseases of the Mucous Membrane of Children," the dangerous forms are so pictured that one is able to recognize typhoid fever from the description: "The fever is high, the tongue dry and leathery, the thirst increased; in other cases a sudden loss of vitality is observed which can in no way be accounted for by the frequency of the intestinal discharges, followed by coma and a look of general exhaustion. The autopsy shows in the intestine, particularly in the ileum, a variety of inflamed and slightly elevated spots sown with small vesicles and ulcers."

Somewhat later Wendt,[4] Evanson and Mannsell,[5] Meissner,[6] Constant [7] and Becqueral [8] more of less thoroughly considered the disease, but Taufin [9] and Rilliet,[10] through careful studies, made known its definite course, and in the "Handbook of Children's Diseases," by Barthez and Rilliet, a true picture of the disease is portrayed. From German authors we find a presentation of typhoid in children from Löschner,[11] in which it is interesting to note that in 104 cases he found 1 case under one year of age, 5 cases between one and four, 17 cases between four and five, 37 cases between five and seven, 20 cases between eight and nine. These facts led him to the conclusion that typhoid most frequently afflicts children between the ages of five and nine years.

The literature of the subject has recently become very rich. The course of the disease is somewhat similar to that in adults, yet in children so many peculiarities show themselves that a special study of the subject is interesting and necessary from a therapeutic standpoint.

ETIOLOGY.

Löschner agrees with the preceding authors that typhoid is more rarely seen in infancy than in later childhood; but this may be only apparent and an error of observation, because it is probable that typhoid in sucklings often is present in cases which are diagnosed as feverish dyspepsia. Further and more accurate observation will be necessary to make this point perfectly clear. Koch,[12] in his latest publication on the prevention of typhoid, alludes to the, as it were, latent typhoid in children. On this account the following observations must be accepted with caution: In the typhoid epidemic [13] in the Saxon village of Eggenslädt, observed by me, there were in 90 cases only 16 children under ten years of age. Henoch, in 97 cases, saw only two under one year of age, 21 between two and five years, 89 between five and ten years. Steffen records 148 cases — two under one year old, 28 between three and six years and 34 between six and nine years of age. In 277 cases observed by Wolberg, the majority were between six and twelve years of age. In the Kaiser und Kaiserin Friedrich Kinderkrankenhaus in Berlin I have observed 88 cases, of which 17 were between one and four years, 41 between four and ten years and 30 between ten and fourteen years old. There were 51 boys and 37 girls.

According to general observation and experience boys are more susceptible to typhoid than girls. This may be from the fact that boys by their superior quickness and more frequent contact with each other are more exposed to infection than girls, through taking water, milk, etc., away from home.

The accumulated evidence of recent years points to the conclusion that typhoid fever is most commonly spread by means of fecal infected water, milk or other liquid nourishment. Thoinot,[14] Vallin, Landouzy and Hanriot have all written concerning the epidemic in Paris in July and August, 1898, following the use of typhoid infected street water; likewise the epidemic in Dresden, reported by Hesse,[15] and the one in Bern, reported by Stoss,[16] were, all, as well as hundreds of others, referred to the result of infected water. The epidemic in Holland, according to Verbeck,[17] Dazy [18] and some others, was caused by infected milk. Koch, in the

already mentioned publication, has somewhat shaken confidence in the above reports, since he has shown that typhoid is more or less transmissible from person to person, and this is particularly liable to be the case with the not seriously ill. That typhoid of children is exceedingly easy to transmit has been apparent for a number of years, to the detriment of the children's department of our hospital. Children are more easily the carriers of infection, because they are naturally more careless about soiling the surroundings. In the hospital a nurse and an assistant became sick from the disease, and only by the observance of the most scrupulous cleanliness were similar occurrences prevented. I had, however, before this, observed the progressive spreading of the disease from person to person and from place to place — the latter being carried by persons. Notwithstanding all this, the spreading of the disease by means of water, milk, infected food, etc., cannot be denied, and the most careful attention must be given to the cleansing of the wells, watercourses and bathing pools. A source of danger to children lies in closed bath houses, as the water may easily become contaminated by germs from the mouth or nose of those infected. The spreading of the disease through the medium of flies, as asserted by Vaughan,[19] and as I myself almost to a certainty believe to have seen, must not be lightly regarded.

The season of the year plays an important part in the spread of the disease, by far the largest number being observed in the autumn; at least, this is true in Berlin, but sporadic cases are observed throughout the year. No one to-day doubts that typhoid fever is produced by a specific germ, the typhoid bacillus. This germ was first seen by Eberth in the intestinal mucous membrane, lymph glands and spleen, and described by him in the year 1880. Almost at the same time Robert Koch observed the germs in the intestinal wall, and proved their existence by coloring and photographing them. The bacilli were then thoroughly studied by Gaffky, who, in 1884, developed a pure culture of them, and also through cultures upon the potato proved their growth and peculiarities. The literature of the subject has now become so voluminous that in this article it is only possible to mention the most essential points, and besides much more remains to be proved on the special bacteriology of typhoid.[20] The difficulty[21] of separating the typhoid bacillus from the great colon group and other intestinal bacteria caused considerable expansion of the literature of the subject. But finally the discovery of certain biological phenomena connected with the growth and life processes of the typhoid bacillus, together with clinical observation, has helped to clarify the subject. This is particularly true of the so-called agglutination process. The typhoid bacilli most closely resemble the colon bacteria in their appearance, size and ordinary circumstances of growth, and are characterized by an exceedingly great motility on account of the large number of flagellæ with which the whole body is supplied. They are not colored after Gram's method form in a sugar culture medium; few or no gas bubbles (in strong contrast to the colon bacilli); grow in sterilized milk without coagulating it (thereby showing the acid formation to be very insignificant), and form in an albuminous medium no indol. The dull appearance when grown upon the potato, looking like a thin mucus, is considered by Gaffky and others to be an essential in its differentiation from the colon bacilli, but this statement, like so many others, has proved uncertain and unreliable. They grow best at the body temperature, and are both aërobic and anaërobic. Gelatin, even after the bacilli have grown on it for a long time, does not become liquid, and still more characteristic, the stab cultures become filled and the surface covered. Colonies upon the gelatin plate after twenty-four hours are characterized as sharply defined, circular or whetstone-shaped bodies, and after forty-eight hours appear brownish in color, more granular, more delicate and thin, growing out in so-called grape-leaf forms. The behavior of the bacilli to the litmus whey is important. Petrushky observed that when the typhoid culture was carried into litmus whey the neutral violet color became reddish, the whey remaining perfectly clear, while on the contrary the colon bacteria make the whey dark red and at the same time cloudy. It is necessary with this otherwise important test to make a control test, comparing the color and general behavior with a pure typhoid culture. The formed acid in the litmus whey culture must not exceed 0.3% of the normal acid. We also distinguish the typhoid bacilli from the colon bacilli by Barsiekow's litmus nutrose solution (1.0 nutrose, ½% whey, 1% either grape sugar or milk sugar). The grape sugar solution becomes acid, reddened and curdled from both the typhoid and colon bacilli, while the milk-sugar solution is changed by the colon group but not by the typhoid bacilli. When grown upon a litmus-colored nutrose medium, the typhoid bacilli do not alter the medium, and the colonies have a blue color, while the colon bacilli redden the medium and the colonies appear red.

All the above reactions must be studied and controlled in relation to each other before we can certainly say that the bacillus in question is a typhoid bacillus. The most important test, however, is the certainty of the biological reaction, which was originally studied by Pfeiffer and Kolle,[22] and which Widal worked out into a standard clinical reaction. Animals previously treated with typhoid bacilli very soon form substances in their blood which in high dilutions are able quite specifically to cause the typhoid

bacilli to come together into clumps. This agglutination test is the most certain, because it is quite specific for the typhoid bacillus. Widal [23] then proved that this agglutination ability of the blood serum also occurs in man, and often during the first days of the illness, so that it may be accepted as a specific diagnostic aid. The typhoid bacilli occur in the stools, the urine, the blood, the saliva and in almost all the organs of the body, and may not only be proved in the above-mentioned secretions and in the skin of the patient during life, but also in the organs after death — and Pfeiffer, Simmonds, Fraenkel, Kilcher and many others have cultivated the bacilli from corpses; Widal and Chantemesse found the bacillus in the placenta of a four months' fetus; Giglio and Frascani found it in fetal blood (see literature by Burdach, *l. c.*, p. 314); Locatello, in the saliva and mucous membrane of the larynx; and Ebermeyer, Quincke and others, in the marrow of the bones. The bacilli may also be found in the pus of abscesses accidentally accompanying typhoid, as I have proved in one case and also as shown by Spirig, Klemm, Hintze and others. Neuhaus, Curschmann and others have proved their presence in the rose spots of the skin, and A. Fraenkel, in pneumonic consolidations of the lungs. The recently much-studied existence of the typhoid bacilli in the urine is very important on account of its contagiousness and peculiar liability to be transported. Konjajeff, Levy and Gisler, Urban, Petruschky, Burdach and a great many more have investigated this branch of the bacteriology of the urine, and have suggested that this may be the cause of albuminuria and inflammatory irritation of the kidneys occurring in the course of the illness. As already said, we must limit ourselves to these few hints from the enormous literature of the subject, but they are sufficient to bring out the clinical importance of the typhoid bacillus.

It is not certainly known how the typhoid bacilli affect the human organism. It is known, however, that they create necrotic processes in the places first attacked, as is observed in the ulceration of Peyer's patches, but other lesions may be characterized as the result of their direct action on the tissues. However, their effects are not only attributable to this direct action, but much more to the action of the toxins which are produced in the system by the bacilli, because the severe general symptoms of typhoid can hardly be considered otherwise than as of a toxic nature. It still remains very questionable whether the metabolic product of the typhoid bacillus made by Brieger and called by him *typhotoxine* ($C_7H_{17}NO_2$) has anything to do with these effects.

PATHOLOGICAL ANATOMY.

The pathological anatomy of typhoid of children is distinguished from that of adults by the greater prominence of the degenerative and necrotic process in the intestine of the former and by the more evident hyperplastic process of the latter. The intestine of children shows solitary follicles and swollen patches which are elevated above the surrounding tissue. These are pink in color and their surroundings profusely injected. The microscope shows new cell formation in addition to simple injection and swelling. Necrotic and ulcerative processes occur very often— Montmollin in Basel recording 77%, Pfeiffer 72% and Gerhard 67.5%. I have seen very extensive intestinal ulceration in children, and have described one important case. Two of my patients died of peritonitis due to perforation. The ulceration is not at all different from that observed in adults. We find the rod-shaped micro-organisms, the bacilli, in the mucous membrane, in the sub-mucosa and as far as the mesenteric glands. The muscles are dry, dark and show what Zenker speaks of as waxy degeneration. In the brain Popoff [24] describes nuclear division in the ganglionic cells and immigration of lymphoid cells, division of protoplasm of the nerve cells, accumulation of migratory cells in the perivascular tissues and along the nerve filaments, and finally deposits of fat and pigment granules in the ramifications of the blood vessels and nuclear division in the capillaries of the brain — all taken together being the result of previous inflammation. These statements in their essential particulars have been recently attacked by Herzog Carl,[25] Blaschko and Rosenthal, although maintained by Popoff. Langworth [26] describes serious lesions of the peripheral nerves and also of the motor cells of the anterior horn (change of the nucleus, dissolution of the Nissl granules) of the spinal cord. The spleen is enlarged, congested and soft; the mesenteric glands are swollen and do not differ from the typhoid glands of adults. The heart is, as a rule, flabby, the muscles brittle, the muscle nuclei very much degenerated, and the muscle fibers have undergone fatty degeneration. The lungs are frequently the seat of atelectasis and catarrhal pneumonia. Typhoid ulcers of the larynx have often been described and fibrinous laryngeal affections with medullary infiltration of the mucous membrane frequently occurs. The statements of Eugene Fraenkel concerning the rose spots of the skin are also interesting, as he found the typhoid bacilli in the surroundings of the blood vessels of the swollen papillæ. Besides these regular conditions we find fibrinous coating of the tonsils, abscesses of the middle ear, swelling of the parotid gland, gangrene of the mouth, cheek and also of all the soft parts of the face. In some cases considerable meningeal effusion has been observed, but real meningitis is very rare. Peritonitis through perforation of an intestinal ulcer is not frequent, but I have observed it in several fatal cases. The kidneys of patients who die during the height of the fever

show parenchymatous swelling and clouding of the epithelium, but rarely a genuine nephritis.

SYMPTOMS AND COURSE.

The majority of cases of typhoid fever in children begin with ill-defined and indefinite symptoms. Particularly is this true of very young children. The beginning is usually marked by headache, pains in the throat, loss of appetite, ill-humor, restlessness, thirst and moderate fever. Sometimes diarrhea is an early symptom, but constipation is more commonly observed. After a time the fever increases, accompanied by decided somnolence. The children sleep a great deal, the lips are dry, the tongue is coated gray white with red edges and a triangular red point. The eyes are somewhat injected, the abdomen is soft upon pressure but at the same time painful. Gradually the spleen becomes swollen — detected in the beginning only by means of percussion, but later by palpation. About this time, usually from the sixth to the ninth day, the roseola appear on the skin as small, isolated, slightly elevated spots. The abdomen is soft and slightly swollen. Epistaxis is an occasional symptom at this period of the illness and may become very misleading, for, as I have observed in a girl eight and a half years old, the blood may be swallowed and when vomited be mistaken for melena. Diarrhea is now frequent, the stools being foamy, brownish, fetid and thin or liquid. The somnolence becomes more and more marked, the child being with difficulty awakened and again very soon falls asleep. The hearing now often becomes difficult and cough is frequently a troublesome symptom. As a rule the physical examination reveals sonorous and sibilant râles and sometimes the percussion note is duller than normal in the lower posterior thoracic border. The facial expression is dull and apathetic, the child lies on his back and sinks into the bed. When being examined he usually cries and struggles, sometimes very energetically, but at other times will permit himself to be disturbed without offering resistance, depending, of course, upon the degree of somnolence. At this time there are two reactions to be observed: the diazo reaction of the urine, described by Ehrlich, and the Widal reaction (agglutination of the typhoid bacilli culture by the blood). This condition continues a longer or shorter time according to the severity of the illness. The lighter cases now improve gradually from day to day, the little patients showing more interest in their surroundings, at the same time becoming capricious and whining. The tongue, which till now has been dry and often red upon the point and edges, becomes pale, the coating more moist and thinner, the lips lose their coating and are not so fissured. Diarrhea ceases, cough becomes more frequent but looser. The roseola vanish. In place of the diarrhea comes an inclination to constipation. In the more difficult cases the advent of convalescence is much longer deferred, sometimes till the end of the third week and even longer; then the child slowly loses apathy and dullness and the individual symptoms in the manner already pictured. Very gradually the condition returns to the normal, at the same time the appetite is markedly increased. In the meantime the patient has lost much flesh, and the low condition now makes itself clearly apparent. The fever now slowly sinks and gradually disappears.

The observation of the course of the temperature is a most important aid in diagnosis. The symptoms are often every indefinite, particularly in the early stage of the illness, and in these cases the fever has often led to a correct diagnosis before the other symptoms were pronounced. In general, especially in older children, the fever comes on slowly, but in younger children it is more apt to begin suddenly, often being characterized by rapidly rising temperature (Wolberg). In the slower forms of onset the temperature seems to rise by degrees. The evening temperature of the first days is always higher than the morning temperature of the same day, and the morinng temperature of the next day is nearly as high as the temperature of the preceding evening. The fever reaches to the height of 40° C. to 40.5° C. (104 to 105° F.), and sometimes higher by the end of the first week, remaining at this height several days when not influenced by treatment, showing a difference of about 1° C. between the morning and evening temperature; then begins a gradual sinking of the morning fever and at the same time the still high evening fever becomes less. Finally the morning fever becomes normal and the evening exacerbations less marked and disappearing, at the same time the morning temperature going below normal. The fever may disappear inside of two weeks, but according to the observations of Hensch, Montmollin and others the larger number of cases require two weeks, while a somewhat smaller number require three weeks. This is proved by a large number of clinical charts and my own observations. It is important to observe the influence of age upon the duration of the fever. Wolberg found the fever duration with children between three and five years to be fourteen days, and with children above that age seventeen days. Long continuous fever comes almost exclusively in older children, and the interesting fact is learned from Montmollin's studies that from the first to the tenth year of life typhoid has a steadily increasing duration. This study showed that during the first year of life the duration was 12.3 days, in the fifth year 15.7 days, in the eighth year 18.3 days and in the tenth year 20.3 days; from then it appears to hold quite constantly to a duration between these limits. Of course these average results must not be applied in attempting to determine the duration of an individual case, but in general we can agree with Montmollin that the course of the fever in children, so far as the duration is concerned, is milder than in adults, but the severity of the illness in its individual phases will be found quite as serious. My observations are in essential accord with the foregoing remarks, and I must once

more emphasize the fact that in single cases of typhoid in children the course of the fever both in its duration and severity is on a par with the worst cases in adults. I have before me a temperature chart showing a fever of 40° C. (104° F.) or higher for more than two weeks, which was reduced only by means of energetic antipyretics, and remained lower but a short time. Such cases generally pursue a very severe course and end fatally. The temperature does not always fall by lysis, but more commonly by crisis similar to pneumonia, and is observed about the end of the second week, after which recovery begins. The frequency of the pulse beat corresponds pretty closely to the elevation of temperature, 100, 120, 140 in the morning, not so rapid as in the evening, and it is usually dicrotic, as in adults. During the height of the fever the pulse is irregular and intermittent, indicating a considerable heart weakness and a threatening heart paralysis. In such cases the heart tone is dull with an absence of the second sound. or the tones are divided. I have treated one case of typhoid complicated by chorea with very pronounced galloping tachycardia,but which was undoubtedly of some duration before the typhoid attack. It is not rare to hear a soft systolic murmur over the heart apex. During the convalescent stage we often observe an irregularity of the pulse and an acceleration of the sphygmograph tracings — a visible evidence of heart weakness.

(To be continued.)

ACUTE FLEXION OF THE GALL BLADDER AS A CAUSE OF BILIARY COLIC. ITS RELIEF BY OPERATION.

BY A. T. CABOT, A.M., M.D., BOSTON,

Surgeon to Massachusetts General Hospital.

IN 1896 Fenger read before the American Surgical Association a paper[1] in which he described cases of biliary colic and jaundice which he believed to be due to an obstruction in the biliary passages, caused by a bending or kinking of the ducts. He also urged that a valvular condition might be brought about by an oblique insertion of the common duct into the duodenum. In supporting his views, he cited what authorities he could find in the literature of the subject, but in his study of these conditions he found no suggestion that a bending of the gall bladder itself could give rise to symptoms requiring an operation for their relief.

I wish to put on record two cases in which characteristic attacks of biliary colic seem to have been caused by the acute flexion of the gall bladder at about its middle. In all such cases when there are adhesions it is difficult to recognize on the operating table the exact condition which is responsible for the colic. As the operation is usually done in a period of quiescence, between attacks, it is plain that in many cases the mechanical obstruction or drag is not in action at the time of operation. It is conceivable and probable, when the stomach or colon are united to the gall bladder or the gall ducts by adhesions, that the drag of these viscera is responsible for the distortion which causes the colic.

This drag may be very much increased when these viscera are loaded and may amount to but little when they are empty. Fully recognizing the uncertainties that surround the determination of the causes of colic in these conditions, I present the following cases with a statement of my reasons for thinking the flexion of the gall bladder responsible for the colic:

CASE I. Mrs. H. E. R., a strong and healthy woman approaching fifty years of age, had for years been subject to attacks of pain in the right hypochondriac region. This pain had a tendency to shoot up into the right shoulder. Nausea associated itself with some of these attacks. Dr. Charles Folsom, who had watched her for years, thought that in some of her attacks the conjunctivæ were slightly yellow, but she never had any distinct icterus. Dr. Folsom and Dr. F. C. Shattuck, who saw her in consultation, both thought the attacks probably due to gall stones, though none had ever been seen in the stools. I saw Mrs. R. in February, 1899, and concurred in the belief that gall stones probably existed. At this time, I felt what I took to be the somewhat distended gall bladder in the usual place. The examination was, however, much interfered with by the thickness of the abdominal wall, which besides a thick adiposa had a strong and rather rigid muscular layer.

An operation was advised and accepted.

On Feb. 25, 1899, I operated. Under ether, when relaxation was complete, I could make out that what I had believed to be the gall bladder was, in fact, the end of one of the floating ribs. The lower ribs curved sharply inward and reached much nearer the umbilicus than usual. An incision was made just below and parallel with the costal margin. The liver lay high up under the ribs and its lower edge was pressed by them inward towards the middle line of the body.

The gall bladder was rather long, with its fundus extending below the edge of the liver and the pressure of the ribs carried this fundus downward and inward, producing a distinct bend or kink in the middle of the gall bladder. When the fundus was drawn outward, this bend was effaced, but it reproduced itself when the gall bladder was allowed to fall back into its usual position. Light adhesions existed between the gall bladder and the colon, but these exerted no appreciable drag on the organ, and certainly could not be accused of producing any distortion of the ducts. The gall bladder was opened, but nothing found within it to account for the attacks of pain. In order to efface the bend above described, the fundus of the gall bladder was drawn outwards and attached to the parietal peritoneum, a drainage tube being inserted within it. Recovery from this operation was satisfactory, and the patient had no more attacks of pain simulating hepatic colic. She did, however, have at times a pain lower in the right side which presently pointed so distinctly to the appendix as its cause that appendectomy was done in the summer of 1902. I found the appendix bent and adherent. Since that operation Mrs. R. has been exceedingly well and strong.

There was no doubt that the first operation was followed by a decided relief of a distinct hepatic colic. There was, however, for a considerable time a sense of uneasiness in the right hypochrondrium which I ascribed to the tension of the gall bladder.

CASE II. Dec. 18, 1901, I saw, in consultation with Dr. C. J. McCormick, J. R., a strong, well-developed and

[1] Retention from Displacement, Bending and Valve-formation (oblique insertion) in the Biliary Tract. Med. Standard, Chicago, Nov., Dec., 1896, and Jan., 1897.

healthy looking man who gave the following history: — Twenty-one months previously he had had an attack of pain in the right hypochondriac region. This pain did not radiate to the shoulder and there was no icterus. The attack gradually passed away. A year later he had a similar attack in which the pain lasted all the spring. Then, he was easier through the summer. Five days before our consultation the pain again attacked him suddenly, and now, for the first time, vomiting was associated with the attack. He was still suffering, though not acutely, at the time of our examination. The abdominal muscles were extremely rigid and he was totally unable by any effort of the will to relax himself. As he was a strong, muscular man, this made the examination of the abdominal contents of practically no value. The only thing that was learned was that there was moderate tenderness at the normal position for the fundus of the gall bladder. In view of the recurrent nature of the attacks and their increasing severity, he was advised that an operation was probably wise, and should certainly be done if the pain continued.

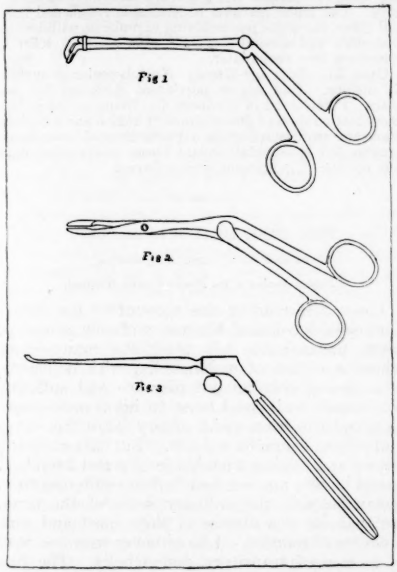
After consideration, he decided to have the operation at once and it was accordingly done on Dec. 24, 1901. On opening the abdomen it was found that the gall bladder was long and rather lax. It projected beyond the edge of the liver and being attached to that organ up to the very edge, it made by its weight and downward pull a distinct sulcus in the lower edge of the liver. At first it was thought that the gall bladder was attached to the colon, but this was found not to be the case. The downward drag of the gall bladder was supplemented by the pressure downward and inward of the rigid abdominal wall and seemed to make a distinct bend about the middle of the gall bladder. It was decided to remove the gall bladder and this was done. The cystic duct was tied off and a gauze wick was introduced down to this point. The patient had considerable pain following the operation, but made a good recovery. I saw him March 14, three months after the operation, at which time he stated that he was entirely relieved of the pains that he had had, although there was a little sense of drawing in the scar.

The experience of these cases would lead me to prefer cholecystectomy as the better operation for the cure of such a condition as I have described While the attachment of the fundus of the gall bladder to the abdominal wall, in the first case, effaced the bend in its body and stopped the attacks of distinctly hepatic colic, it left a sense of dragging in the right hypochrondrium which prevented our regarding the operative result as a perfect one. The subsequent history of chronic appendicitis introduces a doubt as to the relation of the gall bladder to the attacks of pain. The disappearance after operation of the pains having distinctly the character of biliary colic, seemed reasonably convincing evidence that the gall bladder had been responsible for them. In the second case entire relief was afforded by the removal of the gall bladder. My experience in cholecystectomy leads me to regard this operation as having no more danger than a cholecystostomy when done in a case of ordinary difficulty. In these cases that I have been considering there were no deep nor extensive adhesions to make the removal of the gall bladder difficult.

SOME REMARKS ON CHRONIC SPHENOIDAL SINUSITIS.

BY ALBERT E. ROGERS, M.D., BOSTON.

FROM my study of the sphenoidal cavity, in the throat clinic of the out-patient department of the Massachusetts General Hospital, last summer, I came to the conclusion that a chronic sphenoidal sinusitis occurs much more frequently than is generally supposed. The cases which I have to report occured in the service of Dr. J. Payson Clark, to whom I am indebted for the privilege.



I found on examining 600 patients, that 29 were cases of accessory sinus disease, or nearly five (4.5-6) per cent of all who came to the throat department for treatment. Chiari and Lichtwitz report an average of only 2%. Of these 29 cases I found the antrum of Highmore affected four times; the frontal sinus once; a mixed frontal and ethmoid two times; the anterior ethmoidal three times; the posterior ethmoidal two times; the sphenoidal sinus sixteen times and a mixed posterior ethmoidal and sphenoid once. This places the empyema of the sphenoid at the head of the list, which does not agree with the majority of clinical observations in placing the maxillary sinus as the most commonly diseased. The great difference of opinion in regard to the frequency of sphenoidal disease is shown by the statement of Bosworth, that true primary disease of the sphenoidal cavity is very rare. He considers that affections of the ethomidal cells are the most common. He is supported by the observations of John Mackie, who reports forty-four cases of ethmoid to eight of sphenoid. In the records of the clinic at the hospital I have been unable to find the diagnosis of chronic sphenoidal sinusitis occurring a single time for the past five years. On the other hand, Lichtwitz states that next to the maxillary the sphenoidal is the most commonly affected. This statement is supported by Grünwald, who has opened 51 sphenoidal and found it necessary to operate on only 14 frontal. Hajek states that the sphenoidal is the most common of the posterior group of sinuses.

Before taking up the subject of diagnosis, it may be well to make a few remarks concerning the anatomy of the sphenoidal sinuses. They are located in the body of the sphenoid bone and are usually two in number, being separated by a delicate septum. Ordinarily the cavity is limited by the spheno-ethmoidal fissure. Its opening is in the anterior wall in the sphenoidal fissure, just above the upper turbinate. In the majority of cases the opening is in the middle part of the anterior wall, though sometmes it may be higher or lower. In most cases it is impossible to see the opening into the cavity, due to the obstruction of vision by the middle turbinate.

In examining a large number of fresh specimens prepared by Professor Zukerkandl while I was a student with Hajek in Vienna, I was struck with the extreme thinness of the upper and posterior wall of this cavity and its intimate relation with the sinus cavernosus. The inferior wall, on the other hand, is very thick. The size and shape of the cavity varies greatly in different individuals. One can never be sure how far backward it may go.

In making the diagnosis of sphenoidal disease I rely mainly on the probe. If pus is seen in the olfactory fissure it may be due either to trouble in

the sphenoidal sinus; the posterior ethmoidal cells; rarely the posterior part of the antrum of Highmore when a division exists therein; the frontal sinus; atrophy of mucous membrane, which I believe is sometimes primary, or to caries of the superior turbinate (as tubercular). Eliminate the last two and begin to investigate the cavities. I commence with the sphenoidal, as I think it the most commonly diseased and the easiest to enter. The probe must be passed in a direct continuation of the line from the inferior nasal spine to the middle part of the middle turbinate. *It must not go anterior to this line.* The distance from the inferior nasal spine to the anterior sphenoidal wall is 7½ cm. and never more. If the probe goes a greater distance one is either in the sphenoidal

sinus, brain cavity or naso-pharynx. If it goes over turbinate in the middle part, in the direct line I have mentioned, one is certainly in the sphenoidal cavity. I have verified this on more than a hundred specimens. The probe must be bent with a slight horizontal concavity (∪) in order to pass around the convexity of the middle turbinate. I also bend the tip very slightly downward, as it is easier to enter the cavity and there is less danger of injuring the posterior wall. Having entered the cavity and feeling roughened bone or the spongy granulation tissue, one is warranted in making a diagnosis of sphenoidal disease and justified in opening the cavity for the relief many obscure symptoms such as somnolency; of numbness of upper lip and general nervousness; cough; deafness; chills; vertigo; diffuse pain in head; pain in back of head; deep-seated pain back of eyes and another symptom not so obscure, namely, post-nasal discharge which, is too often treated as an ordinary "catarrh" by post-nasal applications.

In opening the sphenoidal cavity I proceed in the following manner: After thoroughly cocainizing the nose I remove a piece of the middle turbinate anteriorly, at its attachment to the outer wall, with a Knight's cutting forceps (Fig. 2). Then with the same forceps I grasp the body of the turbinate and bend it toward the outer wall, then by quickly twisting in the opposite direction fracture it along its attachment. The forceps, still grasping the bone, is now removed and usually the whole turbinate comes away, leaving a free and easy approach to the sphenoidal opening. The hemorrhage is generally brisk at this time, but it is not of long duration and further bleeding is exceptional. I do not use adrenalin solution at the time of the removal of the turbinate, but for after treatment I give the patient a spray of the 1-1000 solution, to use twice a day for ten days when I proceed to the opening of the sinus. This is done under cocaine with a forceps which I have constructed on the principle of Grünwald's downward-cutting forceps, but with shorter jaws, fenestrated, and with a stouter rivet at the joint. I have also had a strengthening clasp placed at the joint (Fig. 1). After the forceps has entered the nose its jaws are slightly opened and while paying attention to the upper jaw only the instrument is passed into the sphenoidal opening in the same manner as a probe. The jaws are then brought together with firm pressure biting out the anterior wall and establishing free drainage. In those cases in which the opening is too small to admit the forceps I first enlarge it by means of Hajek's sphenoidal hook (Fig. 3). Usually this is all that is necessary to obtain complete relief. In two cases only have I found it necessary to curette and syringe out the cavity.

This method has given complete relief in the eleven cases, the notes of which follow, and the more extensive operation by way of the antrum of Highmore, as recommended first by Jansen and later by Luc and Furet, has not been necessary in a single case.

CASE I. Man, age twenty-four. No tubercular or syphilitic history. For five years has had a constant dropping in pharynx. Had been under treatment for three years, receiving post-nasal applications and nasal douches. For a year complained of severe pain in back of head. Examination showed an hypertrophy of right middle turbinate. Pus in olfactory region and considerable pus in naso-pharynx. No atrophy of mucus membrane. Probe passed into sphenoidal cavity discovered roughened bone. Middle turbinate was removed under cocaine. Considerable hemorrhage, which soon subsided. Ten days later the anterior wall of sphenoidal cavity was removed, establishing free drainage. Three weeks later patient was entirely relieved of symptoms.

CASE II. Woman, age thirty-seven. No tubercular or syphilitic history. Always in good health. Nine years ago began to be troubled with nasal polypi. During the past eight years came to hospital four or five times to have the polypi removed. For five years has had a constant dropping in back of throat. Examination showed a moderate hypertrophy of right middle turbinate, remains of polypi and a slight post-nasal discharge. Probe revealed roughened bone in sphenoidal cavity. No disease in other sinuses. Polypi and middle turbinate were removed and two weeks

later the sphenoidal cavity was opened. The discharge continued for about five weeks, when it entirely ceased.

CASE III. Woman, age thirty-two. No tubercular or syphilitic history. Complained of severe diffuse headache, vertigo, specks before the eyes. For five years had been troubled with a, copious post-nasal discharge. She had been treated with nasal douches and post-nasal applications without relief. Examination showed an enlarged left middle turbinate and a great deal of muco-pus in the naso-pharynx and olfactory region. Probe showed roughened bone in sphenoidal cavity. Middle turbinate was removed and ten days later the anterior wall of sphenoidal cavity was removed. Three weeks later the headache and dizziness had disappeared. The discharge was greatly diminished, but as it still existed I curetted and syringed out the cavity. Two weeks later all discharge had ceased.

CASE IV. Woman, age thirty-nine. No tubercular or syphilitic history. For three years had been troubled with a copious post-nasal discharge. Had severe diffuse headaches and dizziness. For over a year had severe cough and frequent chills. Noises in left ear and hearing in same affected. Examination showed an enlarged left middle turbinate, polypi, and pus in olfactory region. Posteriorly there was to be seen a copious muco-purulent discharge. There was a chronic laryngitis. The probe revealed roughened bone in the left sphenoidal cavity. Polypi and middle turbinate on the left removed and two weeks later the cavity was opened. For two weeks more the discharge continued to flow freely, after which it began to diminish until six weeks after the cavity was opened it had practically disappeared. There was complete relief of all the other symptoms except the cough, which although diminished still persisted. This will undoubtedly cease as the laryngitis is secondary to the pharyngitis which was caused by the post-nasal discharge.

CASE V. Woman, age twenty-six. No tubercular or syphilitic history. Has had a continued dropping in throat for over a year, Complained of deep-seated pain in right side of head. Examination showed the right middle turbinate to be moderately enlarged. There was a very slight amount of muco-pus in the olfactory region. The probe revealed roughened bone in the sphenoidal cavity. The middle turbinate was removed and two weeks later the sphenoidal cavity was opened. When the anterior wall was removed considerable pus escaped. Three weeks after operation the discharge and pain had ceased.

CASE VI. Man, age forty-one. No tubercular or syphilitic history. For many years had been troubled with a post-nasal discharge. Three years ago had an attack of facial erysipelas. Complained of vertigo and deep-seated pain back of eyes. Examination showed no hypertrophy of turbinates and there was no discharge anteriorly. Posteriorly there was considerable muco-purulent discharge. The probe revealed roughened bone in both sphenoidal cavities. The middle turbinates were removed and both cavities opened, resulting in complete relief to the symptoms four weeks after operation.

CASE VII. Woman, age twenty-seven. No tubercular or syphilitic history. Two years ago had an attack of facial erysipelas. Had had a copious post-nasal discharge for two years. Complained of severe headache in top and back of head. Examination showed a very large middle turbinate on right side. No pus seen anteriorly. Posteriorly naso-pharynx filled with pus. Probe revealed a large area of roughened bone. The middle turbinate was removed and two weeks later the cavity was opened. The pain in head was relieved, but as three weeks later the pus continued, I curetted and syringed the cavity twice a week for two weeks, when the discharge ceased.

CASE VIII. Woman, age forty. No tubercular or syphilitic history. For four years had a copious post-nasal discharge. Complained of a diffuse pain through head, deep seated back of eyes. Examination showed polypi on both sides and enlargement of both middle turbinates. There was a great deal of muco-pus seen posteriorly. The probe showed spongy tissue in both sphenoidal cavities. Both turbinates were removed and the anterior wall of both sphenoidal sinuses taken away. Considerable polypoid tissue was curetted out of both cavities and after a few weeks' syringing the symptoms were entirely relieved.

CASE IX. Man, age twenty-five. No tubercular of syphilitic history. For two years complained of difficulty in breathing through right nostril. Had a deep seated pain back of eyes. Complained of being dizzy at times. Upon examination the right middle turbinate was found greatly enlarged. No pus to be seen either anteriorly or posteriorly. The probe found roughened bone in the right sphenoidal cavity. No other sinuses were found affected. A fine pointed catheter was next passed into sphenoidal cavity and a small amount of muco-pus was syringed out, thus confirming the diagnosis. The middle turbinate was removed and one week later the anterior wall of sphenoidal cavity was taken away. The symptoms were entirely relieved.

CASE X. Man, age forty. No syphilitic or tubercular history. Was being treated in the nerve department for neurasthenia and was referred to throat department for examination of nose. He complained of a pain in back of head; a numbness of upper lip and was generally very nervous. Examination showed a moderate enlargement of left middle turbinate. No pus either anteriorly or posteriorly. The probe revealed considerable roughened bone and there was some pus adhering to probe on withdrawal. Operation was advised and done, with complete relief to symptoms five weeks later.

CASE XI. Boy, age fifteen. No tubercular or syphilitic history. Had severe post-nasal discharge for two years. Complained of dizziness and frequent headaches. Examination showed pus in olfactory region and a copious discharge in naso-pharynx. Probe showed roughened bone in left sphenoidal sinus. Three weeks after sinus was opened all symptoms were relieved.

THE CASE OF LOUIS BITZER.[1]

BY EDWARD B. LANE, M.D., BOSTON,

Superintendent of the Boston Insane Hospital.

UPON first reading the account of the Bitzer homicides I believed his was probably a case of acute melancholia. It read like many cases where a victim of melancholia, with delusions, who, seeing nothing but disgrace and suffering for himself and loved ones, in his frantic desire to save them from awful misery takes their lives and then commits suicide. But after seeing Bitzer and talking with his family and friends, I found he was not nor had he been suffering from melancholia in the ordinary sense of the term. Melancholia is a disease of slow onset and runs a course of months. I have never seen nor read of a case of transitory melancholia. The line of reasoning in the writing is strikingly similar to that of a homicidal melancholiac. And here the similarity ends.

Transitory frenzy is described and after much debate upon the subject is, I think, now admitted as a rare form of mental disturbance. In transitory frenzy there is evidence of cerebral congestion, flushed face, congested eyes, furious excitement followed by a deep, profound sleep. During this excitement the victim runs amuck and may commit violent and unprovoked assaults upon any one he chances to meet. This case was clearly not one of transitory frenzy. There was no evidence of great physical excitement; the shooting of his family was deliberate and planned and intended suicide was confessed. There was no deep sleep. But in this case we still have to face the fact that a fond husband and a loving

[1] Read at the annual meeting of the Massachusetts Medico-Legal Society, June 9, 1903

father attempted suddenly to annihilate his family, and the ordinary man is inclined to use his common sense and say, such a person must have been insane. Such a horrible, unnatural act is of itself evidence of an abnormal state.

To the medical man Bitzer did not appear insane at the time of his examination, in February, nor was there any evidence that he had previously suffered from any of the ordinary forms of insanity as observed in our hospitals for insane. The serious question arises, What was the explanation of this terrible deed? and was he responsible for it?

Then follow the very practical questions, What shall be done with him? How shall the law be enforced and society protected? Unfortunately, laws cannot be so framed as to meet all individual cases and deal equitably with each one.

To find an answer to the medical question in this case, I made a careful study of Bitzer, personally, and inquired into his history. The case was much simplified for all by the unusual document which he wrote immediately after the shooting of Ida. In this his state of mind is revealed and his intentions disclosed.

Upon examination by four physicians (Drs. Quinby, Houston, Scribner and myself), all familiar with the insane, we agreed that Bitzer impressed us as a man " not quite up to par mentally." He was poorly nourished, weak and emotional. He was born in Germany, and no trace of mental or nervous disease was discovered in the family. He is said to have had a prolonged and exhaustive illness when a small child. His habits as to intoxicating drinks were very temperate, judged from the standard of his nationality. He drank a little ale or beer daily. Used spirits rarely. Did not drink while at work and was never drunk. He was liable to lose his self-control under slight provocation. It is related at one time that he was holding an auction when some one remarked that he must be about to fail in business or he would not hold an auction sale. He lost his self-control and smashed his hat and a piece of furniture near him. He admits this fact, but says he does not remember all the incident.

From childhood he walked in his sleep. His wife tells of repeated incidents of his sleep-walking. She would find him asleep on the floor in another room from that in which he had gone to bed. When anxious about his store, thinking of fire or burglars, he has been known to leave his bed and go to the store and in the morning have no recollection of it. One night his wife missed him from their bed and got up to look for him. She found him lying in a ludicrous position in the child's cradle with his head and legs hanging over either end. Only four nights before the tragedy she missed him and found him walking about another room. and had she not caught hold of him he would have walked out of the window.

His brother was a somnambulist as a boy. Two of his most intimate friends describe him two weeks before the tragedy as peculiar and " morose." He failed to greet them in his accustomed manner when they entered his store; he answered them in monosyllables and appeared nervous and his hands were trembling. At other times he was as usual. Bitzer failed to recall these incidents when I questioned him about them later.

Six years ago, when recovering from the grip, he became very excited and tried to bang his head against the wall. It took two or three men to prevent him from injuring himself. They believed he was attempting suicide. He went to sleep after this temporary frenzy. He states that he knows nothing of this and that he never heard of it until questioned about it months after his arrest.

His account of the shooting was substantially this:

" Ida asked me to put away two revolvers. I closed one quick and it went off and Ida fell on the floor on her back. I did not examine her to see if she were dead. I did not touch her. I first thought of running away, as I was afraid of being arrested, and I took the money out of the drawer. I then thought of doing away with myself. I thought of going to the girl's home. Then I wanted to see my people before I died. I remember going to get a paper and kneeling at the table to write. The last thing I remember was putting on my hat and coat, which I did before I wrote. At the house I remember my wife's arm pulling at my neck and hearing her say something about shooting. I remember the officer at the lockup saying my boy was shot, when I got the same feeling I did when the girl was shot. I remember I came to the Greenfield jail in a sleigh. I came to myself here in the jail the next morning."

His wife says that when he entered the house he looked like a crazy man. His appearance was so unnatural, she asked him what was the matter. He made no reply, but went out into the kitchen.

Assuming that Bitzer's account of the shooting is true and that it is also true that he does not remember anything after the shooting of Ida, save the few incidents related, we must conclude that he was not in a normal state at the time of shooting the family. The coherent statement he wrote, his finding his way home and selecting his family in order are against the idea of his suffering from ordinary delirium. Nor is there any evidence that he was an epileptic. But he was subject to periods where there was a divided or dissociated consciousness. As is well known, this condition is not rare in epileptics and hysterics, and is identical with the hypnotic state. It is not uncommon for such a condition to succeed a mental shock. It usually lasts for hours, but may endure for months or even years.

In this condition it is not uncommon for there to be islands of memory; that is, there will be a memory more or less distinct of certain incidents, as in this case: Bitzer remembered feeling

his wife's arm about his neck and hearing her voice as in a dream and of feeling the cold steel of the handcuffs as they were put on his wrists by the arresting officer. Very important is the circumstantial evidence in this case that Bitzer was a somnambulist. That is to say, it was well recognized that he was frequently subject to disturbances of consciousness. The somnambulism was frequent from childhood. The periods at the store when he appeared preoccupied and failed to greet his friends in his usual manner and answered in monosyllables, and his denial of such occurrences, may possibly be explained in a similar way.

No one would think of holding one who had committed a crime during delirium or while dreaming, responsible. Yet, strictly speaking, is either the result of insanity? The defence of hypnotic influence has been set up in one or two cases. But there was grave doubt as to the criminal being in that state, but if we were satisfied that a crime was committed when the criminal was in a hypnotic condition it is certain the popular verdict would be for acquittal.

What then shall be said of the responsibility of Bitzer if he was in a state of divided consciousness and impelled by the horrible fears of a disgrace while in a condition of partial consciousness, as shown by his peculiar expression and no memory of the horrible and unusually exciting events? It has been found that in the half-waking or hypnagogic state people are particularly susceptible to depressing emotions. Depression tends to continue the hypnagogic state (which is practically identical with the hypnotic condition), and a case is told of a young man who was slow in waking and his sister, to arouse him, told him that his oldest sister had died suddenly and he must get up. Instead of awakening, he began to sob convulsively and finally alarmed his sister so that she called the oldest sister, who tried to reassure him by showing herself alive and well. It was of no avail and he had a series of convulsions and it was several days before he recovered his normal condition.

I believe that Louis Bitzer was profoundly shocked by the discovery that he had killed his clerk. As a result of that shock he at once passed into an abnormal mental state of partial consciousness, analogous to the post-epileptic, somnambulistic, hypnotic and hypnagogic states, where his judgment was largely suspended, his actions were automatic and the result of profoundly depressing emotions of fear and shame. Reflection and will power were largely in abeyance. He was an automaton and as is to be expected, he has no memory of the events. He is as irresponsible for them as if he had committed these crimes during sleep.

I do not believe it at all probable that he would again be guilty of a similar crime. It is probable that if he were hypnotized he would be able to recall the events that took place in his home. It is understood that I believe he was in a normal condition and responsible when he shot his clerk.

A BRAIN HARDENED BY KAISERLING'S METHOD SHOWING THE TRACK OF A BULLET.[1]

BY WM. F. WHITNEY, M.D., BOSTON,

Curator Warren Anatomical Museum, Harvard Medical School.

I WISH to call attention to a brain preserved by Kaiserling's method, which I think should always be adopted in the case of any injury, as it is the only one by which the seat and extent of the lesion can be accurately determined. The delay incident to this method of preparation would be rarely any obstacle in the course of a legal inquiry. The following case of suicide is an illustrative one:

A man who had been drinking hard fired two shots from a 32-caliber revolver at himself at 10.35 A. M. He was brought to the hospital at 11.07 A. M., and in the right frontal region were two ragged wounds, each one inch in length with powder-stained edges, one lying on either side of the temporal ridge. About one inch towards the median line from wound nearest median line, a bullet could be felt lying subcutaneously, which was easily removed and no bony injury felt. Through the other wound a round hole could be felt in the skull. There was considerable hemorrhage, pupils normal in size, equal and reacted. No bleeding from ears or nose. Heart, lungs and abdomen negative. Patella reflexes were equally exaggerated, superficial reflexes absent. He moved his arms and legs about freely, apparently with equal strength and required restraint. Pulse 140, irregular, temperature 97.8 in axilla. Half an hour after admission the patient had a clonic convulsion which lasted about one minute and affected both sides of the face and extremities equally.

At 12.30 P. M. noticed that he did not move right extremities while the left were moved about freely. Right knee jerks more active than the left.

At 1.30 P. M. the left pupil was larger than the right and there was slight exophthalmos of the left eye. Increasing coma.

At 2 P. M. deep coma, but on painful stimulation there was slight motion of both arms, and the right extremities were flaccid. Pupils and other reflexes as before noticed. Pulse 128.

At 3 P. M. trephine opening made by the surgeon in charge, on left side, 1.5 inches behind and 1.5 inches above external condyloid process. Posterior branch of middle meningeal artery exposed and seemed to be formed by two small branches which formed a main branch at about the middle of trephine opening. Dura bulged, with a bluish tinge, no pulsation, arteries tied and dura opened. A dark blood clot escaped, followed by fresh blood and disintegrated brain. No trace of bullet seen. Hemorrhage rather profuse, direction not determined. Pulsation of brain returned after relieving pressure, but he never regained consciousness. Respiration stertorous. Pulse continued to fail, and died at 6.45 A. M.

[1] Read at the annual meeting of the Massachusetts Medico-Legal Society, June 9, 1903.

Brain. Was hardened in bulk in Kaiserling's fluid [2] for about two months. It was then cut in a series of sections each 1.5 cms. thick and the track of the bullet located as follows:

It entered at about 4 cms. from the front of the right anterior lobe, passed directly across, traversing both lobes. In the left one was a cavity the size of the end of the thumb, filled with blood clot and disintegrated brain substance. This opened upon the surface at the point where the trephine wound had been made. From this cavity the track turned almost at right angles and proceeded directly backwards, passing through the white substance of the left hemisphere and along the upper part of the convolutions of the island of Reil, in the middle part of which it was found to be lodged.

The case is interesting in the different courses which the two bullets followed. Either there must have been a great difference in the charges of powder, or the skull must have been very much harder or denser at the point where one struck than the other. Moreover, the one that penetrated the skull must have struck the opposite side, rebounded, turned around and destroyed the brain substance extensively at that point. It then went in a direction at nearly a right angle to that in which it was originally fired, and finally lodged at about the middle of the hemisphere.

In concluding I wish to express my thanks to Dr. Bottomley for his kind permission to use the clinical notes of this case, and to Medical Examiner Harris for the opportunity of obtaining the specimen, which is preserved at the Warren Anatomical Museum at the Harvard Medical School.

WHAT WAS THE CAUSE OF DEATH? [1]

BY A. ELLIOTT PAINE, M.D., BROCKTON, MASS.,

Medical Examiner, Brockton.

On the morning of Jan. 3, 1903, I was notified of the death of Mrs. S., aged thirty-nine, whose death was supposed to have been caused by poison.

The autopsy showed a well-nourished female, who weighed about 130 pounds. All the organs of the body were normal except the stomach, which contained one quart of grayish fluid. The mucous membrane on its posterior surface was somewhat congested in an area of 2 by 3 inches.

[2] KAISERLING'S METHOD FOR THE PRESERVATION OF SPECIMENS WITH THEIR NATURAL COLORS.

Slices of organs from 3–5 cms. thick are placed from 3–5 days in

1. Formaline	200 c. c.
Aq.	1,000 c. c.
Nitrate of Potash	15 grm.
Acetate of Potash	30 grm.

They are then removed, the fluid allowed to drain off and placed in

2. Alcohol 80% for 6 hours, then
Alcohol 95% for 2 hours

From this directly into

3. Aq.	2,000
Acetate of Potash	200
Glycerine	400

for permanent preservation in a dark place.

Further details for the preservation of whole organs, etc., should be studied in the original article.

[1] Read at the annual meeting of the Massachusetts Medico-Legal Society, June 9, 1903.

The stomach, one pint of its contents and sections of the liver, kidney and brain were sent to Prof. E. S. Wood for further examination.

Investigation showed that Mrs. S. had been divorced for two years, and had been given the custody of her children, a girl aged thirteen and a boy aged nine, together with $10 per month as alimony.

In September, 1902, while living in Whitman, her daughter became ill. The mother reported at that time and later that her child was being poisoned by its father, and that the child was under the influence of some woman. The father visited the child and consulted a clairvoyant, from whom he obtained two bottles of medicine, part of which was given to the child.

A physician who attended her found no evidence of the administration of poison. She was, however, extremely nervous.

The mother said that she found a white powder scattered upon the bed, floor and window sill in the child's room.

She told the child and others of her powers as a medium, and that she could tell the future and know what was being done by others, etc.

In November she and her children moved to Brockton, taking the rooms in which she died. Soon after going to Brockton Mrs. S. mixed the child's medicine and took them to the chemist of the Board of Health for examination. He did not tell her, but after her death, he informed me that the medicine contained a large amount of arsenic.

Some three weeks before she died, Mrs. S. was found in bed with a man. They were immediately arrested. He pleaded guilty and paid his fine. She appealed her case.

On Dec. 29 she and the children drank cocoa with their breakfast. In the afternoon she went to Whitman, refusing the company of her landlady, who offered to accompany her. At 5 P. M. she returned, complained of being very sick and distressed and was helped to her room and put to bed. She was nauseated. A physician attended her until Jan. 1. She said that her husband had poisoned her, repeating this statement to a lawyer who had been called to make her will, also saying that she would live but a short time. The lawyer advised her to call Dr. B. Dr. B. found her very nervous, but did not believe that she had been poisoned and made a favorable prognosis. On his next visit, however, the following day, she was vomiting and had burning pains in the stomach and intestines, a dry skin, an excited pulse and was passing only a very small quantity of urine.

He then accused her of taking poison. This she denied and said that she did not want to die. After considerable resistance she allowed him to pass a stomach tube. The stomach was washed out and its contents examined.

Her urine was drawn; it was scanty and highly colored. She grew rapidly worse, and at midnight her ante-mortem statement was taken. She said, realizing that she was dying, that her husband had poisoned her, and that she had

taken no poison by her own free will. She died at 3 A. M.

A legal investigation followed.

The contents of her stomach from the washing, with the stomach tube, and the cocoa and milk found in her room, were examined for poison with negative results.

Witnesses testified that, in September, 1902, at the time her daughter was ill, she had purchased an ounce of arsenic. The daughter said that she saw the powder in her room in Whitman on the bed, floor and window sill; that her mother put a teaspoonful of the powder in the medicine which had been examined by the Board of Health; that she knew her mother was poisoned with arsenic and told her so, and that she persuaded her mother in consequence to join the church, which she did, about ten days before her death. The child is old for her years.

Another witness testified that Mrs. S. had on two occasions attempted suicide by jumping into a cistern. On each occasion she regretted her act, hollered for help and was fished out. Early on one morning, while her husband was away, she, in her night clothes, ran toward the river, saying that she would drown herself. A friend took her home. She begged of him that he should not inform her husband.

Several testified that for two years she had been saying that she and her children were being poisoned by her husband.

It was proved that Mr. S. had not seen her for several months and there had been no opportunity for him to give her any poison.

She did go to Whitman on the trip mentioned, where she drew some money on a check.

On her way home she called on a lawyer and paid him a retainer to defend her case. He assured her that she would only be fined if found guilty.

Prof. E. S. Wood examined the specimens sent him for poisons, with negative results.

The return of death was "Cause unknown."

This woman purchased arsenic, put arsenic in the medicine, had a chemist examine it, told her friends that she and her children were being poisoned, was taken sick, sent for priest and lawyer, told them she was poisoned and was going to die, and did die.

She had burning pains in the stomach and intestines, vomited, had retention of urine, a dry skin, pulse quick and weak, face showing distress, etc. What could have done it?

The case has been of interest to all who were brought in contact with it and now I want to know, what was the cause of death?

New Instrument.

A NEW FRAME FOR THE TREATMENT OF FRACTURES OF THE LOWER EXTREMITIES.

BY JOHN H. CUNNINGHAM, JR., M.D., BOSTON.

THIS fracture frame which has been in use especially on the services of Dr. Abner Post and Dr. Fran-

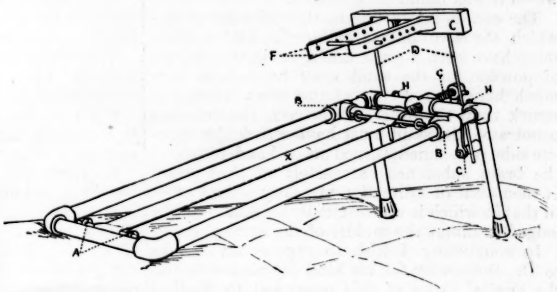


FIG. 1.

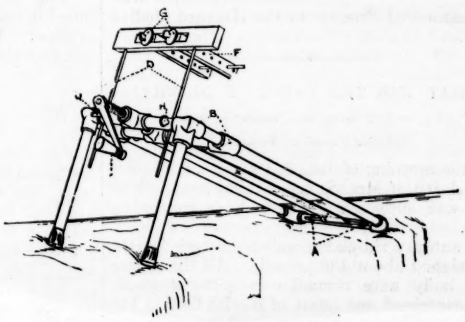

FIG. 2

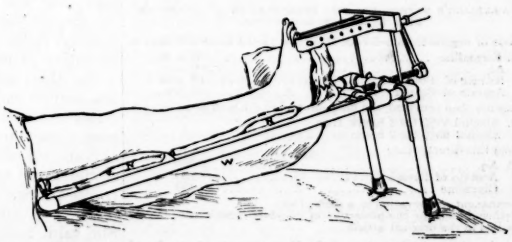

FIG. 3.

cis S. Watson, at the Boston City Hospital, was designed for fractures of the leg, both upper and lower, which because of their nature were difficult to hold in a corrected position during the application and setting of a plaster cast.

It was the writer's desire to make it a mechanical device to maintain the fractured bones in a corrected position by preventing posterior bowing, inversion or eversion, to keep the foot at right angles with the leg, and to allow of an easy and accurate method of approximating the ends of the fragments and of holding them by means of a plaster of Paris cast.

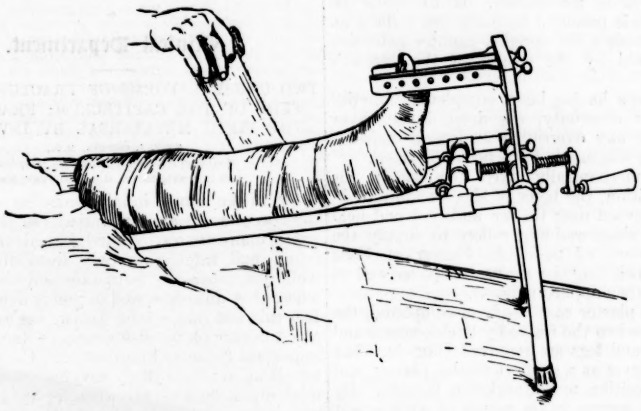

Fig. 4.

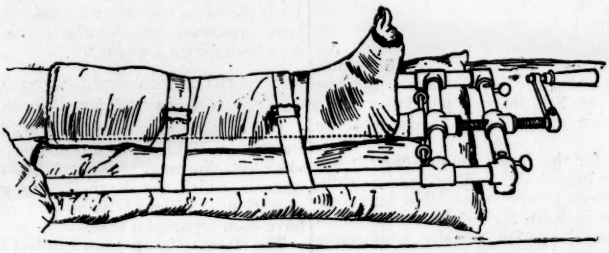

Fig. 5.

The apparatus (Figs. 1 and 2) consists of a pipe frame 40 by 14 inches, with two detachable legs 13 inches high which are screwed into one end. This frame serves as a support for a strip of canvas about 3 inches wide and 30 inches long (X, Figs. 1 and 2). The canvas is made with a loop at either end, large enough to admit a ½-inch brass rod. The lower rod is held in position by 2 screw-eyes in the lower end of the frame (AA, Figs. 1 and 2). The upper one is held in position by 2 screw-eyes placed in a piece of piping which plays back and forth over the long arms of the frame for a distance of 6 inches by means of a thread-screw and crank (BB, Figs. 1 and 2). By the latter two devices the canvas strip is drawn sufficiently tight to prevent sagging by the weight of the leg.

The upright at the end of the frame consists of two ¼-inch brass rods 11 inches long fastened into a piece of oak (DDD, Figs. 1 and 2). This piece of wood has a slit 8 inches by 1 inch into which there are fitted two wooden braces perforated by ¼-inch holes at corresponding points (FF, Figs. 1 and 2). The braces slide sidewise and may be fixed at the desired point by thumb-screws (GG, Fig. 2). The two brass rods (DD, Figs. 1 and 2) play up and down through two holes in the upper end of the frame, and may be held by two thumb-screws at the desired level (HH, Figs. 1 and 2).

The canvas strip having been drawn tight, giving a firm, straight surface to work on, it is covered with two or three layers of sheet-wadding long enough to fold up over the sole of the foot (W, Fig. 3). The leg is placed upon it and the normal curve at the ankle and in the popliteal

space is padded (N, Fig. 3). Any anterior or posterior bowing may now be corrected by placing pads at the proper points. The upright is then raised to such a level that a round piece of wood placed through corresponding holes in the braces will be at the upper part of the ball of the foot. This round of wood is placed in that hole which will bring the foot at right angles with the leg. The braces are now brought in contact with the foot, one from either side, and the foot turned to right or left as the case may be, thus correcting any inversion or eversion and giving the proper alignment of the big toe, inner side of patella and anterior-superior spine of the ilium. By setting the thumb-screws the proper relation of these points is maintained. If extension be necessary it is procured by some one pulling on the foot through the upright, counter extension being secured by the weight of the patient's body.

These steps having been completed, anterior or posterior deformity, toe drop, inversion or eversion, or any overriding or lateral displacement of the fragments have been corrected.

Having mechanically fixed the leg in the desired position, the layer of sheet-wadding (W, Fig. 3) is turned over the leg and foot and held by enough sheet-wadding rollers to supply the proper amount of padding. Plaster of Paris bandages, including the canvas strip, as well as the leg, are then applied (Fig. 4).

After the plaster cast has been completed, the leg is strapped to the frame by buckle-straps and its upright and legs are removed (Fig. 5). The frame then acts as a support to the plaster and is left in position until the latter is hard. By cutting the canvas in its points of attachment to the frame, it is removed and the canvas strap drawn out of the cast.

Besides being useful in the more difficult simple and comminuted fractures, the apparatus has been especially servicable in those which are compound, requiring operation. By its means, fractures that otherwise would have had to be wired have been held in good position without the introduction of a foreign body into the bone.

When used for this latter class of cases it has secured better immediate position; and as sufficient wadding can be applied to allow for subsequent swelling without fear of losing the alignment of the leg, the patient remains comfortable without the plaster being split.

The dressing of a wound is rendered more easy, as the cast is really a fracture-box, from which the dressing can be taken and replaced without disturbing the leg; while the ordinary plaster cast follows the contour of the leg too closely to make this procedure an easy one.

In the treatment of fractured femurs by extension, good results have been attained by incorporating the leg in plaster by the use of this apparatus. In this class of cases special attention is paid to supplying considerable padding over the dorsum of the foot and above the condyles, and to applying the plaster so as to cause the extension to be made from these two points. The extension straps are incorporated in the plaster cast, and therefore the disagreeable feature of adhesive strips applied to the skin for extension is overcome. This method of applying extension has been the most comfortable for the patient and the easiest and most accurate for the surgeon.

Another feature of the frame is that but one person is required to apply a plaster accurately in the majority of cases, thus dispensing with the necessity of holding the leg, which has always been a disagreeable and often unsatisfactory part of the treatment of fractures of the lower leg by plaster-of-Paris casts.

Clinical Department.

TWO UNUSUAL FORMS OF FRACTURE — FRACTURE OF THE CAPITELLUM; FRACTURE OF THE FIFTH METATARSAL BY INVERSION.

BY F. J. COTTON, M.D.,
Assistant Surgeon, Boston City Hospital,
AND C. P. SYLVESTER, M.D., ROXBURY, MASS.

Of all the almost infinite varieties of fractures that occur some are but variants of the common types, many are obvious and typical enough when found and interesting only from their rarity, while yet others are both rare and obscure even where they do correspond to pretty definite types. It is this last class — the class we are especially liable to overlook or misinterpret — that it is really important for us to know about. Common types we all know; the utterly atypical cases we must work out as best we can when we meet them, but in other cases it may be only the knowledge of the occasional occurrence of a lesion that makes it possible for us to recognize it when it does occur. Both the cases here recorded belong to this class; both presented lesions which the writers had long been on the lookout for.

FRACTURE OF THE CAPITELLUM.
(Fractura rotuli humeri partialis.)

Hahn,[1] a number of years ago, described this fracture on the basis of a post mortem on a case observed clinically. Kocher[2] has recorded five cases in which the diagnosis was confirmed by operation. Wright,[3] Steinthal[4] and Stimson[5] have each reported a case.

The fracture in all cases consists of a splitting off of the anterior articular surface of the external condyle — the face with which the head of the radius articulates — described as the capitellum (or capitulum) humeri. The fracture thus involves but a portion of the total mass of the external condyle. The fragment has no firm attachments and hence lies practically free in the joint. For this reason the displacement may be forward or backward; for this reason also there

[1] Hahn: Deutsche Chirurgie, Billroth and Lucke, Lief 63a, 1886, p. 728.
[2] Kocher: Praktisch wichtige Fracturformen. Mitth. a. d. klin. u. med. Inst. d. Schweiz, Heft 10-12, ref. in Cbl. f. Chir., 1896, 545.
[3] Steinthal: Cbl. f. Chir., 1898, xxv, p. 17.
[4] Stimson: Fractures and Dislocations, 3d Ed., p. 256.
[5] Wright: Guy's Hosp. Rep., 1879, iii, s. xxiv, p. 51.

is practically no chance of firm union of the fragment with the shaft of the humerus.

Wright's case and one of Kocher's were in children (twelve and fourteen years), all others were in adults ranging up to over sixty years of age. The cause seems to be direct trauma.

CASE I. Mrs. P., aged forty. Jan. 24, 1902, fell down six steps and struck on the left elbow. Two days later she went to the hospital. The elbow was by this time much swollen and discolored. No definite diagnosis seems to have been made, but the arm was put up in an "internal angular" splint and the patient told to return for massage. This she did not do, but shortly began to use the arm. The appended X-ray was taken within a month of the injury.

She was first seen by the writers six months later. At this time she was able to use the arm moderately, but had a good deal of pain after use, especially at night.

The general outline of the arm was normal, but there was slight general thickening about the elbow, and notably just in front of the external condyle. At this point an abnormal, hard, moderately movable mass was to be felt. Extension at the elbow was checked at 40° beyond the right angle; flexion was possible to a right angle only. Pronation and supination were much limited: and rotation, especially in supination, brought out a very definite, rather soft crepitus at about the point where the loose fragment seemed to be. It was obvious that there was a loose fragment in the joint and the diagnosis was made on the clinical evidence alone.

FIG. 1.

X shows loose fragment in front of the external condyle.
Y shows, apparently, the gap from which the fragment came.

The X-ray previously taken was obtained and showed (Fig. 1) a joint substantially normal except for the presence of a loose fragment (X). This fragment, flat on one side, shows on the other an even curve, which can only be from an articular surface. There is no articular surface here save the capitellum which can give such a curve; moreover, there seems to be at (Y) a defect in the articular face of the external condyle roughly corresponding to this fragment. Evidently this is then a case of Kocher's "fractura rotuli humeri partialis," a splitting off of the face of the capitellum, leaving a fragment which has not been united and which (in combination with the small callus masses) greatly interferes with norma lmotion and use of the joint. The patient was advised to have the fragment removed, but declined any operation, disappeared and has not returned.

In all the recorded cases there has been failure of bony union; and interference with function varying[6] according to whether the fragment is as here anterior to the joint or has, as in three of Kocher's cases, slipped into the capsular space between radius and olecranon behind.

The operations done to date have been very successful; there is no tendency to restoration of full function by palliative treatment. It is evident that these cases (given the diagnosis and the patient's permission) should be operated on whenever they occur. The symptoms may be generalized as follows:

Limitation of joint motion following trauma (limitation of extension and supination especially).

No displacement of any of the landmarks.

Crepitus on motion.

Local thickening and a more or less palpable fragment of relatively small size, either above and in front of the external condyle or below and behind.

The skiagraph may help, as in the case presented, by showing a curved articular surface that could only come from the capitellum.

FRACTURE OF THE FIFTH METATARSAL BY INVERSION OF THE FOOT,

In the *Annals of Surgery* for 1902, Vol. XXXV, p. 697, Robert Jones of Liverpool reported a half dozen cases of fracture of the fifth metatarsal bone apparently caused by so turning the ankle as to bring the weight to bear suddenly on the outer edge of the foot. This was a new cause for such fracture. We present here a like case:

CASE II. Mrs. N. M., age forty-five. Was dancing in very thin-soled and rather worn shoes. Came down with

FIG. 2.

Oblique fracture of fifth metatarsal, from inversion of the foot.

[6] In Hahn's case there was forward displacement with limited flexion and extension but with pretty free rotation. Three of Kocher's cases, however, showed the backward displacement with marked interference with rotation. Steinthal's case showed "extension to 150 degrees, flexion to 135, pro and supination present with crepitus."

her weight on the outer side of the right foot with the heel raised; felt something give way; stopped dancing and went home, not without some difficulty, but unassisted. The foot became swollen and painful and discolored on the outer side, but she managed to do her housework, and only after a week did she appear at the City Hospital Outpatient Department, where we saw her Oct. 31, 1902.

There was moderate swelling of the right foot, localized over the fifth metatarsal. There was sharp pain when she bore her weight on the ball of the foot. There was no obvious deformity, but on manipulation distinct crepitus was obtained.

The X-ray herewith reproduced shows an oblique fracture of the fifth metatarsal with some displacement.

A pad was applied to the dorsal surface and a padded plantar splint to the sole of the foot. She did not reappear for treatment, but was looked up on Nov. 28, 1902. There was then firm union with slight callus. No palpable deformity. The usefulness of the foot was already substantially normal.

Save for the obliquity of the fracture line this is the exact counterpart of Jones' cases — the causation by weight bearing on the inverted foot is in this case beyond question. The probability is, as Jones suggested, that this fracture is not very rare; how easily it may be passed over as a sprained foot is evident from the history given in this case.

Reports of Societies.

AMERICAN PUBLIC HEALTH ASSOCIATION.

PROCEEDINGS OF THE THIRTY-FIRST ANNUAL MEETING, HELD AT WASHINGTON, D. C., Oct. 26, 27, 28, 29 AND 30, 1903.

THE Association met in the Assembly Hall of the New Willard Hotel under the presidency of DR. WALTER WYMAN, Surgeon-General of Public Health and Marine Hospital Service, Washington, D. C.

OPENING ADDRESS.

This was delivered by GEN. GEORGE M. STERNBERG.

He spoke briefly of the Association as an important factor in promoting the welfare of the people of the United States, not only from a sanitary point of view, but also in the way of national prosperity. He called attention to the epidemic of 1878, which caused a loss of $15,000,000 to New Orleans alone, and more than $100,000,000 to the entire section invaded. Having now an exact knowledge of the method by which yellow fever was transmitted, its prevention had become comparatively easy, and sanitarians had no longer any fear of the recurrence of extreme epidemic of the disease within the limits of the United States. In Washington there was still much to be accomplished in the way of sanitary improvements, the necessity for which was generally recognized. The sewer system was incomplete and in the alleys of the city there were many houses which had no sewer connections and no water supply except from a street hydrant. These alley houses, occupied principally by the more ignorant class of the colored population, were usually overcrowded and were the hot-beds of vice, immorality and disease. The high death rate from typhoid fever, tuberculosis and diphtheria and the excessive infant mortality among this class of the population gave to the nation's capital a mortality rate which did not compare favorably with that of many other cities in this country or of the great capitals of Europe. A law for the condemnation of unsanitary houses was urgently needed. The sewer system should be pushed to completion and the health department should have the authority and the money necessary for the sanitary reclamation of these plague spots which disgraced our otherwise beautiful and healthful city.

REPORT OF THE COMMITTEE ON CAR SANITATION.

This report was read by the Chairman, Dr. GRANVILLE P. CONN of Concord, N. H. While the committee was not prepared to suggest reform which would at once settle the much vexed question, yet it was believed progress was being made, and the managers of railroads were coming more nearly in accord with public opinion, and that the problem was gradually being solved. The house on wheels not only had the atmospheric influences which at all times surrounded the dwelling, but at different rates of speed this pressure was immensely greater than that upon the ordinary domicile. One should always consider the character of the occupants, who, for the time being, were tenants and had but little or no thought of the sanitation or well being of those who might be the next passengers to occupy the same seats, and who, perhaps, had little or no appreciation of what an expert in sanitation would consider a healthy condition of personal cleanliness or of a habitation. The more permanent the means and methods adopted by health authorities, the more satisfactory they would prove to the commercial world and the general manager.

TRANSPORTATION OF PERSONS SICK WITH TRANSMISSIBLE DISEASES.

DR. J. H. HURTY, Indianapolis, Ind., read a paper with this title. Among other things, the author stated that leprosy was not so easily transmitted as tuberculosis and compared with the latter malady in its destructiveness to human life it amounts to nothing at all; yet the mere mention of the word "leprosy!" caused a shudder, and a riot would result if an attempt was made to introduce a leper into a railway car. Influenza, also a transmissible and very destructive malady, killed a thousand where leprosy killed one, still people did not fear it sufficiently to take even ordinary precautions against it. The public welfare could in no degree or manner be advanced through risking the increase of transmissible diseases. All intelligent observers could clearly see the possible harm which might attend the transportation in railway trains of cases of smallpox, yellow fever, bubonic plague, diphtheria, scarlet fever and leprosy, and in consequence

public opinion would not tolerate such a thing. An equal understanding in regard to pulmonary tuberculosis, influenza and typhoid fever would develop a public opinion, demanding patients having these diseases, that rational regulations intended to prevent transmission must be rigidly enforced. Special compartments for persons sick with communicable diseases were impracticable.

CAR SANITATION IN THE REPUBLIC OF MEXICO.

DR. JUAN BRENA of Zacatecas said it was a well-known fact that the infectious germs of diseases were floating in the air and were by it deposited in the veneers, mouldings and ornaments of furniture, and thence again taken up by the air and inhaled with it, and for that reason writers on hygiene and sanitary authorities had again and again recommended simplicity of ornamentation, hardness of materials and polished surfaces for the interior of cars. He referred to the construction of railway cars, the methods of cleaning them, the drinking water, water closet, and ventilation.

The suggestions and observations made by scientific writers had been neglected and very little or no attention paid to them up to date, and thus the grave defects were still existing. These obstacles, however, should not dishearten sanitarians, but they should incite them to preach and work with the tenacity of the water drop which falls upon a hard stone.

REPORT OF THE COMMITTEE ON ANIMAL DISEASES AND FOOD.

DR. D. E. SALMON of Washington, D. C., Chairman, presented the report of this committee. He said the experiments and comparative studies of Theobald Smith had attracted special attention to the difference in virulence shown by tubercle bacilli from human and bovine sources when inoculated upon cattle. Smith also pointed out certain morphological and cultural differences in bacilli from these two sources, and in the location and histology of the lesions in cattle produced by such bacilli. He did not conclude, however, that bovine bacilli could not produce disease in the human subject, but said that bovine tuberculosis might be transmitted to children when the body was overpowered by large numbers of bacilli, as in udder tuberculosis, or when certain unfavorable conditions existed. He adduced evidence that four human cultures caused generalized tuberculosis in cattle; but Kossel suggested that it might be possible that the bacilli in cases of human tuberculosis under certain circumstances could likewise attain a very high pathogenic activity for cattle without their being for that reason bovine bacilli.

Of 39 cases of human tuberculosis tested, 4, or over 10%, were virulent for cattle, and would be classified as of bovine origin; but these 4 cases were all found among the 16 cases of tuberculosis in children which the German Commission investigated; hence it was plain that 25% of the cases tested of tuberculosis in children by Koch's method would be classified as of bovine origin.

While the Committee agreed that it was advisable to scrutinize clinical evidence as carefully as possible before it was accepted as influencing the decision of such an important question, consistency demanded that one should accept clinical evidence bearing upon the transmission of bovine tuberculosis to man on the same terms that evidence was accepted as to the transmission of the disease from man to man.

The Committee concluded that it would require much work to decide with even approximate accuracy the proportion of human tuberculosis caused by animal infection; but the fact that 25% of the cases in children investigated by the German Commission, and 50% of similar cases investigated by de Schweinitz, showed by this test that they were caused by animal infection was sufficient to convince the Committee that measures should be taken and enforced at once to guard against infection from this source.

GEN. GEORGE M. STERNBERG said that the Koch school was disposed to differentiate very closely between pathogenic bacteria along specific lines, but investigation had shown that all pathogenic bacteria varied greatly in virulency. Pasteur, in his earlier researches, showed how attenuated varieties might be produced. Motile bacilli might lose their motility, etc. Furthermore, pathogenic bacteria might become practically non-pathogenic as the result of cultivation, as in the case of the diphtheria bacilli, and the tubercle bacillus showed the same characteristics.

DR. GARDNER T. SWARTS mentioned the shaking of the hide of the cow as a means of transmission of tuberculosis through milk, in addition to shaking the udder during the milking process.

DR. JOHN GUITERAS said the results in Cuba tended to show the transmission of tuberculosis through milk was not as frequent as was generally supposed. No milk was used in Cuba that was not boiled, and yet he believed infantile tuberculosis was as frequent in Cuba as elsewhere.

DR. J. M. LINDSLEY did not believe consumption, strictly speaking, was a contagious, infectious or hereditary disease. He said it was a product of wrong living. This wrong living might be from taking milk from tuberculous cows, or from living in a tuberculous house.

DR SALMON said that while Cuba sterilized its milk more than America did, yet it might also be the case that if Cuba did not sterilize its milk it would have more tuberculosis than it did at present.

REPORT OF THE COMMITTEE ON THE CAUSES AND PREVENTION OF INFANT MORTALITY.

This report was read by DR. HENRY MITCHELL of Asbury Park, N. J., Chairman. Among the measures which were most promising for a further reduction of the mortality among infants, the Committee directed attention to the following:

(1) To secure a more general adoption of cleanly methods of the collection, cooling and handling of cows' milk. It was not enough to destroy bacteria which had been permitted to gain entrance into the milk, for while pathogenic bacteria might be rendered innocuous, the toxines already formed were not affected by high temperature, hence no manipulation of the milk could be safely substituted for cleanliness in its collection and distribution. (2) To abolish breeding places for flies in dwellings and to exclude them from contact with food. (3) To encourage the erection of improved tenements in cities and to show the dwellers in crowded districts the advantage of residence in the suburbs. (4) To more effectually isolate all cases of the dangerous communicable diseases.

IMMIGRATION AND PUBLIC HEALTH.

DR. A. J. MCLAUGHLIN of Washington, D. C., read a paper on this subject. In considering the danger to the public health from immigration, he said three factors must be taken into account: First, the physique of the immigrant. Second, his destination. Third, the presence or absence of communicable disease. The physique of the immigrant was by far the most important factor. Destination was scarcely less important than physique, and it was the rule that aliens of a race having a low physical standard would invariably herd together in the overcrowded unsanitary tenement districts of our great cities; while the sturdy races of unskilled laborers were scattered over a wide territory and tended to establish little homes of their own in the country or in the suburbs of manufacturing towns or cities. As to the question of communicable diseases among immigrants, the ordinary quarantinable diseases were eliminated by efficient quarantine methods, but certain communicable maladies, classed as loathsome or dangerous contagious diseases, existed among immigrants, and constant vigilance and considerable skill were necessary on the part of medical inspectors of immigrants to detect these cases and separate them from the healthy immigrants. The most important of these diseases, because of its frequency, was trachoma. Of the total number of cases of loathsome or dangerous diseases found in immigrants, 87% was due to trachoma, and 10% to favus.

The writer concluded that if the thousands of recruits for the sweat-shop army which arrived each year could thus be checked for ten years, the present existing tenement-house problem would solve itself. The terrible congestion of the tenements would be relieved; the scale of wages for the sweat-shop worker would be elevated; and the general sanitary conditions of life in such districts as in the lower East Side, New York City, improved sufficiently to reduce the menace to the public health from this cause to a minimum.

PREPARATION OF VACCINE VIRUS.

DR. JOHN F. ANDERSON of Washington, D. C., said experimental work had shown that the germicidal action of glycerine was feeble. Recently some valuable work had been done with other substances than glycerine to be used in the destruction of the bacteria found in vaccine. These substances were sodium biborate, boracic acid, carbolic acid, chloroform and potassium cyanide. Of these, chlorof rm seemed the most valuable.

According to Green of England, by the use of chloroform vapor the crude pulp was freed from non-sporebearing germs in from a few hours to seven days, while the active agent of the vaccine remained potent as long as in the glycerine controls, and in some cases longer. The quick elimination of the extraneous bacteria by this method was a great saving in time as compared with the use of glycerine, which rarely exerted its full effect before the fourth week. Chloroform being extremely volatile could be allowed to evaporate from the vaccine under aseptic precautions after being allowed to act as long as desired. It would be especially useful in hot countries where the active agent in vaccine does not retain its potency long, or when, as in epidemics, sudden calls were made for large quantities of virus.

DR. EDUARDO LICEAGA, of Mexico City, offered some suggestions in regard to the desirability of an agreement between the sanitary authorities of adjoining countries for mutual defense against transmissible diseases.

ADDRESS OF WELCOME.

This was delivered by HON. H. B. F. MACFARLAND, President of the Board of Commissioners of the District of Columbia. After expressing his gratification that the Association had assembled in Washington, he stated that the city had a particular claim upon the interest of the Association at present because of the work of improving the water supply and sewer systems which was in progress, and also because there was being made an earnest effort to secure legislation from Congress to enable the city to end the unsanitary conditions in its alleys where the slums existed. It was fully realized that the health of the people was the first duty of the statesman, and that all else that could be done for this or any capital went for nothing if its health was not protected and promoted.

PRESIDENT'S ADDRESS.

Following Mr. Macfarland's welcome, SURGEON-GENERAL WYMAN, President of the Association, delivered his annual address, during the course of which he gave an exhaustive review of the history of the Association, its aims and objects, the researches into the fields of medical science which it had conducted, and the results it had accomplished. Coupled with this, he gave an epitome of the causes that led to the formation of the Association and the history of its growth by the addition from time to time of the various countries of the Western Hemisphere, the last of which to join the Association and take up its part in the field of scientific research being Cuba, only recently liberated from the bonds that had pre-

vented her from assuming her proper sphere in a study of one of the most deadly plagues with which she had been for years afflicted.

After reviewing the need and effect of sanitation, the sanitary laws of states and municipalities, Dr. Wyman paid a tribute to the unselfish medical men who for the good of science and from a sense of civic pride had repeatedly carried out investigations in the interest of the public health and given their services without thought of compensation to the public good.

He cautioned the members against being placed in the role of reformers, who, he said, often sought one worthy object and attained it at the expense of many other objects no less meritorious; that their dependence upon an enlightened public sentiment and the careful scrutiny of every proposed message forefended them against inconsiderate, spasmodic or overzealous action, but that they might exhort others in behalf of those measures which would insure to the rich protection from the dangers surrounding the very poor and to the very poor sanitary dwellings, pure air, good water and sunlight in abundance, the God-given blessings of the human race, which should be inalienable. This would then create an aristocracy to which all might belong — the aristocracy of sunshine.

REPORT OF THE COMMITTEE ON THE DISPOSAL OF REFUSE MATERIALS.

MR. RUDOLPH HERING, New York City, read this report. The committee pointed out that (1) different local conditions demanded different methods of collection and disposal; (2) that each municipality should select the method which, after a careful study of specific local conditions, and a further careful investigation of the cost of securing satisfactory results, proved to be the most economical in construction and maintenance; (3) that the problem must include the consideration of the methods and cost of handling all of the several kinds of refuse between the origin in the house and on the streets and the points of final disposal; (4) the several kinds of refuse being ashes, street sweepings and manure, dry rubbish, and kitchen garbage, swill or slop. In conclusion, the Committee said that while there were several methods of satisfactory disposal, every one would not be the best for all cities. Each city should study the question as related to its own special condition, and from a large experience both in Europe and at home, select what was found best for itself.

REPORT OF THE COMMITTEE ON THE ETIOLOGY OF YELLOW FEVER.

DR. JOHN W. ROSS, U. S. N., Washington, D. C., read this report. Reference was made to contributions to the subject of yellow fever since the last annual meeting. A table was presented of cases treated at Las Animas hospital, Havana, from Oct. 20, 1902, to Oct. 20, 1903, showing the number of cases of yellow fever and of other diseases; also of the patients immune and non-immune to yellow fever.

He said during the past summer there had been a sharp epidemic on the Mexican littoral. Havana was in constant communication with the infected ports; ten regular passenger steamers plied to and fro each month with a considerable passenger traffic, not to mention the number of other vessels. The quarantine was rigid in preventing the entrance of persons who had been exposed to infection until the period of incubation had passed, and also against the entrance of mosquitoes from these ports; but no precautions were taken against the entrance of baggage, bedding or household goods from those ports. Such things came in without let or hindrance; yet not a single case of yellow fever originated in Havana. Seven cases of yellow fever occurring among men from these vessels were treated in the hosiptal in Havana during the last yellow fever season, with no precautions except to prevent the access of mosquitoes to the patients, still with no case of yellow fever contracted therefrom.

Attention was called to the fact that this was but a repetition of the experience of the previous year. The chances of this being an accident, considering the former history of Havana, seemed scarcely worthy of consideration. The Committee stated that there were minor problems in the etiology of yellow fever yet to be investigated.

REPORT OF THE COMMITTEE ON THE CANTEEN IN ARMIES.

DR. GEORGE M. KOBER, Chairman, Washington, D. C., read this report. Reference was made to the introduction of the canteen system, and after dwelling at great length on the increase of drunkenness, the increase of trials by summary or other courts for drunkenness and for offenses caused by drunkenness, increase of desertions; increase in abscene without leave; effects of the abolition of the sale of beer at the posts on the morality and discipline of the command, the Committee recommended the presentation to the Senate and House of Representatives in Congress of the following resolutions, which were adopted by the Association:

Resolved, that this body deplores the action of Congress in curtailing the authorization of the army canteen or post exchange and in the interests of general and military sanitation recommends its establishment on its former basis at the earliest possible date.

Resolved, that this body, in the interest of temperance and humanity, cordially invites the intelligent co-operation of a very large element of good citizens, who have been active in securing legislation against the sales in the military service of alcholics of any character, in taking successive steps toward the betterment of existing conditions, and thus assist in controlling and largely curtailing an evil which it is powerless at present to prevent.

Recent Literature.

A Manual of Operative Surgery. By SIR FREDERICK TREVES, Bart., K.C.V.A., C.B., LL.D., F.R.C.S. New edition, revised by the author and JONATHAN HUTCHINSON, JR., F.R.C.S. In two volumes. Vol. I. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

This volume (Vol. I of this new edition) of 750 pages is a book which at once attracts attention. First it is conspicuous by its ornate appearance, its binding and rough edged leaves. Again the reputation and previous work of its author are of such a character that one examines with interest this his latest production.

Appreciating the many changes that have occurred during the past decade, Mr. Treves has attempted to entirely revise his previous edition of this work, which appeared in 1891. Many sections have been rewritten or remodelled, and great effort has been made to bring the work thoroughly up to date. This applies to the illustrations as well as to the text. For the convenience of the reader historical details relating to operations and sections of minor importance are printed in smaller type. The subject matter is classified as follows:

Part I. General principles of operative surgery, including details relating to the preparation of patients for operation, to dressings, post-operative treatment of wounds, the selection of instruments, the elementary principles of operative technique.

Part II. Ligation of arteries.
Part III. Operations on nerves.
Part IV. Amputations.
Part V. Operations on bones and joints.
Part VI. Tenotomy.

The operative measures described are those which have appeared best to the author, as tested by an extended personal experience in the operating theater and repeated studies on the cadaver. Also the comparative merits of the various operations described are discussed. The introductory chapters, especially that in which the indications and contraindications for operation in the individual patient are discussed, are forcible and instructive; notably so in the present era of operative enthusiasm. The chapter on aseptic technique is interesting as compared with the methods of this country, since it presents some differences. The plan adopted for the presentation of special operative procedures is as follows: First, the history of the operation in general is described and its indications stated. Next, the instruments required are enumerated. Then the arrangements of patient, operator and assistants, the anatomy of the region by layers (the anatomical landmarks and guides being noted), the operative technique, the dressings and, finally, the after treatment, with often the final results are presented. In the section on amputations the general consideration of the subject is unusually full, and contains many valuable suggestions relating to the formation of and the secondary changes in stumps, the instruments used, the methods of flap-formation and other interesting data. In the section on excisions the statements of after-results of operations are of especial interest and importance, particularly to a surgeon of limited experience, or to the student. The new illustrations are a feature of the volume, and greatly increase the facility with which the reader masters the text.

The book is carefully and well written, and is an excellent presentation of modern surgery. The subject is well classified. It is systematically arranged. The story is effectively told. It is a work fully up to the established standard of its noted author, and the next volume, which will contain the surgery of special regions, much of which may be termed atypical, will be awaited with great interest.

The Diagnosis of Diseases of Women. A Treatise for Students and Practitioners. By PALMER FINDLEY, B.S., M.D. Illustrated with 210 engravings in the text and 45 plates in colors and monochrome. Lea Brothers & Co. 1903.

As stated in the preface, medical literature in the English language has not hitherto included a work on this subject.

To justify the making of a book of 494 pages on a single department of a specialty, albeit that most important one, diagnosis, the author ought to furnish much more complete and much fuller information on his subject than can be found in the best of contemporaneous textbooks. It is a question whether Findley has done this so as to offer to the student and practitioner what cannot be found in the usual treatises.

From the standpoint of the specialist who is studying diagnosis the book is a decidedly good one. The ground is carefully gone over, the style is clear, the illustrations are remarkably good, especially those of instruments and appliances, and the subject matter is in accord with the latest teachings. Lea Brothers have produced a handsome volume which maintains their usual high standard in typography and binding.

Diseases of the Skin. An Outline of the Principles and Practice of Dermatology. By MALCOLM MORRIS. With two colored plates and 58 plain figures. New edition. Chicago: W. T. Keener & Co. 1903.

The author states that the revised edition of this book, which was published in 1898, has been out of print for some time. In the present new edition much new matter has been added and there has also been some judicious pruning. Of the new illustrations, many are extremely good. For its size the book is quite complete, as almost all of the more recently described affections are at least touched upon.

The Principles and Practice of Surgery. By George Tully Vaughan, M.D. (University of Virginia), Assistant Surgeon-General, Public Health and Marine Hospital Service of the United States. Philadelphia and London: J. B. Lippincott Co. 1903.

This is a compactly written volume of convenient size (569 pages) and moderate price, designed to present the subject of general surgery in a way best adapted for the use of the general practitioner and student. For this reason the consideration of surgical specialties have been omitted. The author's purpose has been to present the subject matter from the most practical point of view, avoiding long theoretical discussion; in other words, a book of ready reference for the student preparing for examination when there is not time to review the more complete works usually studied; or for the busy practitioner who must at times refresh his memory in the most concise practical manner possible.

The subject is presented in two parts: Section I, which treats of the usual general subjects, such as inflammation, wounds, anesthesia, infection and infectious diseases, tumors and cysts; also, operative and minor surgery, bandaging, skiagraphy.

Section II, which comprises more than three-fifths of the book, is devoted to the surgery of "Systems and Regions," classified physiologically into the vascular, osseous, respiratory, degestive, genito-urinary and other systems. In this section are chapters on orthopedic surgery and tumors of the breast.

The text is illustrated by 281 wood-cuts, diagrams and reproduction of photographs, which graphically present clinical, pathological and traumatic conditions, details of surgical technique, instruments and apparatus.

Any work in which modern surgery is condensed into 533 pages must necessarily deal only with the more important and ordinary subjects. The task of making this selection is a very difficult one. In this volume it has, on the whole, been satisfactorily accomplished, and except, perhaps, in minor details the reviewer finds little to criticise and much to commend. It seems to be well adapted to occupy the position for which it is intended.

To a student in books of this type it is often difficult, on account of the arrangement of the text, to distinguish between what he is to consider as a complete presentation of a given subject, what is a statement of accepted facts or demonstrated actualities; and what is incomplete, merely the opinion of to-day, or a temporarily accepted method of treatment on account of ignorance of something better. It would be well, perhaps, if this distinction should be more definitely made than it is in this volume, although often this point is purposely ignored in order to prevent confusion of the readers' impressions. However, to make a subject too simple incurs the risk of creating a false impression of accuracy. An illustration of this is the description of aseptic technique, the treatment of osteomyelitis, or the post-operative treatment of club-foot.

It is as a rule well that a student should be able to separate clearly facts from theories; what is satisfactory, productive of definite results and practical, from that which is only used as an expedient in the absence of what is surely efficient.

Ambulance Work and Nursing. A Handbook on First Aid to the Injured, with a Section on Nursing, etc. Profusely illustrated. Chicago: W. T. Keener & Co.

This rather ornately published volume in blue cloth and gold with its numerous illustrations is a book which by its "exterior," so to speak, attracts attention. It is according to its preface intended to be strictly a "First Aid" book, since great emphasis is placed on the importance and value of this class of knowledge to non-medical people.

It consists of two parts, the first of which deals with "First Aid to the Injured," while the second is devoted to Nurses and Nursing, Massage Bone Setters and Bone Setting.

Part I is classified as is usual in this type of book. The essentials of anatomy and physiology are concisely described and are well illustrated. Then the subjects of bleeding, wounds, bandaging, fractures, obstruction to respiration, insensibility, burns and scalds, "fire," poisoning, foreign bodies, transportation of the injured and stretcher exercises are successively treated.

Part II consists mainly of the details usually found in nurses' manuals, with the exception of the chapter on bone setting, and is based on English ideas and methods.

The book is a small quarto of 305 pages and 173 illustrations. It is well indexed. As above stated it is written with the evident intention to produce a book intelligible to the non-medical part of the community, and of as practical a nature as possible. It is indeed unusually free from technical phraseology. The name only of its publishers appears on its title page. Its style is at times fragmentary. It contains many valuable suggestions and shows the influence of practical experience and a practical mind in its compilation. On closer inspection one notes here and there minor details which cause the reader to gradually form the opinion that it is a book (like many of its class) which requires a technical knowledge sufficient to separate the "wheat from the chaff;" also in certain subjects, as for example, "disinfection," that it is not in accordance with the most recent ideas. Again it has a characteristic common to this class of book that occasionally extraneous material is introduced in a detailed description of treatment which impairs its conciseness, confuses the reader and much diminishes the definiteness of the description of details.

It is not intended by the above criticisms to imply that the book has nothing to commend it, for, on the contrary, it is very interestingly

written and is full of valuable practical points. It presents also many instructive and suggestive illustrations. Its title page without an author's name and its evidently English character, while presenting the name of a Chicago publisher, stimulates one's curiosity to learn the personality of its writer and its history.

Compend of Gynecology. By WILLIAM H. WELLS, M.D. Third edition revised, enlarged, with 145 illustrations. Philadelphia: P. Blakiston's Son & Co. 1903.

This third edition of Dr. Wells' compend has been improved by the addition of a chapter on the general therapeutics of gynecology. It is a valuable book of its kind for the student who wishes to refresh his memory.

It has the disadvantages of all compends in that the detailed descriptions are necessarily cursorily treated and incomplete. It would seem to be of more advantage for the student to have full directions for the performance of a limited number of selected operations rather than scanty directions as to many.

It is to be doubted whether a short paragraph is sufficient to give an adequate idea of Dudley's operation for anteflexion, for instance (page 126). Many operators find this operation difficult to understand even with the aid of the best illustrations of the various stages and an abundant descriptive text. With the exception of the figuring of a few obsolete instruments and pessaries the book is well up to date and should maintain its former popularity.

A Text-Book of Surgery for Students and Practitioners. By GEORGE EMERSON BREWER, A.M., M.D., Lecturer on Clinical Surgery at the College of Physicians and Surgeons, Junior Surgeon to the Roosevelt Hospital, Surgeon to the City Hospital, etc., etc., etc. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1903.

This book is a handsomely published volume of 706 pages, illustrated by 280 engravings and 7 plates in color and monochrome.

The first eight chapters are devoted to general subjects such as infection, inflammation, acute and chronic infections, surgical diseases, tumors, shock, technique and anesthesia. The remainder of the work deals with the surgery of regions, systems and organs classified anatomically; but with the exception of the chapters on deformities, genito-urinary surgery in the male and the rectum, "special" surgery has been omitted.

The title of the book indicates its purpose. It has been written to furnish a comprehensive yet abridged text-book in surgery which presents the accepted modern views of pathology and treatment as well as the essential practical facts as concisely as is compatible with clearness. The surgery of to-day has developed so rapidly that the modern text-book usually comprises two large-sized volumes. Hence one opens the single compact octavo of Dr. Brewer's with curiosity and interest to learn how he has condensed his subject into its present convenient form without essential sacrifice. As one reads, however, the plan becomes apparent, and the reader's doubt as to the possibility of the task gradually disappears and he is ready to congratulate the author on his success, for certainly he has produced a text-book which is a well balanced, well adapted work for students. This has been accomplished by attention to several details, First mention of special surgery, as for instance, the eye, ear *et alii*, has been omitted. Next no bibliography or citation of authorities is introduced except when recent methods are mentioned which have not yet received general recognition. Again, when several or many methods or opinions exist, only one or two (the ones in the author's opinion mos satisfactory) are selected and described.

The book is a presentation of the most advanced ideas both as regards pathology, laboratory work, operative technique and treatment. This is shown in the chapter on abdominal affections, especially the surgery of the stomach and biliary passages, the surgery of aneurism, acetonemia, etc.

One must not expect in a book of this size to find full details, and often the description given is very brief; but when one reads carefully what is presented, one finds the essentials are usually given. For example, the "Edebohl" treatment for chronic nephritis which is condensed to a single paragraph, but in that paragraph is stated the procedure, its originator's name, the supposed pathological effect of the operation of decapsulation, the manner of cure, a statistical summary of the results and an opinion of its practical value.

The whole book shows the same concise style, pregnant with facts, well classified and systematically arranged, excellently well presented from a "graphic" standpoint.

It will without doubt be received by students with favor and its author is to be congratulated on the satisfactory, commendable manner in which he has performed a most difficult task.

Medical Jurisprudence, Insanity and Toxicology. By HENRY C. CHAPMAN, M.D., Professor of Institutes of Medicine and Medical Jurisprudence in the Jefferson Medical College, Philadelphia. Third edition, thoroughly revised, greatly enlarged and entirely reset. pp. 329, fully illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

This, as its name implies, is a small volume on the general subject of medical jurisprudence, being essentially the lectures given on this subject by the author to his medical class at the Jefferson Medical College during the years 1891 and 1892. The author discusses the usual matters which bring medicine into relation with the law, and offers them in brief, readable form, with adequate illustrations in the text. This third edition has been revised to meet the advances in the subject, and the book, although far from exhaustive in its treatment, should still find a place of usefulness, particularly as was originally intended, in the crowded curriculum of the modern medical student.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 31, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE CANCER QUESTION.

IN spite of the somewhat negative results hitherto obtained in the investigations regarding the etiology of cancer, interest in the subject does not appear to be in the least on the wane. On the contrary, the elusiveness of the problem apparently adds a certain zest to the zeal of its investigators, and the literature is continually growing in consequence.

We have before us the fourth annual report of the work of the Cancer Laboratory of the New York State Board of Health. This laboratory, under the direction of Dr. Roswell Park of Buffalo, has been assiduously engaged in the cancer research for the last four years. This fourth report is a pamphlet of upwards of one hundred and sixty pages, containing the results of the work done by the various persons connected with the laboratory during the past year.

Dr. Park in his report draws attention to the fact that the work is now being conducted along three principal lines and in three laboratories. Investigations on the pathological, the chemical and the bacteriological sides are being used in correlation in the hope of reaching results which a single line of investigation has hitherto been unable to accomplish. Metabolism in the broadest sense is being studied in relation to cancerous disease.

Regarding the much disputed protozoa and the part they play in the genesis of cancer, Dr. Park makes the following remark:

"There is not a practising physician in the United States who has anything more than a rudimentary knowledge of this subject, and yet the question of cancer is becoming more and more a biological problem."

To meet this need Prof. Gary Calkins of Columbia University has been added to the laboratory staff as consulting biologist. Dr. Gaylord contributes several articles in continuation of the work he has hitherto done, and which is already well known to many of our readers. A paper of the report to which we desire to call special attention is from the pen of Professor Calkins, whose authority on the subject of the protozoa is wide reaching. In this paper, under the title "Suggestions for the Biological Study of Cancer," Professor Calkins maintains in the first place that, inasmuch as the specific organism of smallpox, as discovered by Dr. Councilman and worked out through its life cycle by himself, is no longer open to doubt, it follows that the contention for a like origin of cancer is strengthened, and that we are therefore justified in considering as a working hypothesis that the cell inclusions in carcinoma are phases of an organism. He thinks that:

> Inclusions in carcinomatous tissues should be studied by specialists trained to the study of protozoa and not left exclusively to pathologists, many of whom regard all structures which are to them incomprehensible as some type of degeneration product of the cell. Such a study, made with the best methods and the best technique that the zoölogical side can afford, should lead to an independent point of view, and should give definite results, which, together with those of the pathologist, the chemist, the physiologist, and the surgeon, should give a clear conception, if not a solution, of the general problem of carcinoma.

Professor Calkins also urges work from the physiological and chemical points of view, with reference especially to the possibility of a specific activity of toxins derived from micro-organisms. Finally he believes that the experimental side of the question may ultimately give definite results. The morphology of the so-called cell inclusions demands further study, and the work hitherto done, although far from complete, leads him to the provisional assumption that the cell inclusions are not secretions, as described by Greenough, or degeneration products of the cell, nor modified centrosomes and spheres, but are phases of an organism belonging to the group protozoa.

Coming from such a source, this statement must attract wide attention and renew the somewhat waning interest in the protozoa as the important etiological factor in cancer. Professor Calkins' remarks, however, are not to be interpreted as a belief that protozoa are the cause of cancer. His contention merely is that evidence is accumulating which, with our increased knowledge of the morphology of the protozoa, is likely to make the demonstration positive that protozoa do

exist in cancerous tissue, whatever their significance there may be, — a contention which gains weight from certain organisms discovered in smallpox, and more recently observed by Mallory in scarlet fever. The remainder of this Buffalo report indicates much earnest work on various phases of the general problem, not as yet conclusive, but at least promising for the future. Certainly the laboratory is to be congratulated upon having obtained the services of Professor Calkins, who stands pre-eminent in his knowledge of these lower forms of animal life.

The *British Medical Journal* for Dec. 12 publishes as the Bradshaw Lecture an address by Mr. Henry Morris on "Cancer and its Origin," together with a series of papers by various authors on the general subject, among which one on the parasitic theory of cancer by H. G. Plimmer will be read with interest. Mr. Morris reviews the various theories which have of late been advanced, and concludes that the so-called tumor germ theory of Cohnheim is deserving of the most faith. Plimmer naturally holds to the view, which he has often previously expressed, that the parasitic theory alone explains the facts and is therefore most worthy of acceptance. From Germany comes a second paper from Feinberg that the parasite of cancer is a protozoön belonging to the special class of sporozoa.

It is not to be doubted that ultimately, out of the various conflicting opinions, a definite and satisfactory solution will come. In the meantime those of us who are not actually engaged in the research must assume the attitude of unprejudiced observers and give to each theory its due. We beg leave now merely to call attention to the fact that the parasitic origin of the disease through protozoa has received a new impetus which must be acknowledged and from which no doubt certain definite results will come.

HYDROTHERAPY AND ALLIED METHODS OF TREATMENT.

ONE of the most noticeable features in recent therapeutic advance is the increasing attention which is being given to what, for want of a better term, we may call physical methods of treatment. Physicians are gradually coming to recognize that such therapeutic measures demand serious consideration, and also that they may be adequately given at home and at relatively small expense. For years past, well-to-do persons have sought foreign baths and health resorts at their physicians' advice for a great variety of ailments and have no doubt, in many instances, been materially benefited thereby. We are not disposed to maintain that equally satisfactory results could always be attained by similar treatment at home, but we are, at least, convinced that very much more could be accomplished than is ordinarily supposed possible by the establishment under strictly medical control of properly equipped institutes for this type of treatment. For many patients it is an impossibility to go abroad or to a distance in this country or even leave their occupations for any length of time in search of health, and for these as well as for the more independent it seems our manifest duty to provide.

It is eminently reasonable, therefore, that cities which pride themselves on their progressiveness in medical matters should be adequately provided with those means of treatment which cannot be satisfactorily given in the individual physician's office. Such an establishment should ensure not only treatment by baths and water generally, but also the possibility of using electricity in its various forms, hot air cabinets, light rays, and, in fact, whatever appears to promise a rational means of benefit or cure.

It should also be remembered that such methods of treatment are not limited to any one class of patients, but that under certain conditions, arterial, cardiac, pulmonary, renal, rheumatoid, joint and nervous affections may all be benefited. Finally, it is desirable, if these methods of treatment are to be applied at all, that they should be given under strict medical control, which alone provides reasonable assurance that harm may not be done in cases requiring special precautions. It is self-evident that unless such treatments are given skillfully and with knowledge they will neither appeal to the intelligent physician nor be of benefit to the patient. On the other hand, we are confident that under proper conditions of management and medical direction a very positive benefit to the community would result.

In consideration of these facts, and recognizing, as we do, the need of such an establishment for hydrotherapeutic and other treatment of an allied sort, we take pleasure in calling to the attention of our readers a letter printed in another column from Drs. Putman, Cutter and Lovett, in which they speak of an enterprise of this character in Boston, which is now well started, but which will require the co-operation of the profession at large if it is to fulfill its completest function. We have no doubt that physicians, in whatever line of practice, will feel the need which we have at-

tempted to express and will rally to the support of an enterprise which should prove a credit to themselves and to the city.

INVESTIGATION OF THE BUTLER TYPHOID EPIDEMIC.

IT is always a sign of progress in the conflict with disease when persons other than physicians take an active and intelligent interest in its cause and prophylaxis. Tuberculosis will no doubt finally be held in check through the efforts of the laity rather than through the direct work of the physician. The cause of typhoid fever likewise is coming to be generally understood by intelligent people without medical training, and no doubt this will in time prove the greatest possible safeguard to the community.

It is, however, extremely rare to see the subject of a typhoid epidemic discussed with the skill and acumen which characterizes a paper in the current number of the *Engineering News* from the pen of George A. Soper, an associate member of the American Society of Civil Engineers. In most systematic form, amply illustrated, Mr. Soper discusses with much detail the cause, the course and the outcome of the phenomenal epidemic of typhoid which has recently visited Butler, Pa. The cause of this epidemic, which fortunately appears now to be under control, was the water supply. Water for some months had been taken from a creek at a point at which it was obviously polluted. No disease appeared, however, so long as filtration was carried on. Filters were discontinued from Oct. 20 to Oct. 31, and the epidemic began Nov. 2.

We have not space to enter into detail regarding the scope of this most admirable paper. We, however, wish to call the attention of our readers to it as a model example of a systematic, succinct and exhaustive treatment from the sanitary point of view of a notable typhoid epidemic. It may well be read by physicians everywhere and should serve as an object lesson of the methods by which such an investigation should be carried on. As we suggested at the outset, this paper is of particular interest as coming from a man presumably not primarily interested in the medical aspects of his subject. It also demonstrates how with the increase of special knowledge it becomes necessary for the civil engineer to encroach upon what formerly would have been called the domain of the physician, and conversely is suggestive of the fact that the modern physician may well devote a part of his time to the scientific investigation of the problems of engineering, particularly as applied to sanitary questions.

So far as this epidemic is concerned, we are gratified to make mention of the fact that even before the complete cessation of the disease the situation has been thoroughly discussed and the facts presented to the medical profession as well as to sanitarians in a way which precludes the necessity of a further medical investigation. If physicians may thus depend upon sanitarians without definite medical training for their investigations into epidemic disease, we may certainly look forward to a still more speedy conquest of what are now coming to be regarded as preventable conditions.

Pennsylvania's misfortune seems to be in a measure merited. We have on more than one occasion alluded to the wholly inadequate provision made for the work of its Board of Health by that state, and it is not difficult, in such typhoid epidemics as this of Butler, to read a lesson which the state should certainly take to heart. If the experience through which this town and Plymouth in the same state has recently passed has no other effect than to stimulate the authorities to an appreciation of the necessity of an adequate health board, a result of much value will have been gained, though at a high cost.

PHYSICIANS FOR THE PHILIPPINES.

IT is announced by the United States Civil Service Commission that on the days of Jan. 27 and 28 examinations will be held at various places to fill vacancies in the position of physician in the Philippine service with a salary ranging from $1,200 to $1,800 a year. Applicants, who must have had at least one year's experience in hospital work or as assistant surgeons in the army in the Philippines, are to be examined in the various fundamental branches of medicine, including questions on tropical diseases.

As inducements to this service it is suggested that the service itself has many attractive features, and involves a visit to a most interesting part of the world. China and Japan are near and are suitable places to visit during vacations. The service is classified, promotions are probable, the climate is good, and as a rule employees maintain excellent health. Liberal arrangements are made regarding traveling expenses and after a certain period spent in the service. Is is suggested that the cost of living in Manila or in its suburbs is relatively small, and that rents will probably be less in the future than now.

We are strongly inclined to think that this service will be attractive to many men of good medical attainment. When one considers the almost hopeless competition at home one wonders why more young men of ambition and proper equipment do not avail themselves of such offers for positions in the government service. Various indications seem to show that medical men are being accorded a more proper position in the army than heretofore, and with this legitimate concession it is not to be supposed that the service will long be lacking in suitable men.

MEDICAL NOTES.

INDEX MEDICUS. — With the following opinion of the *Medical News* we are in entire agreement:

This valuable publication has now some 450 subscribers — a meager list and unfortunately a commentary on bibliographical scholarship. We learn that there is every reason to believe that if 500 bona fide subscribers can be secured the Carnegie Institute will continue its appropriation and make the *Index* a permanent affiair. American physicians should not rest under the imputation that there are only 500 of its 120,000 practitioners who are up and alive to the interests that the *Index Medicus* represents. There should be thousands of active, wide-awake men in this country ready to support the *Index*. American physicians are proud of their institutions. Surely the extent of this is not measured by a paltry $5

THE GERMAN EMPEROR. — The *British Medical Journal* is authority for the statement that the German Emperor has practically entirely recovered from his local ailment. His voice is again clear and resonant. Professor Schmidt has been honored by an effective privy councillorship, which carries with it the title " Excellency." Professors von Esmarch, von Bergmann and von Behring are hitherto the only physicians who have received this distinction.

REAPPOINTMENT OF CHICAGO'S HEALTH COMMISSIONER. — Dr. Arthur R. Reynolds has been reappointed Commissioner of Health of Chicago, by Mayor Harrison, and his appointment has been confirmed.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Dec. 30, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 55, scarlatina 54, typhoid fever 9, measles 129, smallpox 0.

A CENTENARIAN. — Mrs. Hannah Newell Barrett has recently died in Boston at the age of upwards of one hundred and three years. In addition to being one of the city's oldest residents, Mrs. Barrett also had the honor of being the oldest daughter of a soldier of the Revolution drawing a pension from the Government.

REPORT OF STATE HOSPITAL AT TEWKSBURY. — According to the annual report of the trustees of the State Hospital at Tewksbury, there were admitted to the institution during the year under consideration 3,493 persons, being 247 more than in the previous year. The whole number cared for was 4,688, or 216 more than in the previous year. Among these, 606 were insane. Of the total number, 3,698 were treated as hospital patients, which gives one an idea of the prominence of this portion of the institution's work as contrasted with the almshouse element. Among the recommendations, the trustees present as the most urgent needs a ward for consumptive women, wards for the isolation and treatment of contagious diseases, a home for male attendants, and additional land for cultivation and pasturage.

LOWELL LECTURES ON BACTERIA IN MODERN MEDICINE. — Dr. Harold C. Ernst, Professor of Bacteriology in Harvard University, will deliver a course of free public lectures under the auspices of the Lowell Institute, beginning Jan. 5, 1904, on the general subject of " Bacteria in Modern Medicine." The lectures will be given Tuesdays and Fridays of each week until the course of eight lectures is completed. Special topics to be considered are:

(1) Considerations in Regard to Infection. (2) General Characteristics of Pathogenic Bacteria. (3) Methods of Action of Pathogenic Bacteria. (4) Defence and Reaction of Living Tissue against Bacteria and their Products. (5) The Condition of Immunity. (6) Immunity, continued. (7) Therapeutic Measures. (8) Hygienic and Prophylactic Measures.

APPOINTMENT OF GEORGE T. TUTTLE, M.D. — It is announced that Dr. George T. Tuttle, who has for many years been connected with the McLean Hospital, will succeed Dr. Edward Cowles as superintendent of that institution. The position of first assistant physician will be filled by Dr. E. Stanley Abbott, at present assistant superintendent of the Boston City Hospital.

WAR UPON CONSUMPTION. — The Boston Association for the Relief and Control of Tuberculosis, to the work of which we have previously alluded, is sending out a leaflet entitled, " A War upon Consumption." This leaflet contains, briefly stated, a list of directions as to the prevention of consumption and as to methods of strengthening

the body against it. These directions are put in popular form and are excellently expressed. The general work undertaken by this association should certainly bear fruit in increased knowledge on the part of the community regarding tuberculosis.

NEW YORK.

Attending Physician to Manhattan College. — At a meeting of the board of trustees of Manhattan College, held Dec. 21, Dr. Arthur J. O'Leary, Registrar of the Bureau of Vital Statistics of the Borough of the Bronx, was appointed attending physician to the college, to succeed his father, Dr. C. N. O'Leary, who was killed recently in a railroad accident. Dr. A. J. O'Leary's grandfather was appointed to the position at the organization of the college, and was succeeded by his son, Dr. C. N. O'Leary.

The Seaman Prize. — The Seaman Prize ($100 in gold) for 1903 has been awarded by the Military Service Institution of the United States to Capt. J. P. Jerrey, Engineer Corps, United States Army, for his essay on "How Best to Promote Rifle Practice." The subject selected for competition in 1904 is Military Hygiene. This prize was established by Dr. Louis Livingston Seaman of New York, who was surgeon, wth the rank of major, of the Volunteer Regiment of Engineers in the Spanish-American War.

Smallpox at Buffalo. — Of nine cases of smallpox taken to the Quarantine Hospital at Buffalo on Christmas day, six were discovered at a dance hall in that city, where a large number of persons were exposed to infection.

Correspondence.

AN ESTABLISHMENT FOR HYDROTHERAPY.

Mr. Editor: We beg leave to call the attention of your readers to the fact that the arrangements are now complete for giving varied and variable treatments by water, in the Farragut Building, 126 Massachusetts Avenue, corner of Boylston Street, at the rooms formerly occupied for the same purpose by Miss Colby.

It must rest with the members of our profession in Boston and its neighborhood whether or not they will take the pains necessary to make this enterprise a success. If this end is gained we shall have a convenient establishment to which we can send patients suffering from local or general disorders of nutrition, such as are treated with benefit at "water cures" of various sorts, the world over. And not only is this true, but we shall be helping to support an establishment of enlarging usefulness; for it is the intention to introduce, also, other methods of treatment, so far as practicable, as by reliable forms of electricity, hot air, massage and the simpler kinds of exercise. This is to be pre-eminently a doctor's enterprise, and Dr. J. H. Pratt, who is in charge of it, will be glad to receive either the criticisms or the suggestions of any doctors who are interested to make them.

Yours truly, James J. Putnam,
E. G. Cutler,
R. W. Lovett.

RECORD OF MORTALITY

For the Week ending Saturday, Dec. 19, 1903.

Cities.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Diseases.	Typhoid fever.

Plymouth	10,730	—	—	—	—	—	—	—

Deaths reported, 3,415; under five years of age, 836; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 714, acute lung diseases 666, consumption 343, scarlet fever 43, whooping cough 15, cerebrospinal meningitis 8, smallpox 30, erysipelas 10, puerperal fever 6, measles 32, typhoid fever 63, diarrheal diseases 63, diphtheria and croup 94.

From whooping cough, New York 6, Chicago, 1, Philadelphia, 2, Baltimore, Pittsburg, Boston, Cambridge, Holyoke and Woburn 1 each. From smallpox, Philadelphia 22, Pittsburg 8. From cerebrospinal meningitis, New York 6, Lynn 1, Somerville 1. From erysipelas, New York 4, Chicago 2, Philadelphia 2, Baltimore 1, Boston 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Dec. 5, the death-rate was 18.6. Deaths reported, 5,364; acute diseases of the respiratory organs (London) 193, whooping cough 87, diphtheria 55, measles 102, smallpox 3, scarlet fever 45.

The death-rate ranged from 7.4 in Kings Norton, to 34.4 in Wigan, London 17.8, West Ham 18.1, Brighton 15.3, Southampton 14.2, Plymouth 19.1, Bristol 16.6, Birmingham 15.7, Leicester 13.5, Nottingham 18.4, Liverpool 22.1, Bolton 19.2, Manchester 21.6, Salford 21.9, Bradford 22.3, Leeds 17.3, Hull 22.8, Cardiff 18.4, Rhondda 19.6, Merthyr Tydfil 19.6, Hornsey 10.6, Sunderland 21.6.

METEOROLOGICAL RECORD.

For the week ending Dec. 19, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING DEC. 17, 1903.

BAILHACHE, Preston H., surgeon. Detailed to represent the Service at the "Convention to Consider the Questions Involved in Mosquito Extermination," to be held in New York Dec. 16. Dec. 4, 1903.

IRWIN, Fairfax, surgeon. Granted leave of absence for two days from Dec. 24. Dec. 17, 1903.

BROOKS, S. D., surgeon. To rejoin station at Savannah, Georgia. Dec. 16, 1903.

WHITE, J. H., surgeon. Granted leave of absence for five days from Dec. 17. Dec. 16, 1903.

CARRINGTON, P. M., surgeon. Three days' leave of absence from Dec. 15, 1903, under paragraph 189 of the regulations.

GUITERAS, G. M., surgeon. Granted leave of absence for three months from Dec. 19. Dec. 16, 1903.

PERRY, J. C., passed assistant surgeon. Detailed to represent the Service at the "Convention to Consider the Questions Involved in Mosquito Extermination" to be held in New York Dec. 16. Dec. 15, 1903.

GREENE, J B., passed assistant surgeon. Upon being relieved at Cleveland, Ohio, by Passed Assistant Surgeon H. S. Mathewson, to proceed to Habana, Cuba, for duty in office of U. S. Consul-General, relieving Assistant Surgeon F. E. Trotter. Dec. 16, 1903.

MATHEWSON, H. S., passed assistant surgeon. Relieved from duty at Detroit, Michigan, and directed to proceed to Cleveland, Ohio, and assume command of the service at that port, relieving Passed Assistant Surgeon J. B. Greene. Dec. 16, 1903.

VON EZDORF, R. H., passed assistant surgeon. Relieved from duty at Laredo, Texas, and directed to proceed to Washington, D. C., and report at Bureau. Dec. 15, 1903.

BILLINGS, W. C., assistant surgeon. Granted leave of absence for fourteen days from Dec. 13. Dec. 14, 1903.

KERR, J. W., assistant surgeon. To proceed to Ellis Island, New York, N. Y., and report to Surgeon G. W. Stoner for duty. Dec. 12, 1903.

GOLDBERGER, Jos., assistant surgeon. To report to Director of Hygienic Laboratory for duty. Dec. 8, 1903.

TROTTER, F. E., assistant surgeon. Upon being relieved from duty at Habana, Cuba, by Passed Assistant Surgeon J. B. Greene, to proceed to San Francisco, Cal., and report to medical officer in command for duty and assignment to quarters. Dec. 16, 1903.

LLOYD, B. J., assistant surgeon. To proceed to Concord, Cal., for special temporary duty. Dec. 15, 1903.

STIMSON, A. M., assistant surgeon. Granted leave of absence for seven days from Dec. 8, 1903, under paragraph 191 of the regulations.

FOSTER, A. D., assistant surgeon. To proceed to Ellis Island, New York, and report to Surgeon G. W. Stoner for temporary duty. Dec. 11, 1903.

BALLARD, J. C., acting assistant surgeon. Granted leave of absence for five days from Dec. 24. Dec. 16, 1903.

SAFFORD, M. V., acting assistant surgeon. Granted leave of absence for four days from Dec. 14, 1903, under paragraph 210 of the regulations.

STEARNS, H. H., acting assistant surgeon. Granted leave of absence for fourteen days from Dec. 18. Dec. 15, 1903.

MAGUIRE, E. S., pharmacist. Department letter of Nov. 21, granting Pharmacist Maguire leave of absence for thirty days from Nov. 1, 1903, amended so as to read thirty days from Dec. 1. Dec. 12, 1903.

GIBSON, R. H., pharmacist. Granted leave of absence for eight days from Dec. 24. Dec. 15, 1903.

RYDER, L. W., pharmacist. Department letter of Dec. 9, granting Pharmacist Ryder leave of absence for fifteen days from Dec. 10, 1903, amended to read fifteen days from Dec. 7. Dec. 11, 1903.

BOARD CONVENED.

Board convened to meet at Philadelphia, Pa., Dec. 17, 1903, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Surgeon Fairfax Irwin, Chairman. Assistant Surgeon W. A. Korn, Recorder.

APPOINTMENTS.

J. N. COOLIDGE, M.D., has been appointed an assistant visiting physician at the Boston City Hospital.

EDWARD N. LIBBY, M.D., has been appointed a physician to medical out-patients at the Boston City Hospital.

S. G. UNDERHILL, M.D., has been appointed as an assistant to the superintendent at the Boston City Hospital.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING DEC. 26, 1903.

W. A. MCCLURG, medical inspector. Ordered to the Bureau of Medicine and Surgery, Navy Department.

M. K. JOHNSON, surgeon. Detached from the naval hospital, New York, N. Y., and ordered to the "Tacoma."

L. H. SCHWERIN, acting assistant surgeon. Detached from the "Southery" and ordered to the "Abarenda."

L. W. SPRATLING, surgeon. Detached from the "Hancock" and ordered to the navy yard, New York, for special temporary duty at the naval laboratory.

D. N. CARPENTER, surgeon. Detached from the naval hospital, Washington, D. C., and ordered to the "Dixie" for duty with the Panama marine brigade.

L. W. SPRATLING, surgeon. Detached from the naval laboratory, Brooklyn, N. Y., and ordered to the "Dixie" for duty with the Panama marine brigade.

G. L. ANGENY, passed assistant surgeon. Detached from the naval hospital, Philadelphia, Pa., and ordered to the "Dixie" for duty with the Panama marine brigade.

RECENT DEATHS.

DANIEL E. KISSAM, M.D. Dr. Daniel Embury Kissam, formerly a surgeon of note in Brooklyn, died at his residence at Huntington, Long Island, on Dec. 23. He was a native of New York City, and was born Oct. 3, 1817. From 1848 to 1888 he practised in Brooklyn, where he was visiting surgeon to the Brooklyn Hospital. During the civil war he served as a surgeon in the army.

HORACE C. TAYLOR, M.D. Dr. Horace Clifton Taylor of Brocton, Chautauqua County, N. Y., died on Dec. 21, at the age of ninety years. He served eleven years as county superintendent of the poor, and was well known as a writer on the care of the dependent classes.
